
#### Anatomy.

The leg is supplied by 5 nerves. Anteriorly, the femoral, obturator, and lateral femoral

cutaneous arise from the lumbar plexus and travel a short distance in a common nerve sheath (Fig. 32-18) (Figure Not Available) . In the pelvis, the lateral femoral cutaneous and obturator nerves exit the sheath. The lateral femoral cutaneous nerve supplies the sensory innervation to the lateral thigh. The obturator nerve supplies the sensory innervation to the anterior medial thigh and the motor supply to the adductor muscles. The femoral nerve continues as the saphenous nerve, which supplies the sensory innervation to the medial calf and ankle.

Posteriorly, the sciatic and posterior cutaneous nerves arise from the lumbar and sacral plexuses and exit the pelvis together in the sciatic notch. The posterior cutaneous nerve supplies sensory innervation to the posterior thigh and buttocks. The sciatic nerve does not supply the thigh but at the knee divides into the tibial and peroneal nerves and supplies much of the calf and foot. The tibial nerve supplies the muscles of the calf and sensation to the plantar surface of the foot. The peroneal nerve supplies sensation to the lateral aspect of the calf and dorsal and plantar aspects of the foot. Both the tibial and peroneal nerves give off branches that form the sural nerve, which supplies sensation to the lateral aspect of the foot (Fig. 32-19) (Figure Not Available) .

**Technique for femoral nerve block.**

With the patient in the supine position, the skin is prepared in an aseptic fashion. The femoral artery is palpated 1 to 2 cm below the inguinal ligament (see Fig. 32-18) (Figure Not Available) , and a wheal of anesthesia is raised immediately lateral to the artery. With the nondominant

**Figure 32-18** (Figure Not Available) Anatomy of the femoral, obturator, and lateral femoral cutaneous nerves and the location of the injection site for the femoral and 3-in-1 nerve blocks. *(Adapted from Winnie AP, Ramamurthy S, Durrani Z: The inguinal paravascular technique of lumbar plexus anesthesia: The "3 in 1 block." Anesth Analg 52:989, 1973. Reproduced with permission.)*

**Figure 32-19** (Figure Not Available) *A* and *B,* Anatomy and innervation of the calf and foot. *(From Shurman DH: Ankle-block anesthesia for foot surgery. Anesthesiology 44:348, 1976. Reproduced with permission.)*

hand placed firmly on the artery, a 1.25-cm, 22-ga needle, attached to an extension tube setup and a 20-mL syringe, is inserted adjacent to the artery at a 90° angle to the skin and underlying vessels. The needle is advanced until a paresthesia is elicited or the needle pulsates laterally, indicating a position immediately adjacent to the artery. If a paresthesia is felt or the needle is assumed to be in the immediate vicinity of the nerve, 10 to 20 mL of anesthetic are injected. If a paresthesia is not elicited, 10 to 20 mL of anesthetic can be injected in a fan-like pattern lateral to the artery in a blind attempt to anesthetize the femoral nerve. The onset of anesthesia should occur in 15 to 30 minutes and should last for 3 to 8 hours.

**Technique for the 3-in-1 block.**

The 3-in-1 technique differs from the femoral nerve block in that it requires a larger amount of anesthetic solution and compression distal to the injection site. In the thigh,

the femoral nerve is sandwiched between the quadratus lumborum and iliopsoas muscles, whose fasciae are continuous with a nerve sheath that contains all 3 nerves higher in the pelvis. A large amount of anesthetic properly placed next to the femoral nerve tracks back along the sheath and anesthetizes all 3 nerves.

The 3-in-1 block requires precise injection of the anesthesia into the nerve sheath. In the 3-in-1 block, once the needle is in the correct position, the fingers palpating the artery are removed and placed gently but firmly distal to the needle while 20 to 30 mL of anesthetic are injected. Distal pressure should be maintained for 5 minutes while the anesthetic diffuses proximally.

A nerve stimulator facilitates the search for the nerve and placement of the needle tip in the fascial sheath. The nerve is covered by a thick insulating fascia. When the needle punctures this sheath, the nerve is stimulated at currents of 0.5 mA or less.

**Precautions.**

The femoral nerve block requires that large amounts of anesthetic be injected close to large nerves and vessels. Standard precautions should be used to avoid intravascular and intraneuronal injection, and recommended anesthetic dosages should be observed.

**Nerve Blocks of the Ankle**

Nerve block of the 5 nerves of the ankle--the deep peroneal (anterior tibial), posterior tibial, saphenous, superficial peroneal (musculocutaneous), and sural nerves--provides anesthesia to the foot. Depending on the desired area of anesthesia, 1 or more of the 5 nerves are blocked. These blocks can be used in operative procedures and repair of injuries to the foot. They are particularly useful in providing anesthesia to the sole of the foot for laceration repair and foreign body removal.

A nerve block of the foot is better tolerated by the patient than local infiltration in all but the most minor procedures. The skin of the sole is thicker and more tightly bound to the underlying fascia by connective tissue septa than is skin in other parts of the body. Puncturing this skin can be difficult and is always quite painful. The fibrous septa can limit the amount and spread of anesthetic. If large amounts of anesthesia are injected, the volume of injected

substance quickly exceeds the space available, possibly leading to painful distention of the tissue and circulatory compromise of the microvasculature. Local infiltrative anesthesia is adequate for treating minor injuries in which only small amounts of anesthetic are needed. For treatment of larger injuries, including incision and drainage, extensive wound care, and foreign body removal, the ankle block is better tolerated.

**Anatomy.**

The foot is supplied by the 5 nerve branches of the principal nerve trunks (see Fig. 32-17) (Figure Not Available) . Three nerves are located anteriorly and supply the dorsal

aspect of the foot. Two nerves are located posteriorly and supply the volar aspect.

The anteriorly located nerves are the superficial peroneal, deep peroneal, and saphenous nerves. The superficial peroneal nerve (also called the *dorsal cutaneous* or *musculocutaneous nerve*) actually consists of multiple branches that supply a large portion of the dorsal aspect of the foot (see Fig. 32-19) (Figure Not Available) . These are located superficially between the lateral malleolus and extensor hallucis longus tendon, which is easily palpated by having the patient dorsiflex the big toe. The deep peroneal nerve (also called the *anterior tibial nerve*) supplies the web space between the big and second toes. In the ankle, it lies under the extensor hallucis longus tendon. The saphenous nerve runs superficially with the saphenous vein between the medial malleolus and tibialis anterior tendon, which is prominent when the patient dorsiflexes the foot. The saphenous nerve supplies the medial aspect of the foot near the arch.

The posteriorly located nerves are the posterior tibial and sural nerves. The sural nerve runs subcutaneously between the lateral malleolus and the Achilles tendon and supplies the lateral border, both volar and dorsal, of the foot (see Fig. 32-19) (Figure Not Available) . The posterior tibial nerve runs with the posterior tibial artery, which can be palpated between the medial malleolus and the Achilles tendon. It lies slightly deep and posterior to the artery.

The posterior tibial nerve is one of the major nerve branches to the foot. After passing through the ankle, it branches into the medial and lateral plantar nerves, which supply sensation to most of the volar aspect of the foot and toes and supply motor innervation to the intrinsic muscles of the foot.

**Technique.**

Complete nerve block of the foot requires blocking 3 SQ nerves and 2 deeper nerves (Fig. 32-20) (Figure Not Available) . Once familiar with the anatomy, the experienced physician can anesthetize all 5 nerves quickly by placing SQ band blocks around 75% of the ankle circumference and 1 deep injection next to the palpable posterior tibial artery and the other under the extensor tendon of the big toe.

The 5 nerves of the foot are commonly blocked in combinations of 2 or more. Small procedures clearly within the distribution of 1 nerve may require only a single nerve block; however, overlap of the nerve's sensory distribution frequently necessitates blocking a number of nerves for adequate anesthesia. Nerve block of the sural and posterior tibial nerves together anesthetizes the bottom of the foot and is the most useful combination.

**Posterior tibial.**

The posterior tibial nerve is blocked in the medial aspect of the ankle between the medial malleolus and the Achilles tendon. The injection site is determined by palpating the tibial artery just posterior to the medial malleolus. A point 0.5 to 1.0 cm superior to this is marked. If the artery is not palpable, a site 1 cm above the medial malleolus and

just anterior to the Achilles tendon is used (see Figs. 32-20 (Figure Not Available) and 32-21) (Figure Not Available) .

A 3.75-cm, 25-ga needle is directed at a 45° angle to the mediolateral plane (the needle is almost perpendicular to the skin), just posterior to the artery. At the estimated depth of the artery, approximately 0.5 to 1.0 cm deep, the needle is wiggled slightly in an effort to produce a paresthesia. If the paresthesia is elicited, 3 to 5 mL of anesthetic are injected after careful aspiration to check for inadvertent intravascular placement of the needle tip. If no paresthesia is produced, the needle is advanced inward, again at a 45° angle, until it hits the posterior aspect of the tibia. The needle is then withdrawn slightly, about 1 mm, and 5 to 7 mL of anesthetic are injected while the needle is withdrawn another 1 cm. A rise in the temperature of the foot, due to vasodilation from loss of sympathetic tone, may herald a successful block. This finding may be used as an indicator of onset and depth of anesthesia.

**Sural nerve.**

The sural nerve is blocked on the lateral aspect of the ankle between the Achilles tendon and the lateral malleolus (see Fig. 32-20) (Figure Not Available) . It lies superficially and is blocked at a level about 1 cm above the lateral malleolus. A band of anesthesia is injected subcutaneously between the Achilles tendon and the lateral malleolus using 3 to 5 mL of anesthetic.

**Superficial peroneal nerves.**

The superficial peroneal nerves are blocked on the anterior aspect of the ankle between the extensor hallucis longus tendon and the lateral malleolus. They lie superficially and are blocked using 4 to 10 mL of anesthetic placed subcutaneously in a band between these landmarks.

**Deep peroneal nerve.**

The deep peroneal nerve is blocked anteriorly beneath the extensor hallucis tendon (see Fig. 32-20) (Figure Not Available) . It is blocked at a level 1 cm above the base of the medial malleolus and between the extensor hallucis longus and anterior tibial tendons. The tendons are palpated by having the patient dorsiflex the big toe and foot, respectively. After an SQ wheal is placed, the needle is directed about 30° laterally and under the extensor hallucis tendon until it strikes the tibia (at a depth of less than 1 cm). The needle is withdrawn 1 mm, and 1 mL of anesthetic is injected.

The saphenous nerve is blocked anteriorly between the medial malleolus and the anterior tibial tendon. It lies superficially and is blocked with 3 to 5 mL of anesthetic injected subcutaneously between these landmarks.

**Nerve Blocks of the Metatarsals and Toes**

Like the nerve blocks in the hand and fingers, the nerve blocks in the foot and toes are commonly used in the emergency department. Indications for using these blocks include repair of lacerations, drainage of infections, removal of toenails, manipulation of fractures and dislocations, and otherwise painful procedures requiring anesthesia to the forefoot and toes.

Digital nerve blocks in the foot and toes are superior to local infiltration anesthesia in all but the most minor procedures. In the toes, the limited SQ space does not accommodate enough injected material for adequate infiltrative anesthesia. Furthermore, the fibrous septa, which attach the volar skin to the underlying fascia and bone, limit the spread and volume of injected substances. On the plantar surface, even small amounts of local infiltrate can cause painful distention and local ischemia of the tissues.

**Anatomy.**

Each toe is supplied by 2 dorsal and 2 volar nerves. These nerves are branches of the major nerves of the ankle. The dorsal digital nerves are the terminal branches of the deep and superficial peroneal nerves. The volar nerves are branches of the posterior tibial and sural nerves.

The location of the nerves in relation to the bones varies with the site of the foot. In the toes, the nerves lie at the 2, 4, 8, and 10 o'clock positions in close relationship to the bone. In the proximal foot, the nerves run with the tendons and are not in close relationship to the bones (Fig. 32-22) (Figure Not Available) .

**Technique.**

The digital nerves can be blocked at the metatarsals, interdigital web spaces, or toes. The bones of the foot can be palpated easily from the dorsum and are used as the landmarks for estimating the location of the nerves. Proximally, the nerves' relationship to the bones is less consistent, making definitive needle placement and successful block less reliable. In the toes, the position of the nerves is more consistent; however, there is minimal SQ tissue space available for the injected solution. At the web space, the nerves are located in close relationship to the bone, and there is ample space for injecting the anesthesia; hence, for most procedures, the web space is the preferred site

for the digital nerve block.

The technique for toe and metatarsal blocks is similar. All 4 nerves supplying each toe are usually blocked because of their sensory overlap. The blocks are performed from the dorsal surface, where the skin is thinner and less sensitive than that on the plantar aspect. A total of 5 mL of anesthetic is deposited in a fan-like pattern in the space between the metatarsal bones (see Fig. 32-22) (Figure Not Available) . A 1-mL skin wheal is placed dorsally between the metatarsal bones. The needle is then advanced until the volar skin tents slightly, and 2 mL are injected as the needle is withdrawn. Without removing it, the needle is redirected in a different volar direction, and

**Figure 32-22** (Figure Not Available) Anatomy and technique for digital nerve block at the metatarsals. *(From Bridenbaugh PO: The lower extremity: Somatic blockade. In Cousins M, Bridenbaugh PO (eds): Neural Blockade in Clinical Anesthesia and Management of Pain. 2nd ed. Philadelphia, JB Lippincott, 1988, p 437. Reproduced with permission.)*

the procedure is repeated. A total of 5 mL is used in each metatarsal space. Again, because of sensory overlap, 2 or more spaces need to be anesthetized for each toe to be blocked.

For the web space block, a site on the dorsum just proximal to the base of the toe is selected. Using a 10-mL

**Figure 32-23** Technique of digital nerve blocks in the interdigital web spaces of the foot.

syringe, a 3.75-cm, 27-ga needle is inserted at the lateral edge of the bone (Fig. 32-23) . A wheal is placed subcutaneously between the skin and bone, using 0.5 to 1.0 mL of anesthetic. This serves to block the dorsal nerve and minimize pain at the needle insertion site. The needle is then advanced just lateral to the bone and toward the sole until

**Figure 32-24** (Figure Not Available) Alternative techniques of digital nerve blocks in the toes. *(From Locke RK, Locke SE: Nerve blocks of the foot. JACEP 4:698, 1976. Reproduced with permission.)*

the needle tents the volar skin slightly. The needle is withdrawn 1 mm, and 0.5 to 1.0 mL is injected. As the needle is withdrawn, another 0.5 mL is injected to ensure a successful block. The procedure is repeated on the opposite side of the toe. In this manner, 2 columns of anesthesia are placed on each side of the toe in the area through which the 4 digital nerves run. A total of 2 to 4 mL of anesthetic is used. For blocks done in the toe itself, the procedure is the same, but smaller amounts of anesthetic are used because of the limited SQ space and fear of vascular compression. A total of less than 2 mL is used. Alternative techniques using a single injection site, as described for the finger, can be performed (Fig. 32-24) (Figure Not Available) .

**Complications and precautions.**

The precautions that apply to the hand and fingers apply to the foot and toes. Ischemic

complications can be avoided by paying attention to skin changes during the injection. Blanching heralds possible intravascular injection or vascular compression. If the skin blanches, halt the procedure and reevaluate the position of the needle and the amount and content of the injected solution. The total volume of anesthesia should not exceed the recommended amount. Although podiatrists commonly use anesthetics containing small concentrations of epinephrine for digital blocks in patients without underlying vascular disease, [16] [21] this practice is generally not recommended because of concern about vasospasm and ischemia (see Complications and Precautions subsection and Chapter 31) .

Note any neural or vascular injuries before the injection. The close proximity of these structures to the skin and bones means that they are frequently injured. Deficits, even if questionable, should be documented in the records and brought to the attention of the patient before the nerve block.

## CONCLUSIONS

Regional nerve blocks of the thorax and extremities are valuable adjuncts to the clinician's armamentarium. They may be used for wound anesthesia prior to exploration, irrigation, debridement, and repair. They may be used to reduce the pain of certain procedures (e.g., arthrocentesis, fracture reduction, or dislocation manipulation). A rib block may permit better thoracic mechanics. When these procedures are performed, the cautions outlined in Chapter 31 and the current chapter should be heeded.

# Chapter 33 - Regional Anesthesia of the Head and Neck

**James T. Amsterdam**

The use of intraoral and extraoral regional anesthesia is both simple and convenient. [1] [2] [3] Nerve blocks are used to attain anesthesia in areas of broad distribution in the face with a minimal amount of anesthetic and resultant tissue distortion. Local anesthetic blocks are effective for closing facial lacerations, especially those of the lips, the forehead, and the midface, where the swelling caused by local infiltration is undesirable. Local anesthetic blocks are also effective for the relief of pain, for anesthesia in debridement, and for diagnostic purposes.

Patients with dental pain who do not get relief with a regional dental block most likely do not have pain of dental origin. Regional blocks are also therapeutic for both surgical procedure anesthesia and pain control for dental emergencies such as toothaches and dry sockets (see Chapter 69) . In cases in which the patient is thought to be seeking drugs and one wishes to avoid narcotics, a dental anesthetic block is frequently the treatment of choice.

Topical anesthetic solutions such as tetracaine-Adrenalin-cocaine (TAC) solution are useful in small lacerations of the scalp and face because of the vascularity of these areas. TAC is not to be used on or near mucous membranes. Detailed information on the use of TAC appears in Chapter 31 . More extensive discussions of the general complications of local anesthetics and of regional anesthesia are provided in Chapters 31 and 32 , respectively. Ophthalmologic anesthesia is discussed in Chapter 67 . Blocks about the ears and nasal anesthesia are discussed in Chapter 68 .

The procedures and techniques described here generally carry a low morbidity. The supraperiosteal and mental nerve infiltrations can generally be learned through reading and experimentation; more sophisticated blocks (e.g., inferior alveolar block) are best learned under the instruction of an experienced physician, a dentist, or an oral and maxillofacial surgeon.

## ANATOMY OF THE FIFTH CRANIAL (TRIGEMINAL) NERVE

The fifth cranial nerve, the trigeminal nerve, is the sensory nerve to the face (Fig. 33-1 (Figure Not Available) *A*) and is the largest of the cranial nerves. It takes its origin from the midbrain and enlarges into the gasserian, or semilunar, ganglion. One gasserian ganglion supplies each side of the face. The gasserian ganglion is a flat, crescent-shaped structure approximately 10 mm long and 20 mm wide that divides into 3 branches: the ophthalmic, maxillary, and mandibular nerves (Fig. 33-1 (Figure Not Available) *B*).

**Ophthalmic Nerve**

The first division, the *ophthalmic nerve* (V1 ), is the smallest branch in the gasserian ganglion. It leaves the cranium through the superior orbital fissure and has 5 cutaneous branches. These branches are as follows:

1. The medial and lateral branches of the supraorbital nerve, which emerge on the face through the supraorbital notch. These two sensory nerves pierce the frontalis muscle and extend to the lambdoid suture on the back of the skull.
2. The supratrochlear nerve, which is sensory to the medial aspect of the forehead just above the glabella.
3. The infratrochlear nerve.
4. The lacrimal nerve.
5. The external nasal nerve.

In addition to being sensory to the forehead, branches of the ophthalmic nerve are sensory to the cornea, the upper eyelid, structures in the orbit, and the frontal sinuses.

**Maxillary Nerve**

The second division, the *maxillary nerve* (V2 ), is sensory to the maxilla and associated structures, such as the teeth, the periosteum and the mucous membranes of the maxillary sinus and the nasal cavity, the soft and hard palate, the lower eyelids, the upper lip, and the side of the nose. The second division exits the cranium from the foramen rotundum and ultimately enters the face through the infraorbital canal; it terminates as the infraorbital nerve. The infraorbital nerve gives sensory branches to the lower eyelids, the side of the nose, and the upper lip.

The anatomy of the maxillary nerve is rather complicated because of its numerous branches. The first branch comprises 2 short sphenopalatine nerves to the pterygopalatine ganglion, also called the *Meckel ganglion* or the *sphenopalatine ganglion.* The next 2 branches of clinical importance are the nasopalatine and the greater (anterior) palatine nerves. The nasopalatine nerve arises from the pterygopalatine ganglion, courses down along the nasal septum, and is transmitted through the anterior portion of the hard palate by way of the anterior palatine canal. This canal is located in the midline approximately 10 mm palatally to the maxillary central teeth and immediately behind the incisors. The nasopalatine nerve is sensory to the most anterior portion of the hard palate and the adjacent gum margins of the upper incisors. This nerve is rarely blocked in clinical practice, except in dental operations (Fig. 33-2 *A*).

The anterior, or great, palatine nerve arises from the pterygopalatine ganglion and passes down through the posterior palatine foramen. The posterior palatine foramen is located 10 mm palatally to the third molar and the bicuspid teeth and intermingles with the nasopalatine nerve opposite the cuspid tooth. The greater palatine nerve is sensory to most of the hard palate, as well as the palatal aspect of the gingiva. It is rarely blocked in the emergency department (Fig. 33-2 *B*).

The next branch consists of the posterosuperior alveolar (PSA) nerve, which courses down the posterior surface of the maxilla for approximately 20 mm, at which point it enters 1 or several small posterosuperior dental foramina. This nerve supplies all the roots of the third and second molar teeth and 2 roots of the first molar tooth. A third branch consists of the middle superior alveolar (MSA) nerve, which branches off about midway within the infraorbital canal and then courses downward in the outer wall of the maxillary sinus. This nerve supplies the maxillary first and second bicuspid teeth and the mesiobuccal root of the first molar. The last branch consists of the anterosuperior alveolar (ASA) nerve, which branches off into the infraorbital canal approximately 5 mm behind the infraorbital foramen, just before the terminal branches of the infraorbital nerve emerge. This nerve descends in the anterior wall of the maxilla to supply the maxillary central, lateral, and cuspid teeth; the labial mucous membrane; the periosteum; and the alveoli on 1 side of the median line. There is an intercommunication among the ASA, MSA, and PSA nerves.

**Mandibular Nerve**

The third division, the *mandibular nerve* (V3 ), is the largest branch of the trigeminal nerve. It exits from the cranium through the foramen ovale and divides into 3 principal branches:

1.  The long buccal nerve branches off just outside the foramen ovale. It passes between the 2 heads of the external pterygoid muscle and crosses in front of the ramus to enter the cheek through the buccinator muscle, buccally to the maxillary third molar. The buccal nerve supplies sensory branches to the buccal mucous membrane and the mucoperiosteum over the maxillary and mandibular teeth. The cutaneous branch is the sensory nerve to the cheek.
2.  The lingual nerve courses forward toward the midline. It runs downward superficially to the internal pterygoid muscle to pass lingually to the apex of the mandibular third molar. It enters the base of the tongue at this point through the floor of the mouth and supplies the anterior two thirds of the tongue, the lingual mucous membrane, and the mucoperiosteum.
3.  The largest of the V3 branches is the inferior alveolar nerve. It is sensory to all of the lower teeth, although the central and lateral incisors and the buccal aspect of the molar teeth may receive additional sensory innervation. The nerve descends, covered by the external pterygoid muscle, and passes between the ramus of the mandible and the sphenomandibular ligament to enter the mandibular canal. It is accompanied by the inferior alveolar artery and vein and proceeds along the mandibular canal, innervating the teeth. At the mental foramen, the nerve bifurcates into an incisive branch, which continues forward to supply the anterior teeth. It gives off a side branch, the mental nerve, which exits from the mental foramen to supply the skin. The mental foramen is located approximately between the apices of the lower first and second bicuspids, or premolar teeth. This is a useful site at which to perform a nerve block, because the mental nerve is sensory to the integument of the chin and the skin and the mucous membrane of the lower lip.

# EQUIPMENT FOR DENTAL AND CRANIAL NERVE BLOCKS

One may easily give extraoral injections with standard injection equipment. Intraoral local anesthesia is conveniently administered with a Monoject aspirating dental syringe, which uses Carpule cartridges of anesthetic and disposable needles (Fig. 33-3) . A needle no smaller than 27 ga is recommended for deep block techniques due to the inability to perform aspiration with smaller needles. Generally, a long needle is used for block techniques, and a short needle is used for infiltrations.

The needle is screwed to the hub of the Monoject syringe, which in turn is attached to an adapter; the adapter may be removed for cleaning. When removing the disposable needle, one must take care not to remove and discard the adapter as well; this would render the syringe functionless (Fig. 33-4) . One pulls back the end of the syringe on its

**Figure 33-3** Local anesthesia--basic setup for intraoral application using an aspirating dental syringe.

spring, allowing room for the Carpule cartridge of anesthetic to be inserted (Fig. 33-5 *A*). The metal end of the Carpule cartridge is inserted, which engages the needle (Fig. 33-5 *B*). The handle of the syringe is then released and tapped to engage a barb into the rubber stopper of the cartridge (Fig. 33-5 *C*). One may then perform simple aspiration by retracting the handle, pulling on the rubber stopper within the Carpule.

To discard a Carpule cartridge, one should leave the needle in place on the syringe. The handle of the syringe is then withdrawn rapidly, disengaging the barb. If the needle has been removed, great care must be taken, because the negative pressure created in the Carpule cartridge upon withdrawal of the barb may cause shattering. Other adjuncts that are helpful in the administration of intraoral anesthesia include topical local anesthetic agents such as gels or sprays. It should be noted that dental syringes are not mandatory for intraoral local anesthesia but do make the procedure more simple. Reusable glass and disposable plastic aspirating syringes that do not use dental Carpule cartridges are also available.

The anesthetic agent most frequently used is 2% lidocaine with a vasoconstrictor, such as 1:100,000 or 1:50,000 epinephrine. Many other anesthetic agents, such as mepivacaine (Carbocaine) and Cetacaine (a combination of benzocaine, tetracaine, butamben, and benzalkonium), with or without vasoconstrictor agents, are also available. Bupivacaine (Marcaine) is a longer acting anesthetic that is often ideal for the procedures performed in the emergency department. When this agent is not available in Carpule cartridge form, a Carpule cartridge containing a different anesthetic may be emptied and bupivacaine drawn up in the evacuated cartridge. Because of the rich vascularity of the oral cavity, vasoconstrictors are important in sustaining the duration of anesthesia and should be used wherever possible in the absence of medical contraindications. Buffering with bicarbonate is not recommended for oral anesthesia.

## GENERAL PRECAUTIONS

Needles no smaller than 27 ga should be used for block techniques, since a higher gauge makes aspiration difficult, with resultant inadvertent intravascular injection. When an intraoral block procedure is performed, the needle should not be inserted to its full length at the hub. Should inadvertent breakage occur in such a situation, needle retrieval may be difficult. Furthermore, the direction of a needle should not be changed while the needle is deep in the tissue. Topical anesthetics can be placed on mucous membranes to make needle puncture painless. One should inject slowly to minimize pain and should always aspirate before injection. A warmed anesthetic solution is also more comfortable for the patient.

An important precaution for intraoral local anesthesia is that the injection should not be made into or through an infected area. This is especially important in inferior alveolar nerve blocks, in which tracking of an infection can be serious and difficult to treat. Trismus with inadequate oral access or direct extension of infection to parapharyngeal spaces can result. Therefore, local anesthesia should be only superficial before incision and drainage, unless a block can be performed far proximal to the site of infections.

## TECHNIQUE

### Topical Anesthesia

Most patients fear dental blocks greatly, and the anxiety and pain may be lessened considerably with the use of topical anesthetics that are applied to the mucous membranes before injection. The area to be injected is first thoroughly dried with gauze. A cotton-tipped applicator is generously coated with 20% benzocaine (Hurricaine, Beutlich, Inc., Niles, Ill.) or 5% to 10% lidocaine. Anesthesia results in 2 to 3 minutes. Note that rather concentrated topical anesthetics must be used, and poor results may be obtained with weaker preparations such as 2% viscous lidocaine.

### Supraperiosteal Infiltrations

The most common technique for intraoral local anesthesia of individual teeth is the supraperiosteal infiltration injection. This technique may supply complete relief of a toothache and is a useful emergency department procedure that can provide non-narcotic analgesia in the middle of the night. The area to be anesthetized is selected and dried with gauze. A topical anesthetic, such as 20% benzocaine or 5% lidocaine ointment, is applied as before. The mucous membrane of the area is grasped with a piece of gauze; the gauze is pulled out and downward in the maxilla and out and upward in the mandible to extend the mucosa fully and to delineate

the mucobuccal fold. The mucobuccal fold is then punctured with the bevel of the needle facing the bone. The area is aspirated, and approximately 1 to 2 mL of local anesthetic are deposited at the apex (area of the root tip) of the involved tooth (Fig. 33-6) (Figure Not Available) . It is helpful to place a finger against the *outer* aspect of the

lip overlying the injection site and apply firm and steady pressure against the lip as the local anesthetic is *slowly* injected into the supraperiosteal site.

The purpose of the injection is to deposit the anesthetic near the bone that supports the tooth. Because the anesthetic must penetrate the cortex of bone to reach the nerve of the individual tooth, the injection may fail if the solution is deposited too far from the periosteum, if the needle is passed too far above the roots of the teeth, or if the bone in the area is unusually thick or dense. If anesthesia is unsuccessful, one may also inject the palatal side. It may take 5 to 10 minutes to achieve full anesthesia with this technique, and the procedure may not be as effective for the posterior molars. Infiltration of the area around the maxillary canine and the first premolars will anesthetize the MSA and ASA nerves; lacerations of the upper lip can be treated by bilateral injection in the canine fossa areas.

## Infraorbital Nerve Block

### Anatomy

The infraorbital nerve block injection can be used to anesthetize the midface (Fig. 33-7) (Figure Not Available) . A solution of local anesthetic deposited at the infraorbital foramen anesthetizes not only the middle and superior alveolar nerves, but also the main trunk of the infraorbital nerve that innervates the skin of the upper lip, the skin of the nose, and the lower eyelid. The nasal mucosa is not anesthetized by this technique.

The infraorbital foramen is difficult to palpate extraorally and almost impossible to feel in the presence of facial swelling. It is found on the inferior border of the infraorbital ridge on a vertical (sagittal) line with the pupil when the patient stares straight ahead. Although 1 volunteer study found similar patient pain scale scores and overall preference in subjects receiving both intraoral and extraoral approaches, the intraoral approach seemed to provide nearly twice the duration of anesthesia. [4]

### Intraoral Approach

A topical anesthetic (e.g., 4% cocaine or 2% lidocaine) on a cotton-tipped swab is applied for 60 seconds prior to introducing the needle for the nerve block. [4] [5] When performing the intraoral approach, one keeps the palpating finger in place. The cheek is retracted, as in the supraperiosteal injection, and puncture is made in the mucosa opposite the upper second bicuspid (premolar tooth) approximately 0.5 cm from the buccal surface (Fig. 33-8 *A* and *B*). Topical anesthetic applied to the mucosa before injection decreases pain. The needle should be directed parallel with the long axis of the second bicuspid until it is palpated near the foramen, a depth of approximately 2.5 cm. If the entry is too acute initially, one will encounter the malar eminence before approaching the infraorbital foramen. In addition, if the needle is extended too far posteriorly and superiorly, the orbit may be entered (Fig. 33-8 *C*). Therefore, the procedure should be halted if the physician is unsure of the location of the needle or if patient cooperation is unsatisfactory.

When the location has been determined and aspiration has been performed, 2 to 3 mL of solution are injected *adjacent to, but not within, the foramen*. A finger should be held firmly on the inferior orbital rim to avoid ballooning of the lower eyelid with anesthetic solution. If one is not certain of the exact location of the infraorbital foramen, one may obtain anesthesia by performing a field block. For the latter technique, 5 mL of the anesthetic solution are infiltrated in a fan-like distribution in the upper buccal fold. This technique is not as precise as a discrete nerve block but usually produces the same effect. Massage of the tissue for 10 to 15 seconds following the injection also hastens onset of the anesthesia.

### Extraoral Approach

The infraorbital foramen may also be approached from an extraoral route (Fig. 33-9) (Figure Not Available) . The extraoral approach, of course, requires external preparation of the skin. In the extraoral approach, similar landmarks are used to locate the infraorbital foramen. The needle can be felt to pass through the skin, the subcutaneous (SQ) tissue, and the quadratus labii superioris muscle. After injection, the infiltrated tissue, usually visibly swollen, should be firmly massaged for 10 to 15 seconds.

Care must be taken not to anesthetize the facial artery and vein, because these may lie on either side of the needle. Vasoconstrictors should be avoided with this technique to avoid vasoconstriction of the facial artery. If severe blanching of the face occurs, warm compresses should be applied to the face immediately. Local phentolamine also may be administered (see Chapter 32) .

## Inferior Alveolar Nerve Block

In the setting of extreme dental pain, the emergency physician may find the use of the inferior alveolar nerve block and the lingual nerve block useful. This injection is somewhat more difficult than the other techniques described, and the emergency physician is advised to view demonstrations of this procedure before attempting it. The inferior alveolar nerve block provides anesthesia to all of the teeth on that side of the mandible and desensitizes the lower lip and the chin via block of the mental nerve. This technique is primarily useful for anesthetizing patients who have sustained severe dentoalveolar trauma; those with complaints of postextraction pain, dry socket, or pulpitis (toothache); or those with periapical abscess.

### Anatomy

The anatomy of the region should first be reviewed (Fig. 33-10 *A*). The patient can be seated either in a dental chair or upright with the occiput firmly against the back of the stretcher, so that when the mouth is opened, the body of the mandible is parallel to the floor. The physician should be ready for an unexpected quick jerk of the head when the anxious patient first feels the needle, despite the use of topical anesthesia. The physician stands on the side *opposite* the one being injected.

The technique first involves palpation of the retromolar fossa with the index finger or thumb. With this maneuver, the greatest depth of the anterior border of the ramus of the mandible (the coronoid notch) may be identified (Fig. 33-10 *B* and *C*). With the thumb in the mouth and the index finger placed externally behind the ramus (Fig. 33-10 *D* and *E*), the tissues are retracted toward the buccal (cheek) side, and the pterygomandibular triangle is visualized (Fig. 33-10 *F*). This technique also moves the operator's finger safely away from the tip of the needle.

**Approach**

The mucosa over the area to be injected may be coated with a topical anesthetic. When topical anesthesia has been obtained, the syringe should be held parallel to the occlusal surfaces of the teeth and angled so that the barrel of the syringe lies between the first and second premolars on the opposite side of the mandible (Fig. 33-10 *G* and *H*). If a large-barrel syringe is used, the corner of the mouth may hamper efforts to obtain the proper angle. The angle is facilitated by carefully bending the 25-ga needle about 30°. Puncture is made in the triangle, at a point that is 1 cm above the occlusal surface of the molars. If the needle enters too low (e.g., at the level of the teeth), the anesthetic will be deposited over the bony canal and prominence (lingula) that house the mandibular nerve, and not over the nerve itself.

The needle should be felt to pass through the ligaments and the muscles covering the internal surface of the mandible. One should stop when the needle has reached bone, which signifies contact with the posterior wall of the mandibular sulcus; bone *must* be felt with the needle. Failure to do so generally results from directing the needle toward the parotid gland (too far posteriorly) rather than toward the inner aspect of the mandible. The needle should then be withdrawn slightly and aspirated, and approximately 1 to 2 mL of solution should be deposited. Three to 4 mL may be required if needle positioning is suboptimal.

In children, the angulation is not parallel to the occlusal surfaces of the teeth; the barrel of the syringe must be held slightly higher, because the mandibular foramen is lower. One may anesthetize the lingual nerve by placing several drops of anesthetic solution while withdrawing the syringe. The anterior two thirds of the tongue can thus be anesthetized. In actual practice, the lingual nerve is consistently blocked with this procedure owing to the close proximity of both nerves. Following injection, it usually requires 3 to 5 minutes to achieve anesthesia.

**Complications**

Complications include inadvertent administration of anesthetic posteriorly in the region of the parotid gland, which will anesthetize the facial nerves (Fig. 33-10 *I*). This is an

annoying but relatively benign complication that will cause temporary facial paralysis (similar to a Bell's palsy) that affects the orbicularis oculi muscle and results in inability to close the eyelid. Should this occur, the eye must be protected until the local

anesthetic has worn off (approximately 2 to 3 hours), and the patient must be reassured. Anesthesia with bupivacaine (Marcaine) presents a more significant problem if this complication occurs, because bupivacaine anesthesia lasts from 10 to 18 hours in some patients.

## Mental Nerve Block

The mental nerve is blocked by the infiltration of local anesthetic about the nerve as it exits its bony foramen (Fig. 33-11) . Introduction of the needle in the mental nerve foramen is to be avoided, as the needle or injection of liquid into the foramen can produce neurovascular damage. Infiltration about the foramen will provide for anesthesia of the lower lip. Lacerations of the midline of the lips require administration of anesthetic about the mental nerve on each side of the face; this practice anesthetizes crossover fibers. Generally a 1.3-cm (0.5-in.), 25- or 27-ga needle on a 3-mL syringe is used.

### Anatomy

The mental nerve is a continuation of the inferior alveolar nerve, which innervates the mucosa and the skin of the lower lip of the ipsilateral side of the mandible, with limited crossover of midline fibers. The nerve emerges from the mental foramen below the second premolar.

### Approaches

Like the infraorbital nerve, the mental nerve may be blocked using an intraoral or an extraoral approach. Syverud and colleagues found that volunteers who received intraoral topical anesthetic followed by an intraoral injection considered the technique to be less painful than the extraoral approach. [5] Before using either approach, the mental foramen should be identified by palpation about 1 cm inferior and anterior to the second premolar. It is generally best to locate the foramen using a gloved finger placed into the labial area over the mandible. Generally the foramen will be just medial to the pupil along a sagittal plane.

When using the *extraoral* approach, the overlying skin is prepped and anesthetized with an anesthetic skin wheal. The mental nerve is approached through the overlying skin using a needle trajectory perpendicular or at a 45° angle to the foramen. As noted above, the local anesthetic is infiltrated about the nerve about 3 to 5 mm *outside* of the foramen. After placement of 1 to 2 mL of local anesthetic about the nerve, the needle is withdrawn and the area over the foramen massaged for 10 to 15 seconds to hasten anesthetic onset.

When using the *intraoral* approach, it is best to use topical anesthesia prior to infiltration. The lower labial fold adjacent to the first or second premolar is topically anesthetized. The mental foramen is again approached at about a 45° angle, and the area adjacent to the foramen is infiltrated with 1 to 2 mL of local anesthetic and the area massaged as

above.

## Scalp Block

Scalp blocks provide surgical anesthesia for the repair of scalp lacerations, drainage of superficial scalp abscesses, and exploration of scalp wounds.

### Anatomy

As shown in Figures 39-12 (Figure Not Available) and 39-13 (Figure Not Available) , the scalp receives its nerve supply from branches of the trigeminal nerve (fifth cranial nerve) and the cervical plexus. The forehead is supplied by the supraorbital and supratrochlear nerves. Both nerves are branches of the ophthalmic division of the trigeminal nerve. The temporal region receives its nerve supply from the zygomaticotemporal (a $V_2$ branch nerve), temporomandibular, and auriculotemporal nerves ($V_3$ branch nerves).

The posterior aspect of the scalp is innervated by the greater auricular and the greater, lesser, and least occipital nerves. The nerves that supply the posterior aspect of the scalp originate from the cervical plexus. All the nerves become superficial above a line drawn from the upper border of the external ear to the occiput and the eyebrows and converge toward the vertex of the scalp (see Fig. 33-12) .

Topographically, the nerves and vessels of the scalp are located in the SQ tissue above the epicranial aponeurosis. From this level they divide into small branches that extend to the deeper layers (epicranium and periosteum) (see Fig. 33-13) . [6]

### Approaches

A scalp block can be accomplished by individually blocking each nerve that supplies the scalp, but this approach is time consuming, difficult, and cumbersome. Because the nerves on the scalp are superficially located, the scalp block can easily be performed by injecting local anesthetic agents into the SQ tissue circumferentially around the area to be blocked. Injection of local anesthetic to the deeper levels is necessary only if bone is to be removed. Note that injection of local anesthetic agents only in the deeper layers without SQ infiltration results in an unsuccessful block and a greater amount of bleeding during surgical intervention. [7]

In preparation for the block, a band of hair may be clipped. (Some physicians prefer to shave the head, but this procedure is of unproven benefit.) A band 1 cm wide and 3 cm away from the wound can be circumferentially clipped. Local anesthetics are injected in the clipped area.

The skin is prepared using an antiseptic solution, and a skin wheal is raised at any point of the shaved skin using a 1.3-cm (½-in.), 25-ga needle. A 7.6-cm (3-in.), 22-ga needle is inserted through the skin wheal into the SQ tissue and advanced along the scalp circumferentially following the previously clipped area. An injection of 0.5% to 1% lidocaine or 0.125% to 0.25% bupivacaine with epinephrine (1:200,000) is used.

Epinephrine should be added to the local anesthetic agent to provide vasoconstriction and to prevent excessive blood loss and local anesthetic absorption. The total dose of the local anesthetic agents should not exceed the recommended dose for the particular agent. It may be useful to inject some local anesthetic solution into the temporalis muscle to prevent contraction of the muscle during the primary procedure.

Colley and Heavner demonstrated that when bupivacaine is used, the peak plasma local anesthetic concentrations occur within 10 to 15 minutes after injection. [8] Thus, the first 10- to 15-minute period after the injection is the most critical period for the occurrence of local anesthetic toxicity. Colley and Heavner also found that despite the scalp's high vascularity, the absorption of local anesthetics from the scalp is not excessive. Using the upper limit of the recommended

dose of bupivacaine without epinephrine (175 mg), they found that peak plasma bupivacaine concentrations were 0.8 mug/mL with a 0.125% solution and 1.2 mug/mL with a 0.25% solution. Considering that the toxic plasma threshold for bupivacaine is 4 mug/mL, these concentrations suggest that a scalp block using bupivacaine has a wide margin of safety, even without the use of epinephrine. When epinephrine is used with bupivacaine, its effect on absorption becomes more pronounced with concentrations of 0.125% than with those of 0.25%. This is probably because at low concentrations (0.125%), bupivacaine has a vasoconstrictor property. [9]

## Greater and Lesser Occipital Nerve Block

This relatively simple block may be useful in the emergency department for treating occipital neuralgia and tension headaches. For occipital neuritis, a long-acting corticosteroid, such as methylprednisolone (20 to 40 mg) may be combined with the local anesthetic.

### Anatomy

The posterior aspect of the head is supplied by the posterior rami of the cervical nerves. Two important branches of these nerves are the greater and lesser occipital nerves. The greater occipital nerve becomes superficial on each side at the inferior border of the obliquus capitis inferior muscle and runs superiorly toward the vertex over this muscle. The nerve is located medial to the occipital artery. The lesser occipital nerve is located approximately 2.5 to 3.5 cm lateral and 1 to 2 cm caudal to the greater occipital nerve (Fig. 33-14) . [10]

### Approach

It is not usually necessary to shave or clip the scalp prior to performing greater and lesser occipital nerve blocks. The greater occipital nerve can best be blocked at the nuchal line, which is in the middle of the external occipital protuberance and the mastoid process. The nuchal line is located between the insertion sites of the trapezius muscle and the semispinalis muscles. At this site, the greater occipital nerve is just medial to

the occipital artery.

The occipital artery is first palpated, and a 3.8-cm, 22-ga needle connected to a syringe that contains 5 mL of local anesthetic is inserted through the skin (see Fig. 33-14) . After obtaining paresthesia at the vertex, 5 mL of local anesthetic solution are injected. The lesser occipital nerve is blocked by a fan-like injection of a local anesthetic solution 2.5 to 3.5 cm lateral and 1 cm caudal to the point described for the greater occipital nerve. [10]

This procedure is not usually associated with any complications; however, intra-arterial injections should be avoided by careful aspiration.

## Ophthalmic (V$_1$ ) Nerve Block [3]

The lateral and medial branches of the supraorbital, supratrochlear, and infratrochlear nerves may be blocked by percutaneous local injection at the point where they emerge from the superior aspect of the orbit. Anesthesia of the

### Anatomy

The subtle supraorbital notch, which is in line with the pupil, may be palpated along the superior orbital rim. This landmark is the site of injection for blockage of the supraorbital nerves. The supratrochlear nerve is found 0.5 to 1.0 cm medial to the notch. The infratrochlear nerve is not usually blocked but is found in the most medial aspect of the superior orbital rim. If the anesthetic is placed on the forehead proper, this block may not produce complete anesthesia of the skin of the upper eyelid if the sensory branches to the eyelid are given off before the supraorbital nerve transverses the forehead.

### Approach

With the patient in the supine position, a skin wheal is raised. Paresthesias in the form of an electric shock sensation over the forehead are sought; these ensure a successful nerve block. One to 3 mL of anesthetic are placed in the area of the supraorbital notch. A finger or a roll of gauze should be held firmly under the orbital rim to avoid ballooning of anesthetic into the upper eyelid (Fig. 33-16) (Figure Not Available) .

If paresthesias cannot be elicited or if the nerve block is unsuccessful, a line of anesthetic solution placed along the orbital rim from the lateral to the medial aspect will ensure block of all of the branches of the ophthalmic nerve (Fig. 33-17) (Figure Not Available) .

Hematoma formation or swelling of the eyelid may occur but requires only local pressure. Occasionally, ecchymosis of the periorbital region will appear the next day, and the patient should be warned of this possibility.

Although this block is infrequently used, it is easily performed and is not associated with serious side effects. Its use should be considered when anesthesia of the forehead or

the anterior scalp is desired.

## CONCLUSIONS

Blocks about the head and neck are relatively painless when done carefully and slowly following topical mucosal anesthesia (for intraoral approaches) or local skin anesthesia (for extraoral blocks and approaches). Patients who appear anxious may benefit from sedation prior to attempting these blocks. These blocks should not be attempted in the uncooperative patient.

# Chapter 34 - Intravenous Regional Anesthesia

**James R. Roberts**

The clinical use of intravenous (IV) regional anesthesia has been well established  as a safe, quick, and effective alternative to general anesthesia in selected cases requiring surgical manipulation of the upper and lower extremities. Although often relegated to the operating room, the procedure is readily applicable to outpatient use. In the emergency department the technique provides quick and complete anesthesia, along with muscle relaxation and a bloodless operating field. The procedure is free from the troublesome side effects associated with other regional blocks, such as the axillary block. The procedure is easily mastered and has a very low failure rate, and consistently good results can be expected.

The first practical use of analgesia associated with IV injection of a local anesthetic agent was described by August Gustav Bier in 1908. [4] Colbern [5] has since proposed the eponym *Bier block*. Although the procedure has been in existence for many years, the need for special equipment and a safe anesthetic agent limited its use. However, the Bier block has now gained wide acceptance as a safe and effective procedure, and several papers extol its virtues. Although complications do exist, no reported fatalities directly attributable to the use of the Bier block have been reported. In this chapter, the techniques and complications are discussed according to their application in the emergency department.

## INDICATIONS AND CONTRAINDICATIONS

Indications for IV regional anesthesia include any procedure of the arm or leg that requires operating anesthesia, muscle relaxation, or a bloodless field. I have used the procedure for the reduction of fractures and dislocations, repair of major lacerations, removal of foreign bodies, debridement of burns, and drainage of infection. The procedure may be carried out on any patient of any age who is able to cooperate with the physician.

The only absolute contraindications are an allergy to the anesthetic agent and uncontrolled hypertension. Relative contraindications include an uncooperative patient and the recent ingestion of a large meal, both of which may only delay the procedure rather than contraindicate it.

## EQUIPMENT

The equipment required for IV regional anesthesia consists of the following:

> 1% lidocaine (Xylocaine), *without epinephrine,* to be diluted to a 0.5% solution ( *note:* 1 mL of 1% lidocaine equals 10 mg)

Sterile saline solution as a diluent

50-mL syringe/18-ga needle

Pneumatic tourniquet (single or double cuff) ( *note:* Do *not* use a standard blood pressure cuff)

IV catheters (18- or 20-ga) or a 21-ga butterfly needle

Elastic bandage/Webril padding

500 mL D5 W (5% dextrose in water) and IV extension tubing.

## PROCEDURE

The procedure should be explained in advance to the patient. If the patient is extremely apprehensive, premedication with midazolam (Versed), diazepam (Valium), or an opioid (e.g., morphine or fentanyl) may be helpful but need not be routinely used. The only painful portions of the procedure are the establishment of the infusion catheter and the exsanguination procedure. The procedure should not be done on patients who are intoxicated or obtunded or on those with a previous reaction to a local anesthetic.

The patient need not be free of oral intake (NPO) for a specific period of time before the procedure, but it is prudent to delay the procedure if the patient has just eaten a large meal. As a precaution, a large-bore catheter and IV line of D5 W are established in the unaffected extremity. Resuscitation equipment, including anticonvulsant drugs and oxygen, should be readily available.

While the patient is being prepared, the lidocaine solution is readied but withheld until the injured extremity is exsanguinated and the cuff is in place and reinflated as discussed below. The standard dose of lidocaine is 3 mg/kg injected as a 0.5% solution (1% lidocaine is mixed with equal parts of sterile saline in a 50-mL syringe). Farrell and associates have described a procedure termed the *minidose Bier block* using 1.5 mg/kg of lidocaine and reported a 95% success rate. [10] This lower dose may decrease the incidence of central nervous system side effects and is more desirable in the emergency department setting. (Additional lidocaine may be infused if the initial dose is inadequate.) Lidocaine with epinephrine should *not* be used. Plain lidocaine is also available as a 0.5% solution, and as such, it can be used directly to avoid the necessity of diluting the stronger solution.

A pneumatic tourniquet with cotton padding (to prevent ecchymosis) under the cuff is applied proximal to the pathology (Fig. 34-1) (Figure Not Available) . *It is strongly advised that one not use a regular blood pressure cuff*, because these often leak or rupture and are not designed to withstand high pressures for any length of time. A specially designed portable double-cuff pneumatic system, such as that marketed by OEC Zimmer Corporation, is ideal (Fig. 34-2) (Figure Not Available) .

The anesthetic is premixed in the syringe. The tourniquet is inflated, and a 20-ga plastic

catheter or a metal butterfly needle is placed in the superficial vein, as close to the pathologic site as possible, and is securely taped in place (Fig. 34-3) (Figure Not Available) . It is usually desirable to use a vein on the dorsum of the hand, but importantly the injection site should be at least 10 cm distal to the tourniquet to avoid injection of anesthetic proximal to the tourniquet. The hub remains on the catheter to avoid backbleeding or the syringe is attached to the butterfly tubing. This catheter will be the route of injection of the anesthetic agent.

The tourniquet is deflated, and the extremity is exsanguinated so that when the anesthetic agent is injected, it will fill the vascular system. Exsanguination may be accomplished by either of 2 methods. Simple elevation of the extremity for a few minutes may be adequate, but wrapping the extremity in a distal-to-proximal direction with an elastic bandage, being careful not to dislodge the infusion needle, enhances the exsanguination (Fig. 34-4) (Figure Not Available) . Wrapping may be painful; this step can be eliminated if it causes too much anxiety to the patient. If the wrapping procedure is not done, the extremity should be elevated for at least 3 minutes. During the wrapping procedure, care must be taken not to dislodge or infiltrate the infusion catheter.

With the extremity still elevated, the tourniquet is inflated to 250 mm Hg, the arm is then placed by the patient's side, and the elastic exsanguination bandage is removed. In a child, the tourniquet is inflated to 50 mm Hg above systolic pressure.

The 0.5% lidocaine solution is then slowly injected into the infusion catheter at the calculated dose. Note that the solution is placed in the arm in which circulation is blocked, *not* in the precautionary keep-open IV line on the unaffected side. At this point, blotchy areas of erythema may appear on the skin. This is not an adverse reaction to the anesthetic agent, but merely the result of residual blood being displaced from the vascular compartment, and it heralds success of the procedure.

In 3 to 5 minutes, the patient will experience paresthesia or warmth, beginning in the fingertips and traveling proximally, with final anesthesia occurring at the elbow. Complete anesthesia ensues in 10 to 20 minutes, followed by muscle relaxation. Note that adequate analgesia may exist even though the patient can still sense touch and position and has some motor function. If the "minidose" technique (1.5 mg/kg of lidocaine) does not provide adequate anesthesia, an additional 0.5 to 1 mg/kg may be infused at this time. Additional lidocaine was required in 7% of cases in one series using the minidose regimen. [10] The physician should be patient, however, and wait a full 15 minutes before infusing additional lidocaine. Alternatively, if analgesia is slow or inadequate an extra 10 to 20 mL of *saline* solution may be injected to supplement the total volume of solution to enhance the effect. *Do not exceed a 3 mg/kg total dose of lidocaine*. The infusing needle is then withdrawn, and the puncture site is tightly taped to prevent extravasation of the anesthetic agent. The surgical procedure or manipulation is performed, including postreduction x-ray films and casting or bandaging (Fig. 34-5) (Figure Not Available) .

Anesthesia from a fingertip-to-elbow direction seems to occur irrespective of the site of anesthetic infusion, but selecting an injection site near the site of pathology will provide more rapid anesthesia at a lower dosage. On completion of the procedure, deflation of

the tourniquet is *cycled* to prevent a bolus effect of any lidocaine that may remain in the intravascular compartment. The cuff is deflated for 5 seconds and reinflated for 1 to 2 minutes. *This action is repeated 3 or 4 times.*

If the tourniquet has been in place for <30 minutes, it is dangerous to deflate it, because adequate tissue fixation of the lidocaine probably has not occurred. This may result in a higher peak plasma lidocaine level, with increased side effects. If the surgical procedure is completed rapidly and the 3-mg/kg limit of lidocaine has been infused, the tourniquet should remain inflated until a full 30 minutes has elapsed, and only then should it be deflated using the cycling technique. It is reasonable to use a 20-minute cutoff if the minidose technique is used, because this dose is equal to a commonly administered IV bolus.

Sensation returns quickly when the tourniquet is removed, and in 5 to 10 minutes, the extremity returns to its preanesthetic level of sensation and function. After 20 minutes of observation, the patient is released (Table 34-1) (Table Not Available) .

If the procedure takes longer than 20 or 30 minutes, many patients complain of pain from the tourniquet, because the tourniquet is not inflated over an anesthetized area. The use of a double-cuff tourniquet alleviates the problem of pain under the cuff.

In the double-cuff system, there are 2 separate tourniquets placed side by side on the extremity. One is termed the *proximal cuff*, and the other is called the *distal cuff*. The proximal cuff is inflated at the beginning of the procedure, and anesthesia is obtained under the deflated distal cuff. When the patient begins to feel pain under the proximal cuff, the distal cuff is first inflated over an already anesthetized area, and the pain-producing proximal cuff is then deflated. One must be certain to inflate the distal cuff before the proximal cuff is released; otherwise, the anesthetic will rapidly diffuse into the general circulation.

## MECHANISM OF ACTION

Some of the anesthesia is undoubtedly related to the ischemia produced by the tourniquet, but most of the anesthesia
is secondary to the anesthetic agent itself. Although the exact mechanism by which anesthesia is produced is unknown, the site of action of the anesthetic may be at sensory nerve endings, neuromuscular junctions, or major nerve trunks. [11] Contrast studies have demonstrated that the anesthetic agent does not diffuse throughout the entire arm, yet anesthesia of the entire limb is obtained. For example, when the anesthetic agent is injected into the elbow and kept in that region with both distal and proximal tourniquets, anesthesia of the entire arm develops. [12] Evidence indicates that the local anesthetic does not simply diffuse from the venous system into the tissue but travels via vascular channels directly inside the nerve. Regardless of where the anesthetic is infused, the fingertips are the first area to experience anesthesia, suggesting that the core of the nerve is in contact with the anesthetic agent initially. Following release of the tourniquet, a considerable amount of the drug still remains in the injected limb for at least 1 hour. [13] This would suggest that at least a portion of the

anesthetic leaves the vascular compartment and becomes tissue fixed.

# PROCEDURAL POINTS

### Anesthetic Agent

Using 0.5% plain lidocaine at a dose of 1.5 to 3 mg/kg is preferred. Other agents have been used without demonstrable advantage and are not recommended. [14] Bupivacaine (Marcaine, Sensorcaine) is *contraindicated* because of the potential for serious cardiovascular and neurologic complications.

Dunbar and Mazze [7] showed that patients with IV regional anesthesia actually had significantly lower plasma lidocaine concentrations than patients with axillary block or lumbar epidural anesthesia for similar procedures. Peak plasma concentrations are reached 2 to 3 minutes after deflation of the tourniquet, and side effects are minimal if the deflation is cycled following the surgical procedure. The plasma half-life of lidocaine is approximately 60 seconds (see the excellent detailed discussion of pharmacokinetics by Covino [17] ), but the drug demonstrates a theoretical 3-compartment model similar to a direct IV infusion once the tourniquet is released. [18] Peak blood levels are related to the duration of vascular occlusion and to the concentration of the anesthetic. [17] [18]

Post-release peak plasma lidocaine levels decrease as the time of vascular occlusion (tourniquet time) increases. If the tourniquet is inflated for at least 30 minutes and the deflation-reinflation technique is used when the procedure is finished, plasma concentration of lidocaine should be approximately 2 to 4 mug/mL, below the 5 to 10 mug/mL level at which serious reactions occur. [7] Tucker and Boas demonstrated a peak plasma lidocaine level of 10.3 mug/mL following a 10-minute period of vascular occlusion, compared with 2.3 mug/mL if the tourniquet was inflated for 45 minutes. [18]

More dilute solutions of lidocaine are associated with lower peak lidocaine levels. When equal doses of lidocaine are used, the peak arterial plasma levels are 40% lower when the 0.5% solution is used than when the 1% solution is used. [18] For example, following 10 minutes of vascular occlusion, the peak plasma concentration of lidocaine has been demonstrated to reach 10.3 mug/mL with the 1% solution, compared with only 5.6 mug/mL when the drug was given under similar circumstances as a 0.5% concentration. [18]

### Exsanguination

Exsanguination of the extremity before injection of the anesthetic agent is considered essential for success by many physicians. Others do not believe that it is a critical factor. Exsanguination by simple elevation of the extremity should be done in all cases, but in certain cases one should consider avoiding the painful wrapping of the extremity with an elastic or Esmarch bandage. (Note that applying an Esmarch wrap over a fracture site is usually quite painful.) A pneumatic splint, such as the type used for out-of-hospital immobilization, is also a reasonable alternative to painful wrapping. The process of exsanguination is believed to allow for better vascular diffusion of the

anesthetic.

**Site of Injection**

Anesthesia is usually obtained no matter where the local anesthetic is injected, but some evidence indicates that the procedure is more successful when the anesthetic is injected distally. Sorbie and Chacho note the following failure rate associated with specific sites of anesthetic injection: antecubital fossa, 23%; middle of forearm or leg, 18%; and hand, wrist, or foot, 4%. [3] For most cases, a vein in the dorsum of the hand or foot is most often used. If local pathology precludes the use of the hand, the midforearm or antecubital fossa of the elbow are acceptable, albeit less desirable, alternatives as long as the infusion catheter is well below the tourniquet to avoid systemic injection.

Although most of the literature stresses the use of this technique on the upper extremity, it may also be used successfully in the leg. It cannot, however, be used for procedures above the knee. Tourniquet pain appears to be a limiting factor when the procedure is used on the leg. One must be certain to avoid damage to the peroneal nerve by using the tourniquet in the midcalf area only.

# COMPLICATIONS

Although IV regional anesthesia is both safe and simple, one should not be lulled into complacency, because complications do occur and are usually related to equipment failure or mistakes in the technique.

**Anesthetic Agent**

Serious complications seldom occur if proper attention is paid to technique. Reactions to lidocaine are rare and are usually systemic reactions from high blood levels. High levels may result from miscalculation of dosages, from too rapid release of the tourniquet before the anesthetic has become tissue fixed ("bolus effect") or, rarely, from advancement of the infusion catheter proximal to the tourniquet, resulting in direct IV infusion. [20] To emphasize the safety of this procedure it should be noted that the dose of lidocaine used in the "minidose" technique is similar to an IV bolus routinely given to patients with significant cardiovascular disease, in the presence of ventricular dysrhythmias.

Generally, the central nervous system effects of lidocaine are minor, resulting in mild reactions such as dizziness, lethargy, headache, or blurred vision. This should not occur in more than 2% to 3% of patients and requires no treatment. [7] Convulsions may occur but are extremely rare.

The most common complication relating to the anesthetic agent is rapid systemic vascular infusion, which occurs when a blood pressure cuff explodes or slowly leaks, resulting in both loss of anesthesia and high blood levels. [21] Similar complications may occur if the cuff is deflated before 30 minutes following the induction of anesthesia. Both

complications are the result of a bolus effect of the anesthetic, resembling an IV injection.

Van Neikerk and Tonkin reported 3 seizures in a series of 1400 patients. [19] Seizures are generally not recurrent and are treated with O2 and anticonvulsant drugs. Transient cardiovascular reactions, such as bradycardia and hypotension, are possible with large doses of lidocaine. Vasovagal reactions do occur. If resuscitation equipment is available and a precautionary IV line is started in the opposite arm, there should not be any serious sequelae.

One case of cardiac arrest for 15 seconds following the use of 200 mg of lidocaine has been reported, but the actual clinical scenario may have been a vasovagal reaction rather than a true cardiac arrest. [22]

**Additional Complications**

Thrombophlebitis can occur following IV administration of anesthetics, and the formation of insignificant amounts of methemoglobin with the use of prilocaine hydrochloride (Citanest) has been reported. [23] Methemoglobinemia also can theoretically occur with lidocaine but has not been reported.

A particularly bothersome problem has been the infiltration of the infusion catheter during exsanguination, resulting in tissue extravasation of the anesthetic agent. Also, there has been some leakage of anesthetic after the infusion needle has been removed. Both problems may result in poor anesthesia but may be minimized if a small, well-secured plastic infusion needle is used instead of a metal scalp vein ("butterfly") needle and if the puncture site is tightly taped following withdrawal of the catheter.

This procedure cannot be used in manipulations or operations in which the pulse must be monitored as a guide to reduction (e.g., supracondylar fractures of the humerus), because the tourniquet occludes arterial flow. The use of the Bier block in patients with sickle cell disease is not well documented. It should be used with caution until the ischemic effect of the tourniquet on the red blood cells of such patients has been clarified. In all patients the tourniquet time should not exceed 90 minutes. Ischemia for less than that amount of time is not associated with serious sequelae.

# Chapter 35 - Systemic Analgesia and Sedation for Procedures

**Kevin R. Ward, Donald M. Yealy**

Pain is a common complaint of patients who present to the emergency department (ED). In addition, many of the diagnostic or therapeutic procedures that are carried out in the emergency setting produce the full spectrum of pain and anxiety. The emergency physician has the task of providing acute pain relief and sedation to all age groups under all circumstances, unannounced. Unfortunately, pain in the emergent setting, especially during procedures, is often underrecognized, underprepared for, and undertreated. Fear of adverse effects, especially oversedation, has led many clinicians to underuse and sometimes withhold systemic analgesia and sedation. [4] Even patient ethnicity has been shown to influence analgesic regimens in the ED in some types of injuries. [5] Emergency physicians should be expert in providing sedation and/or analgesia and should make it a high priority that all patients receive pain relief and sedation commensurate with their individual needs during any procedure.

## BACKGROUND

Depending on the circumstance, the emergency physician may be required to produce analgesia, sedation, or a combination of both. The related terms used in this chapter are defined below :

1. Analgesia: Relief of pain without intentional production of an altered mental state such as sedation. An altered mental state may be a secondary effect of medications administered for this purpose.
2. Anxiolysis: A state of decreased apprehension concerning a particular situation in which there is no change in a patient's level of awareness.
3. Conscious Sedation: A medically controlled state of depressed consciousness that:
   a. Allows protective reflexes to be maintained.
   b. Retains the patient's ability to maintain a patent airway and adequate oxygenation and ventilation independently and continuously; and
   c. Permits arousal of the patient to physical or verbal stimulation
4. (*Note*: It is possible to vary the degree of conscious sedation in a dose-dependent fashion.)
5. Deep or Unconscious Sedation: A state in which sedation is profound enough to result in the loss of 1 or more of the 3 components of conscious sedation.
6. General Anesthesia: A state that produces the following 5 conditions: sensory, mental, reflex, and motor blockade and concurrent loss of all protective reflexes.

The major differentiation among the states of conscious sedation, deep sedation, and general anesthesia is the degree of intact protective reflexes. Short of maintaining the ability to sit up and cough, the value of various degrees of "protective" reflexes is unclear. In reality, the personnel providing sedation and analgesia are the patient's best

protective reflexes.

The progression from light analgesia and sedation to conscious and deep sedation to general anesthesia should be viewed as a continuum. The need to produce a state of general anesthesia outside the operating room is infrequent outside of brief inductions associated with rapid-sequence intubation (see Chapters 2 and 3) . However, creation of a state of conscious sedation is frequently required to permit the humane performance of procedures, with a state of deep sedation being less frequently required. Although this has not been studied, it is likely that some patients cross over between states without the provider's knowledge. This is especially likely in states of conscious and deep sedation. Therefore, careful monitoring must be instituted prior to the sedation process.

## PRINCIPLES OF SYSTEMIC ANALGESIA AND SEDATION

Common therapeutic mistakes resulting in inadequate analgesia and sedation include using the wrong agent, using the wrong dose, using the wrong route and frequency of administration, and poor use of adjunctive agents. With proper training and technique, adequate analgesia and sedation can be provided under almost any circumstance.

The correct agent (or combination of agents) and the route and timing of administration depend on the following factors: How long will the procedure last? Will it be seconds (e.g., simple relocation of a dislocated joint, incision and drainage of a small abscess, cardioversion) or minutes (e.g., complex fracture manipulation for reduction, breaking up loculations in a large abscess and then packing it)? Can local anesthesia be used as an adjunct? Does the patient only require sedation for a diagnostic study? How likely is it that the procedure will need to be repeated? The latter is mainly of import in acute fracture care, where repeat manipulation and reduction may take place.

No agents exist that are totally void of adverse effects. For the most part, agents chosen for systemic analgesia and sedation in the ED should act rapidly on the central nervous system (CNS), produce their effect reliably, last throughout the procedure, and allow for quick recovery and timely disposition of the patient.

Table 35-1 provides a list of agents and their properties used to provide analgesia and sedation for painful and diagnostic procedures. A dose-dependent continuum exists for all centrally acting agents. This continuum spans a range from simple relaxation and decreased anxiety to unconsciousness. Increasing doses of analgesics or sedatives are associated with a nonspecific sedative effect and less of the drug's specific effect.

*IV titration of agent(s) to patient response is the best method of obtaining rapid and safe analgesia and/or sedation.* For example, when using opioids, doses administered in 2- to 5-minute increments, observing for side effects such as miosis, somnolence, decreased responsiveness to verbal stimuli, minimally impaired speech, and diminished pain on questioning,

**TABLE 35-1** -- Agents for Analgesia and Sedation

| Drug | Class | Actions | Adult Dosing [*] | Pediatric Dosing [*] | Contraindications (Other Than Hypersensitivity) |
|---|---|---|---|---|---|
| Morphine | Opioid | Analgesia Sedation | 0.08-0.15 mg/kg IV | 0.1 mg/kg IV | Hemodynamic instability Active bronchospasm |
| Meperidine (Demerol) | Opioid | Analgesia Sedation | 1.0-3.0 mg/kg IV in divided doses | Usually administered IM as 2-4 mg/kg with 1 mg/kg of promethazine and chlorpromazine (DTP) | As plain meperidine: Hemodynamic instability Active bronchospasm *When used as DPT:* Age <6 mo Neurologic illness History of dystonic reaction |
| Fentanyl (Sublimaze) | Opioid | Analgesia Sedation | 1-5 mug/kg IV | 1-5 mug/kg IV 5-20 mug/kg transmucosally by oral route | Use with caution when age <6 mo Use with caution with nitrous oxide |
| Sufentanil (Sufenta) | Opioid | Analgesia Sedation | | 0.7-1.0 mug/kg nasally | |

| | | | | | |
|---|---|---|---|---|---|
| Ketamine (Ketalar) | Phencyclidine derivative | Dissociative anesthesia with: Analgesia Sedation Amnesia | 0.5-1.0 mg/kg IV 2-4 mg/kg IM | 1.0-1.5 mg/kg IV 2-5 mg/kg IM 50 mg/kg rectally 5-6 mg/kg orally Often used with atropine | Head injury Hypertension/CAD States of sympathetic depletion Active URI History psychosis Age <3 mo |
| Nitrous oxide ($N_2 O$) | Anesthetic gas | Analgesia Anxiolysis Sedation Some amnesia | 50:50 mix of $N_2 O$ and oxygen | 50:50 mix of $N_2 O$ and oxygen | Pregnancy (chronic exposure) Impaired mental status Uncooperative |
| Midazolam (Versed) | Benzodiazepine | Anxiolysis Sedation Amnesia | 0.02-0.1 mg/kg IV in divided doses | 0.05-0.15 mg/kg IV 0.05-0.15 mg/kg IM 0.5-0.7 mg/kg PO 0.2-0.5 mg/kg nasally | Concurrent CNS depression |
| Thiopental (Pentothal) | Barbiturate | Sedation Amnesia | 1-3 mg/kg IV | 1-3 mg/kg IV 25 mg/kg rectally | Hemodynamic instability Bronchospasm |
| Methohexital (Brevital) | Barbiturate | Sedation Amnesia | 1-3 mg/kg IV | 1-3 mg/kg IV 25 mg/kg rectally | Hemodynamic instability Bronchospasm |

| Etomidate (Amidate) | Imidazole-containing compound | Sedation Amnesia | 0.1-0.3 mg/kg IV | 0.1-0.3 mg/kg IV Not fully approved for ages <12 | See text |
|---|---|---|---|---|---|
| Propofol (Diprivan) | Isopropylphenol compound | Sedation Amnesia | 50-70 mug/kg/min IV continuous infusion | 50-70 mug/kg/min IV continuous infusion | Hemodynamic instability |
| Chloral hydrate | Sedative | Sedation | | 50-75 mg/kg PO or rectally | Renal or hepatic impairment |

CAD, Coronary artery disease; URI, upper respiratory infection

* For IV dosing, careful titration is recommended. Usual full therapeutic dose is shown.
Atropine dose 0.02 mg/kg IM.

are appropriate initial end points. If sedation is desired, similar end points such as ptosis (rather than miosis), somnolence, slurred speech, and gaze alteration should be sought. Repeated doses may be given in a titrated fashion based on the patient's response during the procedure. Careful titration of agent(s) and experience will help reduce the number of patients who complain of pain at the height of the procedure.

Oral, transmucosal, and intramuscular (IM) routes are more convenient means of administration but for the most part are much less reliable for timely dose titration to a desired response. The main advantage of the other routes is use in individuals (e.g., children) in whom IV access may be problematic or for procedures that may require only sedation in conjunction with the use of local anesthetics. These routes also may be advantageous for simple sedation for diagnostic procedures.

The oral and transmucosal (intranasal and rectal) routes of analgesics and sedatives are becoming increasing popular, especially in children. These routes may be useful in given situations if their limitations are understood. The first-pass effect of hepatic metabolism may increase the time of onset and decrease the ability to titrate effects or agents administered by the oral and rectal route.

With the exception of ketamine, agents administered IM have erratic absorption and a variable onset of action. As such, prolonged preprocedural and postprocedural observation may be necessary. When required because of limitations in obtaining IV access, the IM route offers little advantage over oral or transmucosal administration.

Another alternative route of analgesic/sedative administration is inhalation. The only available inhaled analgesic/sedative for use in the ED is nitrous oxide. It offers the advantage of being self-administered and somewhat titratable.

Because individual needs may vary widely, application of arbitrary ceiling doses of analgesic and sedative regimens is unwarranted. In most situations, the true ceiling dose of an agent is that dose that provides adequate pain relief or sedation without major side effects such as excessive and prolonged sedation. Side effects such as nausea, severe pruritus (mild nasal itching is common), and hypotension also should halt administration of the offending drug. However, these side effects are not strictly dose dependent and may be seen even with small doses.

When an expected response is not achieved after the administration of an agent, either a higher-than-anticipated need exists or the agent was not successfully delivered. The former is corrected by increasing the titrated dose of the agent, whereas the latter is corrected by ensuring that the correct dose was given and that the route of delivery is intact.

There are only 2 absolute contraindications to providing systemic analgesia or sedation for a procedure: the presence of severe clinical instability requiring immediate attention, and refusal by a competent patient. Relative contraindications include hemodynamic or respiratory compromise, altered sensorium, or inability to monitor side effects. However, even in many of these circumstances, appropriate agents can be given to provide analgesia and sedation while minimizing the chances for further deterioration. Although patients at the extremes of age represent monitoring challenges and require careful titration to effect, age is not a contraindication to analgesia and/or sedation.

**Risk Reduction**

An important aspect of successful administration of analgesia and sedation in the ED is choosing the correct modality for the patient. A presedation evaluation should be performed to identify patients who are at risk for complications or for reactions to certain agents. Although most patients in the ED have recently eaten, this factor is not an absolute contraindication to sedation. Others at risk for aspiration include pregnant and obese patients. In the event that deep sedation is needed, additional precautions should be considered. This may include delaying the procedure, placing a nasogastric tube, or special positioning of the patient.

Other important factors to be taken into account are the presence of recent alcohol and illicit drug ingestion. In addition, prescribed medication recently ingested, administered, or not taken as scheduled should be considered. This might include analgesics given

prior to the procedure or cardiovascular medications not taken as scheduled by the patient. Other important aspects of evaluation may include assessment of the patient's upper airway, assessment of the patient's ability to move the neck (should subsequent intubation be required), notation of dental prostheses, past medical and mental history, current medications, and the availability of a responsible escort at disposition.

Although no formal ED evaluation guidelines exist, incorporation of the American Society of Anesthesia (ASA) physical status classification might prove helpful in determining the need for consultation with an anesthesiologist. Table 35-2 lists the ASA physical status classification. However, it should be understood that the use of carefully titrated doses of analgesics and sedatives will not increase the risk of adverse events. In fact, the reverse is true. Untreated pain or anxiety can increase morbidity and mortality. Myocardial ischemia, dysrhythmias, cerebral ischemia, impaired host defenses, and impaired $O_2$ utilization are but a few complications that may result from poorly treated acute pain. [8] Some institutions require written informed consent for all patients undergoing elective conscious sedation in the ED.

## Pediatric Procedural Analgesia and Sedation

Sedation and analgesia of even infants will reduce the associated physiologic stress of clinical procedures. The principles of analgesia and sedation in children do not differ significantly from those outlined above. [7] [8] [9] [10] Variation in pediatric pharmacokinetics means that no one sedation or analgesic protocol will work for every child, or even for the same child in differing situations. As with the elderly, children may exhibit a paradoxical response to sedation, and the clinician should be prepared to deal with such events. Close attention must be paid to appropriate weight-based dosing. In addition, special consideration must be given to the route of administration, especially since more options exist and IV access may be more problematic. IM injections (with the exception of ketamine) should be avoided unless IV access is unobtainable and oral, nasal, and rectal routes are not practical.

Common pitfalls in pediatric analgesia and sedation include mixing 2 opioids or 2 sedatives, producing analgesia when only sedation is required, failure to choose agents that can be easily titrated, inexperience with pediatric airway management, and impatience. [9] Finally, because monitoring is more challenging and side effects are less predictable, additional care should be taken when administering analgesia and sedation to infants and neonates. The procedure should, of course, be thoroughly discussed with the caregiver prior to its being undertaken. Extreme care must be taken

| TABLE 35-2 -- American Society of Anesthesiologists Physical Status Classification | |
|---|---|
| Class I | A normal healthy patient |

| Class II | A patient with mild systemic disease (controlled chronic obstructive pulmonary disease [COPD], hypertension, diabetes mellitus, prior myocardialinfarction, etc.) |
|---|---|
| Class III | A patient with severe systemic disease that is not incapacitating (moderate to severe COPD, coronary artery disease with angina) |
| Class IV | A patient with severe systemic disease that is a constant threat to life (marked congestive heart failure, unstable angina) |
| Class V | A moribund patient not expected to survive without the operation. |

 in children with heart conditions (e.g., septal defects or other anomalies) or respiratory problems (e.g., severe asthma or cystic fibrosis).

# AGENTS

In the discussion below, elimination half-lives are given for the various agents. This should not be confused with the actual duration of clinical effect of the agent. Agents with a very high lipid solubility have long elimination half-lives but short clinical durations of action. This occurs because the highly lipid-soluble agents redistribute rapidly from their main site of action to other nonactive sites, making their clinical duration short but increasing the length of elimination from nonactive lipid stores, such as fat. Although redistribution from nonactive to active sites occurs, it usually does not do so in concentrations high enough to produce a secondary profound clinical response if used for short durations.

## Opioid Analgesics

### Morphine

#### Pharmacology.

The prototype opioid to which all other opioids are compared is morphine. It produces analgesia, euphoria, and sedation. Even low doses of morphine increase the pain threshold and can modify the perception of a noxious stimulus so that it is not experienced as pain. [11]

Because morphine penetrates the blood-brain barrier poorly, plasma concentrations following IV administration do not correspond well with its pharmacologic activity. Following IV administration, peak pain-relieving effects occur between 15 and 30 minutes, which correlate with cerebrospinal fluid (CSF) levels of morphine. It is estimated that <0.1% of morphine given IV enters the CNS at the time of peak plasma concentrations. Reasons for poor penetration include its low lipid solubility, protein binding, high degree of ionization at physiologic pH, and conjugation with glucuronic acid. Morphine is principally metabolized by conjugation with glucuronic acid in hepatic and extrahepatic sites (principally the kidney). It does not undergo significant first-pass uptake by the lung. Its elimination half-life is 114 minutes, with its "active" half-life much less. [11]

**Adult dosage and use.**

If the goal is production of long-lasting analgesia, morphine is an ideal and inexpensive agent. When it is given in 0.08- to 0.15-mg/kg (IV) increments every 5 to 10 minutes, most adults will experience good pain relief at a total dose of 10 to 20 mg, although higher doses may be needed. [11] Because of delays in achieving peak CSF levels, morphine is not a good choice for short procedures. Morphine should be administered cautiously in critically ill patients in whom volume status is unknown.

**Pediatric dosage and use.**

Morphine may be used in the same manner in infants and children as in adults. It is best used as a long-lasting agent for continuous pain in 0.1-mg/kg increments (IV). [6] [10] As in adults, it should be administered cautiously in children with a tenuous or unknown volume status.

**Adverse effects.**

Morphine can cause nausea and pruritus, especially around the nose. Although morphine is not a direct myocardial depressant, it may cause hypotension by a number of mechanisms, including reducing sympathetic nervous system tone to peripheral veins, resulting in venous pooling; drug-induced bradycardia via stimulation of the vagal nucleus in the medulla; and histamine release. [14] [15] Histamine release may also cause bronchospasm. These effects can be greatly reduced by optimizing intravascular volume prior to administration and giving the agent slowly.

**Meperidine**

**Pharmacology.**

Meperidine (Demerol) is a synthetic opioid agonist derived from phenylpiperidine and is one tenth as potent as morphine. It is the most commonly administered opioid agent for

acute pain in the United States. [11]

Meperidine is rapidly cleared, with about 90% metabolized in the liver. However, its active metabolite, normeperidine, has one half the analgesic effect but twice the seizure-producing properties, although seizures are rare in the acute setting. Unlike morphine, plasma levels of meperidine correlate reasonably well with levels of analgesia. [16] Peak effect begins 10 to 20 minutes after IV administration. Absorption of meperidine by the IM route is extremely erratic, making it a poor choice to be administered in this manner. [11] Despite a longer elimination half-life (180 to 264 minutes) than morphine, the duration of effect of meperidine is shorter.

**Adult dosage and use.**

Most adults undergoing a painful procedure will require a total IV meperidine dose of 1.0 to 3.0 mg/kg or more in divided doses, depending on the duration and intensity of the procedure. [17] The clinical duration of the analgesia and sedation produced by adequate doses may be longer than needed for short outpatient procedures.

**Pediatric dosage and use.**

Because of a pharmacodynamic profile similar to morphine, meperidine offers no advantage over morphine as an IV titratable agent for acute, long-lasting pain. Because it cannot be easily titrated, it is not an appropriate agent for titration during painful procedures.

The popular combination of meperidine (2 mg/kg), promethazine (Phenergan) (1 mg/kg), and chlorpromazine (Thorazine) (1 mg/kg), better known as DPT, has been a time-honored IM "package" of analgesia and sedation. In addition to its 2:1:1 mixture, it can also be used in a 4:1:1 ratio. [6] [10] Although it provides moderate sedation and analgesia, the onset and duration of the effect are delayed and unpredictable and cannot be titrated. When this was carefully studied, only 70% of patients were moderately to well sedated after receiving this regimen. In addition, the mean time to release home approached 5 hours, with return to normal behavior averaging up to 19 hours. [18] Because of these many factors, the Agency for Health Care Policy and Research (AHCPR) Task Force on Acute Pain Management has discouraged the use of DPT. [19]

**Adverse effects.**

In equipotent doses, meperidine will produce as much euphoria, sedation, nausea, and ventilatory depression as morphine. Meperidine possesses direct myocardial depressant effects and produces a histamine release similar to that produced by morphine, making it a poor choice in hemodynamically sensitive patients. [14] [20] Seizures may be seen in patients who develop high levels of its active metabolite, normeperidine.

**Fentanyl**

This agent is from a family of opioid agonists that also includes alfentanil and sufentanil; all are

related to meperidine. Fentanyl is 75 to 125 times more potent than morphine and is capable of causing profound sedation but has no intrinsic anxiolytic or amnestic properties. [11] A single dose given IV has an extremely rapid onset (<30 seconds), with a peak at 2 to 3 minutes and shorter clinical duration of action (20 to 40 minutes) than morphine or meperidine. This increase in potency and onset of action is in part related to its greater lipid solubility, which facilitates its passage across the blood-brain barrier. Most (75%) of a fentanyl dose undergoes first-pass pulmonary uptake. When large doses are used and lung sites are saturated, a prolonged effect may result. Fentanyl is rapidly metabolized into inactive forms and is excreted into bile and urine. Despite its shorter duration of action, the actual elimination half-life of fentanyl is 185 to 219 minutes, longer than that of morphine.

**Adult dosage and use.**

Because of its rapid onset and relatively short duration of action when administered IV, fentanyl is an ideal agent when analgesia is required for painful procedures, because it can be easily and rapidly titrated. [21] It has commonly been described as a "20-minute drug for a 20-minute procedure," highlighting this opioid's excellent utility for the ED. Doses between 1 and 5 mug/kg are usually sufficient, especially if a sedative is also used. However, *it is paramount that vigilant respiratory monitoring be performed when using this drug.* When fentanyl was given in a bolus dose of 2.0 mug/kg to healthy adult volunteers, half developed hypoxemia ($SaO_2$ <90%) and significant depression of ventilatory response to $CO_2$ , but not apnea. When 0.05 mg/kg of midazolam was given concomitantly, almost all patients developed hypoxemia, and half developed transient apnea. [22] When fentanyl was given in a titrated fashion during a painful procedure, the incidence was much less. [21]

In the absence of significant ethanol intoxication, hypovolemia, or concomitant drug ingestion, hypotension is rare, with even large doses of fentanyl. Because of its safe hemodynamic profile, fentanyl is an ideal analgesic agent for use in critically ill or injured patients. During acute painful procedures in which fentanyl is used, most patients will benefit from the addition of a pure sedative. The exception to this may be when it is used as an analgesic supplement to local anesthesia when application of the local anesthetic may be extremely painful, such as to the ear or genitalia (e.g., prior to drainage of a Bartholin's abscess). With fentanyl, nausea and vomiting are rare, in distinction to analgesia with morphine or meperidine.

**Pediatric dosage and use.**

The same IV dosing regimen may be used in pediatric patients. [6] [10] However, because fentanyl is capable of causing impressive sedation in children, many opt to use the agent alone, without a pure sedative, for painful procedures or as a supplement to local anesthesia. However, when used in this manner, amnesia to the procedure may not occur. In addition to the potential complication of chest wall rigidity, described below, infants and children are at greater risk for bradycardia when fentanyl is given rapidly at higher doses.

In addition to IV administration, fentanyl may be administered as a transmucosal preparation. Oral transmucosal fentanyl (OTF) in the form of a lollipop may decrease anxiety and pain in a child prior to a painful procedure, such as application of a local or regional anesthetic. [23] At doses of 10 to 20 mug/kg, adequate analgesia and sedation occur within 30 minutes in 85% of patients. The frequency of nausea and vomiting (20 to 47%) increases with the dose. The role of this agent in the ED is promising but awaits further study.

**Adverse effects.**

A commonly observed patient reaction to administration of fentanyl is pruritus, often of the face (patients invariably scratch their nose). Fentanyl causes little nausea, vomiting, hypotension or other cardiovascular changes, and virtually no histamine release, making it an ideal agent for the critically ill patient or patient with bronchospastic pulmonary disease. [15] However, in the neonate, fentanyl may produce bradycardia secondary to central vagal nucleus stimulation and a prolongation of the refractory period at the AV node. A rare side effect in rapidly administered doses (5 mug/kg) is chest wall rigidity, which may not be readily reversible with naloxone and may require assisted ventilation and, occasionally, pharmacologic paralysis. [6]

**Sufentanil and Alfentanil**

**Pharmacology.**

Sufentanil, an analogue of fentanyl, is 5 to 10 times more potent than fentanyl, which is reflected in its greater affinity for opiate receptors. [11] Despite its high lipid solubility, its volume of distribution is smaller because of protein binding. Sufentanil is metabolized rapidly, with an elimination half-life slightly less than that of fentanyl. Compared with similar doses of fentanyl, sufentanil produces a longer period of analgesia with less ventilatory depression, although once apnea occurs, there is no significant difference in time of return of spontaneous respiration.

Alfentanil is another fentanyl analogue but is one fifth to one tenth as potent as fentanyl and has just one third the duration. The onset of action is rapid, peaking at 1 to 2 minutes, because 90% of it exists in a nonionized form at physiologic pH. Its volume of distribution is 4 to 6 times smaller than fentanyl, because it is slightly less lipophilic and more protein bound. [26] The actual elimination half-life is 70 to 98 minutes.

Although there may be some pharmacodynamic advantages to the use of these drugs for painful outpatient procedures, a large experience with them has not been reported. They may not have a significant advantage over fentanyl in terms of clinical effectiveness and cost-effectiveness in the adult population.

**Pediatric dosage and use.**

Despite its limited application in adults, sufentanil has been used in children as a nasally administered agent. When used nasally at a dose of 0.7 to 1.0 mug/kg, its onset is 5 to 15 minutes, and its duration is 30 to 60 minutes. [27] It is effective when used for the same indications as fentanyl. Nasally administered midazolam (0.2 mg/kg) may be used concomitantly. When this is done, the dose of nasal sufentanil should be limited to 0.7 mug/kg. [10]

**Adverse effects.**

These agents have a complication profile similar to that of fentanyl.

## Nonopioid Analgesics

A large variety of nonopioid analgesic agents are available for use in the treatment of acute pain. These include nonsteroidal anti-inflammatory drugs (NSAIDs), the dissociative anesthetic ketamine, and the inhalational analgesic nitrous oxide. Although NSAIDs aid in decreasing the need and amount of other analgesics during and after many procedures, most are available only in oral or rectal form and require 1 hour or longer for peak effects. This limits their

utility for performing emergent procedures of short duration. Although ketorolac can be given parenterally, it offers little practical benefit and is relatively costly. In addition, it is not approved for use in children.

### Ketamine

**Pharmacology.**

Ketamine may be the most common anesthetic agent used throughout the world. Its safety profile has permitted its use in rather primitive surgical settings. The drug is a phencyclidine derivative and is unique among sedative, hypnotic, and analgesic agents because of its ability to produce all three states. Its actions are thought to be caused from a dissociation between the cortical and limbic systems. The result is a seemingly awake patient (catatonic) who is dissociated from the environment but in whom intense analgesia and sedation is present. [28] [29] Its analgesic and anesthetic effects are likely mediated by different mechanisms and probably involve interaction with opioid receptors as well as antagonizing *N*-methyl-ᴅ-aspartate (an excitatory amino acid). Ketamine is a water-soluble molecule but is highly lipophilic. It is hepatically metabolized, with an

elimination half-life of 1 to 2 hours but a much shorter clinical half-life secondary to its rapid redistribution.

Ketamine can be given IV, IM, orally, transmucosally, and rectally. The pharmacodynamics depend on the route of administration. Clinical effects occur within 1 minute when given IV at a dose of 1 mg/kg with return of coherence in 15 to 20 minutes. When given IM, the same effect is achieved with 4 to 5 mg/kg but with an onset of 5 minutes and recovery in 20 to 30 minutes. [28] [29]

**Adult dosage and use.**

Ketamine is an effective agent for use in acute fracture or joint care, burn and wound debridement and dressing, large laceration repair, large abscess incision and drainage, and analgesia for other painful procedures during the resuscitation of acutely ill or injured patients who are hemodynamically unstable but not sympathetically depleted. An initial IV loading dose of 0.5 to 1.0 mg/kg should be given over 30 to 60 seconds while observing for signs of dissociation. Additional 5- to 10-mg doses may be given as needed to maintain adequate analgesia and sedation. The IM route (2 to 4 mg/kg) may be used for those in whom IV access is problematic.

For adults, concomitant benzodiazepine administration is recommended. Lorazepam at a dose of 1 to 4 mg IV just prior to use is reported to be very effective in preventing emergence phenomena. [30] [31] Our experience demonstrates that 0.01 to 0.05 mg/kg of IV midazolam given in divided doses during the procedure will also suffice. In nonintubated patients, the use of an anti-sialagogue is also recommended. Since atropine is a centrally acting agent and may potentially aggravate emergence delirium, glycopyrrolate should be used.

**Pediatric dose and usage.**

The safety and efficacy of ketamine has been documented in over 11,000 children. Indications for use in children are essentially the same as for adults. [32] [33] In addition, it may be used as a sedative agent for children undergoing diagnostic procedures. Ketamine is also valuable for use in repair of intraoral lacerations. Doses of 1.0 to 1.5 mg/kg IV or 2 to 5 mg/kg IM are effective. As with adults, the routine use of an anti-sialagogue is recommended. However, since emergence phenomena is rarer in children, especially those <10 years of age, atropine is most commonly used. The addition of a benzodiazepine such as midazolam (0.025 to 0.05 mg/kg) is recommended in children older than 10 years. The IM route of administration is popular in children, and if this is used, atropine and midazolam may be mixed with ketamine, and all 3 given as 1 injection.

Ketamine may also be administered to children by other routes, including nasal, oral, and rectal. [6] Effective anxiolysis and moderate sedation can be achieved with an oral dose of 5 to 6 mg/kg for outpatient procedures. Rectal ketamine in a 50-mg/kg dose is capable of producing a dissociative state in 4 minutes without cardiorespiratory

depression.

**Adverse effects.**

Compared to equipotent doses of other agents, ketamine has by far the best safety profile in terms of cardiorespiratory complications. Spontaneous respiration and upper airway tone are preserved, making intubation unnecessary, even in states of deep sedation. Protective airway reflexes such as swallowing and coughing are not depressed and may be slightly exaggerated. Ketamine may also cause hypersalivation and bronchorrhea. For these reasons, laryngospasm is occasionally produced with ketamine administration, especially in those with an active upper respiratory tract infection. The bronchorrhea and hypersalivary effects of ketamine can be reduced with prior administration of atropine (0.01 mg/kg to a maximum of 0.5 mg) or glycopyrrolate (0.005 mg/kg to a maximum of 0.25 mg).  Profound respiratory depression is rare, except after rapidly administered doses in children or in those with central nervous system injuries. Although vomiting is relatively common with ketamine, intact protective reflexes generally prohibit aspiration.

Although ketamine is a direct myocardial depressant, this is counteracted by its sympathomimetic actions, which are caused in part by its effect in inhibiting catecholamine uptake. This usually results in a net increase in heart rate and blood pressure after IV administration and is in part why it is valuable as an induction agent in hypovolemic patients. By the same token, because of this sympathomimetic effect, its use in those who may be catecholamine depleted or in those with severe coronary artery disease is cautioned.

Ketamine also has been inconsistently noted to increase intracranial pressure. The usual result, however, is a net increase in cerebral perfusion pressure because of increases in mean arterial pressure. Consideration of these factors should take place prior to its administration in those patients with potential head injury. Ketamine occasionally causes a transient erythematous papular rash involving the face and neck, but this is of no clinical significance.

The major concern with the use of ketamine has been its ability to cause hallucinations on emergence, even at subanesthetic doses. The true incidence of this occurrence is unknown, but maximum incidence has been estimated to be 50% in adults and 10% in children. Risk factors may include age >10 years, female gender, personality disorders, history of frequent dreaming, excessive stimulation during recovery, and rapid IV administration. The incidence of emergence phenomena can be reduced with IM or slow IV administration; a quiet environment for recovery; and, most importantly, concomitant administration of a benzodiazepine. Adjunctive benzodiazepine use can virtually eliminate emergence phenomena, although no exact dose has been studied in the outpatient setting. The precise mechanism for this

effect is not known but may be due in part to increased time of ketamine metabolism and prolonged recovery.

**Nitrous Oxide**

**Pharmacology.**

Nitrous oxide-$O_2$ mixtures provide anxiolysis and moderate analgesia when inhaled. [34] In U.S. EDs, it is used as a 50:50 mix at or near sea level or a maximum of 60:40 at higher elevations. In this concentration alone, general anesthesia cannot be provided. In its pure form, nitrous oxide is colorless, sweet smelling, heavier than air, and nonflammable. When mixed with $O_2$, however, it supports combustion. Nitrous oxide is highly soluble in plasma (30 times greater than nitrogen) and quickly diffuses across biologic membranes. This accounts for its rapid onset of action (30 to 60 seconds). Maximum effect occurs after about 5 minutes. Cortical function is depressed rapidly, and basically all sensations are affected. [34] These include decreases in taste, smell, hearing, and sensation to touch, pain, and temperature. The cardiovascular system, as well as the respiratory system and airway reflexes, are not significantly altered.

Inhalation of a 50:50 nitrous oxide-$O_2$ mixture has been reported to produce analgesia equivalent to 10 to 20 mg of morphine. However, patients experience a wide range of levels of relief. About 25% report marked pain relief, with 40 to 50% reporting mild to moderate relief, and the remaining 15 to 25% experiencing no relief. Because of this variable response, when extremely painful procedures are performed, carefully titrated doses of an opioid may be required to supplement analgesia. Conversely, nitrous oxide may be used as a means to reduce the amount of opioid analgesics required for procedures.

**Equipment.**

In the ED, nitrous oxide is self-administered via a hand-held mask or mouthpiece attached to a demand valve (Fig. 35-1) . A negative pressure of 3 to 5 cm $H_2O$ must be produced within the mask or mouthpiece to activate the flow of gas. This provides for patient-controlled delivery in cooperative adults or children above the age of 8 years and acts as a fail-safe control, because if the patient becomes too somnolent, delivery will not continue.

In the United States, a double-tank system is used to deliver the nitrous oxide and $O_2$ mixture. The system relies on a mixing valve preset to deliver a fixed 50:50 ratio and will only deliver gas when $O_2$ is flowing. The double-tank system contains a fail-safe device that automatically stops the flow of nitrous oxide when the $O_2$ supply is depleted. In addition, through special reference pressures, the unit provides automatic $O_2$ enrichment at very shallow breathing rates.

**Adult and pediatric use.**

The use of nitrous oxide is helpful as an adjunct during local or regional anesthesia administration prior to repair of a variety of soft tissue and orthopedic injuries. It may also be administered during difficult pelvic examinations, for cardiac- and

noncardiac-related chest pain, during attempts at difficult IV access, and as initial pain treatment of sickle cell pain crisis and renal colic. In general, nitrous oxide is ideal for procedures or conditions that are associated with a continuous baseline pain level, but it may afford insufficient analgesia when a particularly painful procedure (e.g., abscess drainage) is performed. As mentioned above, the addition of an opioid may be required for patients who do not receive moderate relief with nitrous oxide, or for more prolonged procedures. [9] Although the patient self-administers the gas, the clinician must be certain that the mask is actively held in place by the patient so that the mask will be released and gas flow stopped should the patient begin to lose consciousness.

**Adverse effects and precautions.**

A scavenging system must be in place to collect exhaled nitrous oxide when it is used. Scavenging devices can be placed in line with the delivery system to collect exhaled nitrous oxide, resulting in levels far below the 1200 ppm considered hazardous for use in the ED. A number of generally minor adverse effects may be seen even with therapeutic dosing (Table 35-3) . Because of concern about increased rates of spontaneous abortions, pregnant ED staff should avoid repeated exposures to the agent. However, its use in pregnant patients for short procedures is considered safe.

Because of its property of high diffusibility, nitrous oxide must be used with caution in the presence of closed-space disease such as bowel obstructions, pneumothorax, or pneumocephaly. The potential exists to greatly increase the size of the closed space, although when nitrous oxide is used in a 50:50 mixture for <30 minutes, increases are likely to be small. [41] Another concern with the use of nitrous oxide is the potential for *diffusion hypoxia*. When nitrous oxide is stopped, diffusion of nitrous oxide back from the blood into the alveoli may displace $O_2$ and produce a state of hypoxia. However, diffusion hypoxia does not occur with a self-administered 50:50 mixture.

Caution is advised in the use of nitrous oxide in the patient with chronic obstructive pulmonary disease (COPD), because the gas is mixed with 50% $O_2$ , which might cause depression of the hypoxic drive. However, 1 study found no increase in $Pa_{CO_2}$ in COPD patients given a 50:50 mixture. [42]

Although the potential for abuse by ED staff exists, such abuse should be rare if several simple steps are taken. As with other agents, a strict protocol of accountability should be in place. A simple locking device can be added to the cylinders of gas. In addition, the delivery valve or mouthpiece may be locked in the same place in the department as the opioids.

## Sedatives

### Benzodiazepines

**Pharmacology.**

Benzodiazepines are a group of highly lipophilic agents that possess anxiolytic,

amnestic, sedative, hypnotic, muscle relaxant, and anticonvulsant properties. [43] These agents lack any direct analgesic properties. Their use in conjunction with analgesics usually results in the need to administer less of the analgesic during the procedure. Diazepam and midazolam are the most common benzodiazepines

| TABLE 35-3 -- Side Effects of Nitrous Oxiide Analgesia | |
| --- | --- |
| Drowsiness | Dizziness or vertigo |
| Giddiness | Dysphoria or panic |
| Nausea | Voice change |
| Amnesia | Inappropriate laughing out loud |
| Paraesthesias | |

used as adjuncts with other agents, such as opioids, for painful procedures. Benzodiazepines in appropriate doses produce 2 helpful effects: anxiolysis and amnesia. Anxiolysis can be produced with relatively low doses. The amnesia produced by benzodiazepines is primarily anterograde in nature and usually dose dependent. Obviously, when used with appropriate doses of opioids, a smaller benzodiazepine dose will be needed to produce amnesia to any perceived pain. The anxiolytic and amnestic properties of benzodiazepines also help reduce the incidence and degree of emergence delirium associated with the use of ketamine.

An additional theoretical benefit for the use of benzodiazepines as an adjunct to painful procedures is their ability to produce muscle relaxation. Preventing the patient from consciously applying counterforces by providing proper sedation is likely the true benefit (e.g., during joint relocation).

Diazepam is insoluble in water and is dissolved in an organic solvent for administration. It is metabolized primarily by the liver and has a long elimination half-life (21 to 37 hours). In contrast, midazolam is water soluble, making IV administration less painful and absorption from the IM or mucosal route more rapid. It also undergoes primary

hepatic metabolism but has a greatly reduced elimination half-life of 1 to 4 hours. Midazolam is approximately 2 to 4 times more potent than diazepam, and its time to peak effect is 2 to 3 minutes (slightly faster than diazepam) when given IV. These differences primarily reflect midazolam's greater affinity for benzodiazepine receptors.

**Adult dosage and use.**

Diazepam offers no advantage over midazolam if a need exists to produce a titratable short state of anxiolysis or sedation. Midazolam given at a dose of 0.02 to 0.04 mg/kg (1 to 2 mg in most adults) every 3 to 5 minutes to doses up to 5 to 7 mg will produce adequate sedation in most patients, especially if opioid analgesics are also used. It may be used IM, but it is difficult to titrate in this manner. Midazolam is most commonly used for sedation for diagnostic procedures and as an anxiolytic and sedative adjunct to opioids during painful procedures. It also is used as an adjunct to ketamine anesthesia in adults and children over the age of 10 years in order to reduce the occurrence of emergence delirium.

Unlike barbiturates, etomidate, and propofol, it is difficult to use midazolam as a sole agent during rapid performance of painful procedures. This is secondary to its slower onset of action and prolonged duration. If midazolam used in doses equipotent (0.3 mg/kg) to those of barbiturates, ketamine, propofol, or etomidate, the onset of action is as rapid, but the duration of action is greatly prolonged. In addition, apnea is likely to occur.

**Pediatric dosage and use.**

Midazolam may be used for the same indications as in adults in an IV dose of 0.05 to 0.15 mg/kg. Some children require much larger doses, and rarely a child will exhibit a paradoxical response (i.e., hyperexcitability). Midazolam is used more frequently for sedation as an adjunct to local anesthesia for laceration repair and as a sedative for diagnostic procedures. Because of its pharmacology and the unique problems with medication administration in children, it has become popular to administer midazolam orally (0.5 to 0.7 mg/kg) and intranasally (0.2 to 0.5 mg/kg). When used intranasally, the technique of administration is as important as the dosing. Care should be taken to slowly apply the agent in a dripping fashion and to position the patient in such a way as to put

as much of the agent in contact with the mucosa as possible. If used in combination with intranasal sufentanil, the dose should be limited to 0.2 mg/kg. Note that midazolam's variable onset, when given orally or intranasally, may render this route inappropriate for many emergency procedures.

**Adverse effects.**

Because of its profile, midazolam has become the agent of choice in emergency medicine to supplement analgesics in the performance of painful procedures. It is associated with a dose-dependent decrease in ventilation that is greatly enhanced in the

presence of ethanol or other depressive drugs, especially opioids. These effects are exaggerated in the elderly. More than 80 deaths from respiratory arrest have been associated with the use of midazolam, and many of these occurred when an opioid was concomitantly used. [22] Careful attention to monitoring should take place when benzodiazepines and opioids are used together. When slowly administered and carefully titrated, these agents are usually void of any serious hemodynamic complications.

**Barbiturates**

**Pharmacology.**

Barbiturates are a class of highly alkaline and highly lipophilic drugs that work at the gamma-aminobutyric acid (GABA) complex and are capable of causing profound sedation, hypnosis, amnesia, and anticonvulsant activity in a dose-dependent fashion. [45] They possess no inherent analgesic properties and in low doses may produce a state of hyperesthesia. The major use of barbiturates has been as induction agents for the production of general anesthesia. In the ED, they have mainly been used as part of rapid-sequence endotracheal intubation protocols.

Thiopental and methohexital are the barbiturates most commonly used IV and are termed *ultrashort-acting*. Because of their lipid solubility, they are also effective when given rectally. When given IV, both produce effects within 1 minute. Clinical recovery in terms of protective reflexes and wakefulness is rapid and reflects the rapid redistribution of these agents from the central nervous system (CNS). The elimination half-lives of methohexital and thiopental are 3.9 and 11.6 hours, respectively. Their rapid redistribution half-lives, however, are similar at 5.6 and 8.5 minutes, respectively. [45] Both agents produce residual sedation.

**Adult dosage and use.**

Barbiturates such as thiopental or methohexital may be useful in such procedures as rapid relocation of a large joint; simple, rapid reduction of a fracture; or incision and drainage of an abscess. Because they provide no analgesia in the doses used, the procedure should be extremely short, so that the duration of acute pain from the procedure is minimized. The use of these agents for emergent cardioversion is not recommended because of the high probability of worsening an already compromised hemodynamic status. Incremental IV titrated doses of methohexital (1 to 3 mg/kg) or thiopental (1 to 3 mg/kg) usually produces sedation within 1 to 2 minutes that lasts for 5 to 10 minutes. Rarely is >2 to 3 mg/kg of either agent required.

**Pediatric dosage and use.**

Thiopental and methohexital may be used in the same manner as in adults and at the same dose. In addition to its IV use, excellent longer lasting sedation for pediatric diagnostic procedures occurs when either agent is given rectally at a dose of 25 mg/kg. Sedation is produced within 8 minutes, and apnea has not been reported to be a

problem. This route and dose also may be used when sedation is required for laceration repair in addition to local anesthetics.

**Adverse effects.**

Use of barbiturates can be associated with major adverse effects, especially if patients are not chosen correctly and dosing and monitoring are not carefully performed. These effects include hypotension in overtly or occultly hypovolemic patients, through a number of mechanisms. Even in normovolemic patients, transient 10- to 20-mm Hg drops in blood pressure and increases in heart rate may occur. [46] Because barbiturates also cause histamine release, airway tone can increase (including laryngospasm) during barbiturate administration. Barbiturates also cause a dose-dependent decrease in ventilatory drive and maintenance of protective reflexes. Unfortunately, the window between light sedation, deep sedation, and general anesthesia produced by these agents can be narrow.

**Etomidate**

**Pharmacology.**

Etomidate is an imidazole derivative that is able to produce sedation, anxiolysis, and amnesia equal to that of barbiturates, but with significantly fewer adverse hemodynamic effects. [28] It has most commonly been used to induce anesthesia in hemodynamically compromised patients, as well as to reduce intracranial pressure while avoiding decreases in mean arterial pressure. Its onset of action and recovery are similar to those of thiopental and methohexital.

**Adult dosage and use.**

The main indication of etomidate may be during the performance of short painful procedures, such as cardioversion, in those individuals who are hemodynamically compromised or have a history of severe coronary artery disease. Doses of 0.1 to 0.3 mg/kg slowly administered IV are usually adequate. As with barbiturates, some residual sedation exists.

**Pediatric dosage and use.**

Etomidate has not been approved for use in children under the age of 12 years. [6] Although experience with this agent as a sedative for painful pediatric procedures is limited, its use in patients with a tenuous hemodynamic status may still be warranted.

**Adverse effects.**

Etomidate is associated with nausea on recovery and benign myoclonic jerks. This latter effect may limit its usefulness as a sedative during diagnostic procedures requiring a motionless patient. Transient reduction in cortisol production has also been documented

after the use of etomidate, but the clinical significance of this is unclear.

**Propofol**

**Pharmacology.**

Propofol is a substituted isopropylphenol. It is highly lipophilic and capable of producing profound sedation, hypnosis, and amnesia, but it is without innate analgesic properties. [28] The characteristic that sets this drug apart from others is its rapid metabolic clearance and redistribution, which is approximately 10 times faster than that of thiopental. Although the elimination half-life is 0.5 to 1.5 hours, the clinical recovery is extremely rapid (within 4 to 8 minutes), even after prolonged administration, and with little residual sedation. Recovery is even faster when subinduction doses are used. Onset after IV administration is rapid, with a "one arm-to-brain" circulation time of 15 to 30 seconds. Propofol has the added advantage of having intrinsic antiemetic effects. [47]

**Adult and pediatric dosage and use.**

Propofol is indicated for use in the same conditions as barbiturates. Experience with propofol in the ED is limited. [48] With proper guidance and sufficient practice, propofol may become the

agent of choice. This may be particularly true in cases where procedures must be repeated within a short time frame (e.g., remanipulation of a fracture after initial reduction is shown on radiographs to be inadequate).

When propofol is used, a carefully titrated dose of 50 to 70 mug/kg/min as a continuous infusion is recommended. [49] [50] [51] [52] At this dose it produces a sleep-like state with minimal respiratory depression and easy arousability to verbal commands, with recovery occurring in 2 to 2.5 minutes after stopping the infusion. If short-acting opioids are needed as an analgesic adjunct, the dose of propofol should be reduced.

**Adverse effects.**

The major drawbacks to the use of propofol for painful procedures are its potent respiratory and cardiac depressant effects. As with barbiturates, patients must be chosen carefully to prevent sudden profound hypotension (i.e., it should not be used when cardiovascular compromise is suspected). A narrow window exists between conscious and deep sedation. When it is used as a constant infusion, patients are awake 2 to 2.5 minutes after stopping the infusion. [47] Recovery is likely to be just as rapid with cessation of a continuous infusion as with administration of flumazenil or naloxone to reverse the effects of benzodiazepines or opioids, respectively. Lower doses may suffice, depending on the procedure. Adjunctive use of short-acting opioids such as fentanyl may be required for supplemental analgesia, depending on the type of procedure and its duration.

**Chloral Hydrate**

Chloral hydrate is a pure sedative hypnotic agent without analgesic properties. Its major use is for sedation as an oral or rectal agent in children during diagnostic procedures or as an adjunct with local anesthetics for painful procedures. [6] It is generally administered in a dose of 50 to 75 mg/kg, given orally or rectally. The average time to peak sedation is 40 minutes, with a recovery time of an additional 40 to 60 minutes and with residual effects (mild sedation) lasting up to 24 hours. [53] Higher doses (e.g., up to 100 mg/kg) are more effective but begin to carry risk similar to that of more potent regimens, without adding any practical benefit. Chloral hydrate is best used in healthy children for scheduled outpatient studies [54] and is generally of little use in emergency patients.

## Adjunctive Agents

Clinicians have long sought agents that would safely potentiate the effects of opioids. Agents that have been used for this purpose include phenothiazines (promethazine, prochlorperazine, and chlorpromazine) and antihistamines (mainly hydroxyzine). However, the major theoretical benefit of concurrent phenothiazine use is for treatment of the nausea that occasionally accompanies the use of opioids. No analgesic benefit has been demonstrated from the combination of opioids and phenothiazines, although the level of sedation is increased. The sedation due to these agents cannot be reversed using opioid antagonists.

Hydroxyzine (Vistaril) is an antihistamine with minor sedative and antiemetic properties. Controversy exists as to its ability to augment the analgesic properties of opioids. One study found that 100 mg of hydroxyzine provided analgesia equal to 8 mg of morphine in addition to providing significant anxiolytic effects. The major disadvantage to this agent is that it is recommended only for IM use.

## Reversal Agents

Reversal agents are generally not required following the use of opioid or benzodiazepine agents for analgesia and sedation. However, patients with underlying pulmonary or cardiovascular disease may benefit from a more rapid reversal, as do those patients who demonstrate apnea not responding to stimulation. Specific agents exist for reversal of both opioids and benzodiazepines.

**Opioid Reversal**

**Pharmacology.**

Naloxone and nalmefene are opioid antagonists that competitively inhibit opioid agents at opiate receptors. They rapidly reverse mainly the respiratory depressant effects of opioids. Both agents may be administered IV, IM, or even sublingually if needed.

**Adult and pediatric use.**

Naloxone at an initial dose of 2.0 mg in adults and 0.1 mg/kg in children will generally reverse the effects of opioids. Doses may be repeated every 2 to 3 minutes to a total dose of 10 mg in both adults and children. Nalmefene at an initial dose of 0.1 mg/70 kg, up to a total dose of 1.5 mg/70 kg in adults, produces the same reversal as naloxone, with the potential added advantage that it has twice the opioid receptor blockade at 8 hours, making resedation with commonly used opioids less likely. Nalmefene's efficacy in children has not yet been demonstrated. For patients with expected continued pain or those with preexisting physiologic dependence, the reversal should be more controlled (see below).

**Adverse effects.**

The opioid reversal agents will *not* induce systemic opioid withdrawal symptoms in a patient without preexisting physiologic dependence. However, some patients will experience nausea with opioid reversal, and those patients with persistent pain following their procedure will be quite uncomfortable. Nonopioid analgesia may benefit these latter patients (i.e., nonsteroidal anti-inflammmatory drugs [NSAIDs]). Rapid reversal also may lead to return of anxiety and sympathetic stimulation. In these situations it is preferred to partially reverse opioid sedation by administering small aliquots of naloxone (e.g., 0.2 to 0.4 mg per dose in an adult; 0.01 mg in a child) every 1 to 2 minutes until the desired level of alertness or respiratory drive is achieved. Close monitoring of respiratory effort will be required as the naloxone wears off.

**Benzodiazepine Reversal**

**Pharmacology.**

Flumazenil is a benzodiazepine antagonist that competitively inhibits benzodiazepine agents at the GABA receptor. It is capable of prompt reversal of benzodiazepine-induced respiratory and CNS depression.

**Adult and pediatric use.**

Flumazenil is effective in adults and children when given in a dose of 0.02 mg/kg in children or 0.1 to 0.2 mg in adults at 60-second intervals up to a total dose of 1 mg.

**Adverse effects.**

Blockade of the GABA receptor may lead to repetitive seizures. Flumazenil should be used with extreme caution in individuals using benzodiazepines for chronic seizure control, in persons with a cyclic antidepressant overdose, and in those with an elevated intracranial pressure. Rapid reversal also may lead to return of anxiety

and sympathetic stimulation. Administering flumazenil in small aliquots (e.g., 0.1 mg/dose) over an extended period of time (i.e., 1 to 2 minutes per dose) will result in a more gradual reversal and will ameliorate some of the benzodiazepine reversal anxiety or hyperactivity seen with rapid bolus injections.

# SEDATIVE-ANALGESIC COMBINATIONS

Patients undergoing procedures primarily associated with anxiety, such as wound repair after local anesthetic infiltration or diagnostic imaging studies, are best managed using pure sedatives. However, most painful procedures that will last more than a few seconds may benefit from the use of both a sedative and an analgesic agent to maximize patient cooperation and comfort. The clinician must use judgment, incorporating the patient's emotional and physical state and the anticipated duration of the procedure and associated pain, to determine the degree of analgesia and sedation required. In all circumstances, careful monitoring and titration of drug doses to effect are required. For most agents, the upper limit of dosing is guided by patient response. Below are some examples of effective combinations for painful procedures.

### Fentanyl and Midazolam

#### Indications

This combination has become a commonly used regimen for painful procedures in both adults and children. The combination is close to ideal, because both agents have approximately the same time to peak action, as well as the same clinically effective duration. In addition, both agents can be reversed if required. Since the combination can easily produce apnea, careful monitoring is required. The combination is effective for fracture reduction, relocation of joints, abscess drainage and packing, chest tube placement, wound and burn debridement, and other painful procedures. In addition, when given in small and frequent aliquots, the combination provides effective analgesia and sedation in victims of multisystem trauma or other patients with critical illness who are intubated and require a prolonged diagnostic workup in the ED.

#### Adult Use

After obtaining written informed consent that is specific for elective conscious sedation (where mandated), and after initiation of proper monitoring (see Monitoring During Use of Analgesia and Sedation), sedation should first be initiated by administering 1 to 2 mg of midazolam over 30 to 60 seconds. Repeat doses should be administered every 3 minutes until mild sedation and anxiolysis are produced. This occurs in the vast majority of individuals with 3 to 5 mg. Fentanyl should then be administered in 100-mug (2-mL) increments every 3 to 5 minutes until adequate analgesia and sedation are obtained (as evidenced by slurred speech, ptosis, and drowsiness, but purposely responsive to painful and verbal stimuli). The best judge of adequate analgesia will be the patient's response in the initial stages of the procedure. In most cases a dose of 4 to 5 mug/kg is

sufficient.

Some clinicians prefer to reverse the above order, administering fentanyl first. With this alternate approach, an adequate analgesic dose is first estimated, and its effects will persist even if the operator chooses to reverse the midazolam portion of the sedation. This approach may be less satisfactory in those procedures where the intensity of pain increases significantly during the procedure. A detailed description of the approach to the combined midazolam/fentanyl sedation/analgesia appears in Table 35-4 .

**Pediatric Use**

The above regimen may be performed in children undergoing painful procedures. Midazolam is given in 0.03- to 0.05-mg/kg increments, and fentanyl is given in 1 mug/kg doses until the desired effect is achieved. As mentioned above, if IV access is problematic, a similar state can be produced with a combination of nasally administered sufentanil (0.7 mug/kg) and midazolam (0.2 mg/kg).

## Midazolam with Other Opioids

**Indications**

Midazolam can be used in combination with other opioids such as morphine and meperidine for analgesia and sedation during painful procedures. However, opioids other than those in the fentanyl family have peak actions in the 15- to 20-minute range, making their rapid titration with midazolam difficult and increasing the necessary period of recovery. If used, sedative agents should be given 10 to 20 minutes after opioid administration in order to take advantage of peak analgesic effects. The main advantage of this regimen may be cost.

**Adult Use**

After initiation of appropriate monitoring (see Monitoring During Use of Analgesia and Sedation), the opioid agent is titrated to light sedation. Generally, morphine sulfate is administered in 1- to 2-mg increments every 3 to 5 minutes until the patient is comfortable and eyelids are heavy or speech is slightly affected ("thick"). Another 15 to 20 minutes are allowed to pass for peak opioid effect to occur. Then, just prior to the procedure, midazolam in 1- to 2-mg increments is used to supplement the sedation until the patient is somnolent or speech is slurred. Asking the patient to count backward from 100 is a useful tool. Often the patient will begin to skip numbers or count repetitively when the appropriate degree of sedation is reached.

## Ketamine and Midazolam or Lorazepam

This combination is ideal in settings similar to those in which fentanyl and midazolam are used. Details of the dosing of this regimen, including use of anti-sialagogues, are

provided in the preceding section on ketamine administration.

## Nitrous Oxide and Fentanyl

### Indications

Nitrous oxide has both sedative and analgesic properties, the degree of which is somewhat unpredictable. However, because of the ease of administration and low incidence of respiratory depression, its use as an adjunct to short-acting

| **TABLE 35-4** -- Procedure for Safe and Successful Conscious Sedation with Midazolam/Fentanyl | |
|---|---|
| **Caveats** | |
| 1. | Don't consider this procedure if you do not have experience with the drugs or the time to perform it properly (15-20 min). Do not attempt the procedure if the pulse oximeter is not working, the IV is not secured, or the room is too small. |
| 2. | This is a 2-person procedure, 1 to monitor the patient and 1 to administer medication and perform the procedure. |
| 3. | Individual response to the drugs is variable and dependent upon the patient's underlying physiologic state and the presence of concomitant drugs/medication. |
| 4. | Maximum drug effect may take 2-3 min following administration. Proceed slowly and be patient, allowing the medication to take full effect before giving more. |
| 5. | Have naloxone and flumazenil at the bedside. Label all syringes with the full names of the drug (not with 1-letter abbreviations). |

| | |
|---|---|
| 6. | If the patient seems overly sedated, perform the procedure. The pain of the procedure often stimulates respiration and lessens sedation. |
| 7. | Give written instructions at the time of release, since even a seemingly awake patient who has received midazolam may not remember anything. |
| 8. | The order of the drugs is one of personal preference. Reversal of the drugs is not routine. If flumazenil alone is used for reversal, the patient awakens, and the analgesic effect of fentanyl remains. |
| 9. | Where appropriate, obtain written informed consent specific for conscious sedation. |

**Protocol**

| | |
|---|---|
| 1. | Establish an IV infusion of normal saline (18-ga catheter preferred in adults) in the supine patient with the bed rails in the up position. |
| 2. | Pulse, respiratory rate, blood pressure, and level of consciousness should be recorded intially, *and every 5 to 10 min throughout the procedure.* |
| 3. | Continuous monitoring of oxygen saturation with a pulse oximeter probe (to maintain at >95% or no less than 3% to 5% less than the initial value) must be performed. Supplemental oxygen via nasal prongs is given at a rate of 4 to 6 L/min. ECG monitoring is optional but suggested in the elderly or those with a cardiac history. |
| 4. | A resuscitation cart with a bag-valve-mask, oral and nasal airways, endotracheal tubes, and a functioning laryngoscope must be nearby. Suction equipment and naloxone and flumazenil should be at the bedside. |

| | |
|---|---|
| 5. | Administer 1 mg midazolam over 30 to 60 sec; if, after 3 to 5 min, there is no evidence of mild sedation (subjective relaxation by the patient with mild drowsiness and normal or minimally altered speech), additional 1-mg doses can be administered in a similar fashion, up to a maximum of 0.1 mg/kg. * The goal is *mild sedation and anxiolysis,* achievable in most patients with 2 to 4 mg of midazolam. |
| 6. | Reassess clinical status (see 2). |
| 7. | Administer fentanyl 100 mug (2 mL) over 60 sec; this may be repeated in 0.5- to 1.0-mug/kg (50- to 100-mug) increments every 3 to 5 min until adequate analgesia and sedation have been obtained (slurred speech, ptosis, drowsy but responsive to painful and verbal stimuli, and good analgesia with initial stages of procedure). The maximal total dose recommended is 5 to 6 mug/kg. * |
| 8. | Administer local anesthesia if indicated (this often serves to help gauge effectiveness or systemic analgesia). |
| 9. | Perform the procedure. Additional doses of fentanyl may be required based on the response and length of the procedure. |
| 10. | If hypoxemia, deep sedation, or slowed respirations unresponsive to external stimuli are seen during or after procedure, ventilation should be assisted with a bag-valve- mask and flumazenil and/or naloxone should be administered. Naloxone should not be given routinely at the termination of procedures, since it will abruptly reverse all analgesia. |
| 11. | Continue close observation until the patient is awake and alert, and release the patient with a friend or relative only after a minimum 1 hr of further observation. Instruct the patient not to drive or operate dangerous machinery for at least 24 hr. |

* For children, fentanyl alone is suggested in 0.5-mug/kg increments, up to a maximum total dose of 2 to 3 mug/kg.
Sublimaze 50 mug/mL.

analgesics such as fentanyl is desirable. Concurrent use of nitrous oxide reduces the

amount of IV analgesic needed.

**Adult and Pediatric Use**

After several minutes of breathing the 50:50 nitrous oxide-$O_2$ mixture, adults and children may receive IV administration of fentanyl in doses of 1 mug/kg given every 3 to 5 minutes until adequate analgesia is produced or the patient cannot coordinate the use of the mask and the demand valve. Rapid reversal takes place with administration of naloxone, removal of the mask, or both.

## Propofol and Fentanyl

**Indications**

Despite a sparsely published use in the emergency medicine literature, this combination may become common in adults and children with no underlying cardiorespiratory problems. The major advantage of this combination is when a painful procedure may have to be repeated, such as with complex fracture manipulation and reduction.

**Adult and Pediatric Use**

For adults and children, fentanyl can be given in a priming dose of 1 to 2 mug/kg over 1 minute. Propofol is then administered as a constant IV infusion at a dose between 50 and 70 mug/kg/min. When the patient is adequately oxygenated, respiratory depression, when recognized, can be reversed within 30 to 60 seconds by cessation of the propofol infusion, without the occurrence of hypoxemia.

# MONITORING DURING USE OF ANALGESIA AND SEDATION

## General Indications

Monitoring has two goals: ensuring adequate analgesia and sedation and detecting adverse effects. While adverse effects

will undoubtedly occur regardless of how much care is taken, most serious adverse effects can be averted when detected at the earliest possible time with well-chosen and applied monitoring. Clinical monitoring of vital signs is required whenever analgesic or sedative agents are administered. The use of adjunctive equipment should be guided by local hospital policy. Generally, $O_2$ saturation and rhythm monitoring are used when conscious sedation is the therapeutic goal. Adjuncts such as expired $CO_2$ monitoring and automatic blood pressure monitoring should be determined by patient status, planned analgesic and sedative agents, and anticipated duration and nature of the procedure.

## Interactive Monitoring

As important as the actual monitoring equipment are the personnel involved in the procedure and monitoring. Regardless of how much monitoring equipment is used, interaction between the clinician and the patient must take place. Monitoring techniques can therefore be divided into interactive and mechanical methods. Interactive monitoring involves contact between the person providing monitoring and the patient.

Assessment of the patient's baseline status is the first step of interactive monitoring. This includes measurement and recording of basic vital signs, such as blood pressure, respiratory rate, and heart rate. Baseline and interval assessment of the patient's level of consciousness should be performed and based on the stimulus required to evoke 1 of the following responses: awake and spontaneously conversant, somnolent but responsive to verbal or painful stimuli, or unresponsive to any stimuli.

Prior to administration of any agent to adults or children over the age of 8 years, some attempt should be made to assess pain. In clinical practice, the use of a simple numeric scale from 1 (barely perceptible pain) to 10 (worst pain imaginable) may work best. For research purposes, visual analog scales are optimal. When appropriate, the patient should be informed of what clinical actions will be taken for various subjective pain scores (a score >3 will be treated with additional analgesia). Ongoing interactive monitoring should take place in at least 5-minute intervals. In addition, certain side effects, such as dyspnea, chest pain, nausea, dizziness, and visual or auditory changes, should be regularly inquired about.

Patients should be carefully monitored until recovery is complete. Depending on the particular agent and dose used, interactive monitoring should take place at frequent intervals for at least 20 minutes or longer after the end of the procedure or the last dose of agent. During the recovery phase, repeat assessments at 5- to 10-minute intervals should continue until the patient is awake and conversant, with appropriate alarms set on mechanical monitoring devices. Reversal of analgesia and sedation for purposes other than hemodynamic or respiratory compromise is generally unnecessary and is discouraged. Rapid reversal may lead to return of pain, anxiety, and sympathetic stimulation.

**Monitoring Equipment**

Monitoring techniques should be chosen based on factors such as the patient's age and general health status, as well as on the procedure being performed and the agents used. Currently all available general monitoring systems used in the operating suite are available for use in the ED. These include electrocardiographic (ECG) monitoring (including monitors with ST segment monitoring capabilities), noninvasive blood pressure monitors, pulse oximetry, and capnography. Although none of these modalities have been shown to have an effect on outcome, because they are used during similar procedures in other parts of the hospital (mainly in the operating room), their use should be considered for involved cases.

Because the most common complication of systemically administered analgesia and sedation is bradypnea or apnea leading to hypoxemia, it would be prudent in most

situations to include pulse oximetry and capnography (see Chapter 6) as part of the monitoring regimen. Several caveats regarding pulse oximetry are important. For a reading to be valid, the oximeter should concurrently indicate the patient's heart rate. The best monitors will include a plethysmograph to ensure proper signal detection. If blood pressure monitoring is used, the pulse oximeter should be placed on a different extremity to prevent interruption of monitoring and unnecessary alarm activation. Both saturation and pulse alarms should be used during and especially after the procedure to ensure detection of adverse events.

Capnography may be helpful for several reasons. Application of supplemental $O_2$ during these procedures is the standard of care, and for this reason most patients will have a functional residual lung capacity that is high in $O_2$ , possibly approaching 100% in some individuals. Because pulse oximetry is not sensitive at this level of the oxyhemoglobin dissociation curve, patients may become apneic for up to 5 minutes before desaturation is detected and reported by the pulse oximeter. It also is difficult to continuously monitor respiratory rate and quality during many procedures, especially if drapes are required over the head or thorax as part of the procedure. Capnography using specially designed nasal cannulae with side-stream sampling capabilities can act as an immediate indicator of bradypnea or apnea and give some indication as to the quality of ventilation. If capnography is not included in the patient's monitoring, an argument could be made to withhold supplemental $O_2$ in order to detect desaturation and reverse it at its earliest time. Combined pulse oximetry, capnography, ECG, and blood pressure units are commercially available. These units may be particularly helpful in certain situations (e.g., pediatric sedation for diagnostic procedures such as computed tomography [CT] or magnetic resonance imaging [MRI]) in which the patient must be "remotely" monitored and interaction is minimized.

Automated blood pressure monitors should be used in the elderly and when certain agents or combinations of agents are used in which hypotension is a risk. These devices can ease demands by eliminating the cumbersome tasks of repeated manual measurements, but the initial reading as well as subsequent suspect readings should be confirmed with a traditional manual blood pressure check.

Although rhythm disturbances are a rare late complication from the agents discussed here, ECG monitoring is recommended in the elderly or in any patient with a known or suspected history of coronary artery disease. Although not studied, the use of ST segment ECG monitoring during the painful procedure may prove to be helpful in patients with certain risk factors.

Whatever monitoring modalities are chosen, proper interval

recording and documentation should be performed. Figure 35-2 is an example of a continuous flow sheet that should be used from the beginning of the procedure until the time of disposition. The clinician should resist the temptation to routinely reverse sedation or analgesia for the sole purpose of reducing the time and personnel required or the recovery time, or to allow for earlier discharge.

## Adjunctive Safety Measures

Formal deep sedation is a 2-person procedure. Because of the complexity of the procedure, 1 operator should be solely responsible for administering the drugs and monitoring the patient's status (vital signs, respiratory function, level of consciousness, etc). If opioids and benzodiazepines are used, it is recommended that naloxone and flumazenil be *available at the bedside.* All syringes should be clearly labeled with the full name of the drug they contain. Simply using initials on the syringes may lead to an "F" solution (fentanyl) being administered inadvertently as a "flush" solution. It is preferred to have an IV bag hung for flushing the line after each drug is administered. Some clinicians prefer to routinely administer $O_2$ during sedation rather than waiting for evidence of desaturation. The operator should be skilled at advanced airway maneuvers and airway equipment, including

| **TABLE 35-5** -- Postsedation and Analgesia Disposition Criteria |
|---|
| 1. Return to baseline verbal skills. * |
| 2. Return to age- and condition-appropriate vital signs. |
| 3. Return to baseline muscular control function (infants able to sit unattended; child or adult able to walk unassisted). * |
| 4. Return to baseline mental status. |
| 5. Patient able to take fluids by mouth prior to release. |
| 6. Pain controlled with oral pain medications. |
| 7. Responsible adult present who understands specific sedation and analgesia emergency department disposition criteria. |

* These items may take into account the patient's specific age and injuries

suctioning devices, which should be within reach of the patient's bedside (see Chapters 1 and 2) .

## Disposition

Prior to disposition, minimum motor, mental status, and cognitive criteria should be met based on age. Suggested disposition criteria are displayed in Table 35-5 . Both children and adults receiving analgesia and sedation should be accompanied home by a responsible adult who understands the disposition instructions. In addition, the patient's pain

---

**TABLE 35-6** -- Sample Adult Disposition Instructions after Systemic Analgesia and Sedation

1. Do not drive or operate heavy machinery for the next 24 hr.

2. Eat a light diet for the next 24 hr.

3. Take only your prescribed medications as needed, including any pain medication you were discharged with. Do not drink alcohol.

4. Do not make any important decisions or sign important documents for the next 24 hr. You may be forgetful due to medications that were administered.

5. If you experience any difficulty breathing or persistent nausea and vomiting, call or return to the emergency department or dial 911.

6. You should have a responsible person with you for the rest of the day and during the night.

---

should be controllable with oral pain medications prior to discharge. Sample

patient/guardian instruction sheets for adults and children are provided in Tables 35-6 and 35-7 .

**Policies**

Ideally, guidelines for administering systemic analgesia and sedation should be developed in a multidisciplinary fashion involving emergency physicians, anesthesiologists, pediatricians, nurses, and pharmacists, with attention paid to the special needs of the emergency patient and the ED environment. All have a vested interest and duty to alleviate acute pain and anxiety, and patients will benefit most when all cooperate to achieve this goal. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) requirements are sparse concerning analgesia and sedation administered by nonanesthesia personnel. [64]

The JCAHO does provide standards for cases in which a reasonable expectation exists that loss of protective reflexes will occur in a significant group of patients after analgesia and sedation is given. Written informed consent that is specific for elective conscious sedation is required by some institutions. Accepted standards include a preanesthesia assessment of patients, a plan for anesthesia, discussion of the

| **TABLE 35-7** -- Sample Pediatric Disposition Instructions after Systemic Analgesia and Sedation |
| --- |
| Your child has been given medicine for sedation and/or pain control. These medicines may cause your child to be sleepy and less aware of his/her surroundings, making it easier for accidents to happen as he/she walks or crawls. Because of these side effects, your child should be watched closely for the next 8 hr. In addition, we also suggest the following: |
| 1. No eating or drinking for the next 2 hr. If your child is an infant, you may resume half normal feedings in 1 hr. |
| 2. No playing for the next 24 hr that requires normal coordination, such as bike riding or jungle gym activities. |
| 3. No playing for 8 hr without an adult to watch and supervise. |

| |
|---|
| 4. No baths, showers, cooking, or use of potentially dangerous electrical appliances for 8 hr unless supervised by an adult. |
| If you notice anything unusual about your child or if your child cannot take fluids within the next 4 to 6 hr, please call the emergency department. |

anesthesia and consent prior to the procedure, appropriate monitoring of the patient's physiologic status during anesthesia, and appropriate disposition of the patient. A flow sheet should be used to document the procedure and recovery period. All of these requirements can be easily met by constructing policies accordingly, obtaining and using interactive and mechanical monitoring, and providing documentation

# Chapter 36 - Principles of Wound Management

**Richard L. Lammers**

Acute traumatic wound management is one of the most common procedures in the practice of emergency medicine. There are many areas of controversy in the medical literature; the clinician must be careful to keep the final outcome in focus and not become concerned with minor or clinically insignificant theoretical details.

Wound care involves much more than closure of divided skin. The primary goal of wound care is not the technical repair of the wound; it is providing optimal conditions for the natural reparative processes of the wound to proceed. Primary wound healing is not an inevitable process. For centuries, victims of wounds commonly experienced inflammation, infection, and extreme scarring; in fact, these processes were considered part of normal wound repair. Only in the late 19th century did surgeons first realize that sepsis could be separated from healing. [1]

The cornerstones of wound care are cleaning, debridement, closure, and protection. The primary objectives in wound care are as follow:

1. Preserving viable tissue
2. Restoring tissue continuity and function
3. Optimizing conditions for the development of wound strength
4. Preventing excessive or prolonged inflammation
5. Avoiding infection and other impediments to healing
6. Minimizing scar formation

This chapter reviews current strategies for achieving these goals.

## BACKGROUND

**Wound Healing**

Emergency physicians should have a basic understanding of the process of wound healing. Highlights of this complex phenomenon as they relate to clinical decision making are presented.

Wounds extending beneath the epithelium heal by forming scar tissue. Inflammation, epithelialization, fibroplasia, contraction, and scar maturation constitute the stages of this nonspecific repair process. [1] [2] [3] Inflammation is a beneficial response that serves to remove bacteria, foreign debris, and devitalized tissue--a biologic debridement. Polymorphonuclear and mononuclear leukocytes concentrate at the site of injury and phagocytose dead and dying tissue, foreign material, and bacteria in the wound. [4]

As white blood cells die, their intracellular contents are released into the wound. In excessive amounts, they form the purulence characteristic of infected wounds. Some

exudate is expected even in the absence of bacterial invasion; however, infection with accumulation of pus interferes with epithelialization and fibroplasia and impairs wound healing. Wounds contaminated with significant numbers of bacteria or foreign material may undergo a prolonged or persistent inflammatory response and not heal. Granuloma formation surrounding retained sutures is an example of chronic inflammation. [5]

As white blood cells remove debris within the wound, epithelial cells at the surface of the wound begin to migrate across the tissue defect. In most sutured wounds, the surface of the wound develops an epithelial covering impermeable to water within 24 to 48 hours. Eschar and surface debris impair this process. The epithelium thickens and grows downward into the wound and along the course of skin sutures. Although there is some "adhesiveness" to the wound edges during the first few days, this is lost because of fibrinolysis.

By the fourth or fifth day, newly transformed fibroblasts in the wound begin synthesizing collagen and protein polysaccharides, initiating the stage of scar formation known as *fibroplasia.* Collagen is the predominant component of scar tissue. Wound strength is a balance between the lysis of old collagen and the synthesis of new collagen "welding" the wound edges together. The amount of scar tissue is influenced by physical forces (e.g., the stresses imposed by movement) acting across the wound. In contrast, a wound that heals by secondary intention closes by contraction. *Contraction* is the movement of skin edges toward the center of the defect, primarily in the direction of underlying muscle.

Significant gains in tensile strength do not begin until approximately the fifth day following the injury. Strength increases rapidly for 6 to 17 days, more slowly for an additional 10 to 14 days, and almost imperceptibly for as long as 2 years (Fig. 36-1) . The strength of scar tissue never quite reaches that of unwounded skin. Although the process of collagen formation is essentially completed within 21 to 28 days, the scar widens for another month, and collagen continues to remodel and strengthen the wound for up to 1 year. [1] [5]

Decisions regarding the optimal time for suture removal and the need for continued support of the wound with tape are influenced by (1) wound tensile strength, (2) the period of scar widening, and (3) the cosmetically unacceptable effect of epithelialization along suture tracks. The wise physician will remind the patient that scars are quite red and noticeable at 3 to 8 weeks following closure. However, the appearance of a scar should not be judged before the scar is well into its remodeling phase. Therefore, any scar revision should be postponed until 6 to 12 months after injury.

Zitelli states, "The most important factor in predicting the cosmetic result is wound location. In general, wounds on concave surfaces heal with better cosmetic results than wounds on convex surfaces....Besides location, other factors such as *skin color, wound size*, and *wound depth* are helpful in predicting the cosmetic results of wounds healing by secondary intention."

Small, superficial wounds in lax, light-colored skin, especially in areas in which the skin is thin, result in less noticeable scars. Wounds on convex surfaces look better after

primary closure than following secondary healing. Repigmentation occurs over 3 to 5 years, even in large wounds that heal by secondary intention.

# INITIAL EVALUATION

The approach to the management of a particular wound depends on information gathered during history taking and on the results of physical examination. The decision on whether to close a wound immediately or after a period of observation is based on a variety of factors that affect the risk of infection. Some wounds may appear benign but conceal extensive and devastating underlying tissue damage. The discovery that an extremity wound was produced by a roller or wringer device, a high-pressure injection gun, high-voltage electricity, heavy and prolonged compressive forces, or the bite of a human or a potentially rabid animal radically alters the overall management of the affected patient. The American College of Emergency Physicians' "Clinical Policy for the Initial Approach to Patients Presenting with Penetrating Extremity Trauma" provides a useful approach to the evaluation of all wounds. [7]

## History

In the initial evaluation of a wound, the physician should identify all of the extrinsic and intrinsic factors that jeopardize healing and promote infection. These include the mechanism of injury, the time of injury, the environment in which the wound occurred, and the patient's immune status.

### Wound Age: The "Golden Period"

The likelihood of wound infection increases with the time that elapses before definitive wound care. A delay in wound cleaning is the most important variable, and may allow bacteria contaminating the wound to proliferate. A delay in treatment of a contaminated wound for as little as 3 hours can result in infection. However, there is evidence suggesting that wounds in highly vascular regions such as the face and scalp can be closed without increased risk as long as 24 hours after injury. [12] Contrary to popular belief, the "golden period"--the maximum time after injury that a wound may be safely closed without significant risk of infection-- *is not a fixed number of hours*.[13]

Many factors affect infection risk, and closure decisions should not be based solely on temporal considerations. Peacock points out that "a clean razor slice of highly vascular skin of the face might be closed safely 48 hours after injury, whereas a stable-floor-nail penetration of the foot of an elderly person might not be closed safely one minute after injury." [3] Berk and colleagues concluded that there is little change in wound infection rates in most areas of the body for up to 19 hours after a variety of traumatic injuries, and infection rates of simple wounds involving the head are essentially unaffected by the interval between injury and repair. [12] Hence, all of the data accumulated in the initial evaluation, both historical and physical, must be considered when making the decision to close a wound in a particular patient. In addition, the techniques of wound care in themselves may extend the golden period; a skillful clinician can often convert a

dangerously contaminated wound into a clean wound that can be safely closed. [3]

**Other Historical Factors**

Other factors that affect wound healing or the risk of infection include the patient's age and state of health. Patient age appears to be an important factor in host resistance to infection; those individuals at the extremes of age--young children and the elderly--are at greatest risk. [14] Infection

rates are reported to be higher in patients with medical illnesses (e.g., diabetes mellitus, immunologic deficiencies, malnutrition, anemia, uremia, congestive heart failure, cirrhosis, malignancy, alcoholism, arteriosclerosis, arteritis, collagen vascular disease, chronic granulomatous disease, smoking or chronic hypoxia, or liver failure), in obese patients, and in patients taking steroids or immunosuppressive drugs or those receiving radiation therapy. Shock, remote trauma, distant infection, bacteremia, denervation, and peripheral vascular disease also increase wound infection rates and slow the healing process. [4] [15] [16]

Additional information pertinent to decision making in wound management includes the following:

*Present medications* (specifically, anticoagulants and immunosuppressive drugs)

*Allergies* (especially to local anesthetics, antiseptics, analgesics, antibiotics, and tape)

*Tetanus immunization status*

*Potential exposure to rabies* (in bite wounds and mucosal exposures)

*Potential for foreign bodies* embedded in the wound, especially when the mechanism of injury is unknown or was associated with breaking glass or vegetative matter [17]

*Previous injuries and deformities* (especially in extremity and facial injuries)

*Associated injuries* (underlying fracture, joint penetration)

*Other factors* (availability for follow-up, patient understanding of wound care or compliance)

## Physical Examination

All wounds should be examined for amount of tissue destruction, degree of contamination, and damage to underlying structures. A common error in wound management is to assume that a traumatic wound is already contaminated and then,

during the examination, to contaminate it further. Despite the fact that all traumatic wounds are contaminated to some degree, these injuries should be examined using aseptic technique. It is prudent for the examiner to wear clean or sterile gloves and avoid droplet contamination from the mouth by maintaining distance or, preferably, by wearing a mask. [18] Traditionally, sterile gloves are used by the operator, but in many countries, this luxury is not available. There are no data quantifying a presumed increase in infection rate when nonsterile gloves are worn.

**Mechanism of Injury and Classification**

of Wounds

The magnitude and direction of the injuring force and the volume of tissue on which the force is dissipated determine the type of wound sustained. Three types of mechanical forces produce soft tissue injury: shear, tension, and compression forces. The resulting disruption or loss of tissue determines the configuration of the wound. Wounds may be classified into six categories:

1. *Abrasions.* Wounds caused by forces applied in opposite directions, resulting in the loss of epidermis and possibly dermis (e.g., skin grinding against road surface).
2. *Lacerations.* Wounds caused by shear forces that produce a tear in tissues. Tensile and compressive forces also cause separation of tissue. Little energy is required to produce a wound by shear forces (e.g., a knife cut). Consequently, little tissue damage occurs at the wound edge, the margins are sharp, and the wound appears "tidy." The energy required to disrupt tissue by tensile or compressive forces (e.g., forehead hitting a dashboard) is considerably greater than that required for tissue disruption by shear forces, because the energy is distributed over a larger volume. These lacerations have jagged, contused, "untidy" edges.
3. *Crush wounds.* Wounds caused by the impact of an object against tissue, particularly over a bony surface, which compresses the tissue. These wounds usually contain contused or partially devitalized tissue.
4. *Puncture wounds.* Wounds with a small opening and whose depth cannot be entirely visualized. Puncture wounds are caused by a combination of forces.
5. *Avulsions.* Wounds in which a portion of tissue is completely separated from its base and is either lost or left with a narrow base of attachment (a flap). [19] Shear and tensile forces cause avulsions.
6. *Combination wounds.* Wounds with a combination of configurations. For example, stellate lacerations caused by compression of soft tissue against underlying bone create wounds with elements of crush and tissue separation; missile wounds involve a combination of shear, tensile, and compressive forces that puncture, crush, and sometimes avulse tissue. [18]

**Contaminants (bacteria and foreign material).**

Numerous factors affect the risk of wound infection, but the primary determinants of infection are the amount of bacteria and dead tissue remaining in the wound. [20] Also of

importance is the ability of the patient's immune system to respond to bacterial invasion and the presence of local tissue ischemia or hypoxia. [21]

Essentially all traumatic wounds are contaminated with bacteria to some extent. The number of bacteria remaining in the wound at the time of closure is directly related to the risk of infection. A critical number of bacteria must be present in a wound before a soft tissue infection develops. In experimental wounds produced by shear forces, an inoculum of $10^6$ aerobic bacteria per gram of tissue inevitably produces wound infection in time. When the mechanism of injury involves a compressive force, the infective dose of bacteria is $10^4$ bacteria per gram of tissue. If bacterial counts after injury (or after wound management) are below this level, the wound has a very low probability of becoming infected.

Surgical operations are categorized on the basis of the relative levels of bacterial contamination of the wounds. Most traumatic wounds fall into one of two categories:

1. *Contaminated wounds.* Traumatic wounds <12 hours old (the most common type of wound seen in emergency departments).
2. *Dirty wounds.* Wounds heavily contaminated with pathogenic organisms, those with significant numbers of bacteria associated with large amounts of devitalized tissue, or traumatic wounds older than 12 hours. [21] Infection rates in series of contaminated wounds of all types range from 1.1 to 21%; rates in series of dirty wounds range from 7 to 38%. [14] The nature and amount of foreign material contaminating the wound often determine the type and quantity of bacteria implanted. The presence of undetected reactive foreign bodies in sutured wounds almost

   guarantees an infection. Although bullet or glass fragments by themselves rarely produce wound infection, these foreign bodies may carry particles of clothing, gun wadding, or soil into the wound. Minute amounts of organic or vegetative matter, feces, or saliva carry highly infective doses of bacteria. The bacterial inoculum from human bites often contains 100 million or more organisms per milliliter of saliva. [28] Inorganic particulate matter, such as sand or road surface grease, usually introduces few bacteria into a wound and has little chemical reactivity; these contaminants are relatively innocuous. However, soil containing a large proportion of clay particles readily promotes infection. Presumably because of their marked chemical reactivity, clay particles damage local tissue defenses. [29] Soils with a high organic content, such as those in swamps, bogs, and marshes, also have a high infection potential. [30] Most wounds encountered in the practice of emergency medicine have low initial bacterial counts. If wound cleaning and removal of devitalized tissue are instituted before bacteria within the wound enter their accelerated growth phase (3 to 12 hours following the injury) and if one uses aseptic technique in examining and managing these wounds, bacterial counts will remain below the critical number needed to initiate infection.

**Wound Location**

The anatomic location of the wound has considerable importance in the risk of infection.

Bacterial densities on the skin surface range from a few thousand to millions per square centimeter. [30] Areas with endogenous microflora in numbers sufficient to infect a wound ($>10^5$ bacteria/cm$^2$ ) include the hairy scalp, the forehead, the axilla, the perineum, the foreskin of the penis, the vagina, the mouth, intertriginous areas, and the nails. In other regions, skin bacteria are sparse ($10^2$ to $10^3$ bacteria/cm$^2$ ) and are not a source of infection. [18] Wounds in regions of high vascularity, such as the scalp and the face, more easily resist bacterial incursions. The high vascularity of the scalp probably accounts for extremely low infection rates with scalp injuries, despite the large numbers of endogenous microflora. Distal extremity wounds, in contrast, are more at risk for the development of wound infections than are injuries of most other parts of the body. [14] Wounds in ischemic tissue are notoriously susceptible to infection. [31]

### Devitalized Tissue

Identifying devitalized tissue is an important part of the examination of a wound. Tissue damage lowers the resistance of the wound to infection. Devitalized or necrotic tissue enhances the possibility of infection in a wound by providing a culture medium in which bacteria proliferate, by inhibiting leukocyte phagocytosis, and by creating an anaerobic environment suitable for certain bacterial species.

### Underlying Structures

Identification of injury to underlying structures such as nerves, vessels, tendons, joints, bones, or ducts may lead the emergency physician to forgo wound closure and consult a surgical specialist. Procedures such as joint space irrigation, reduction and debridement of compound fractures, neurorrhaphy, vascular anastomosis, and flexor tendon repair are best accomplished in the controlled setting of the operating room, in which optimal lighting, proper instruments, and assistance are available.

## CLEANING

The wound should be cleaned as soon as possible after evaluation. Although most wounds are contaminated initially with less than an infective dose of bacteria, given time and the appropriate wound environment, bacterial counts may reach infective levels. The goals of wound cleaning and debridement are the same: (1) to remove bacteria and reduce their numbers below the level associated with infection, and (2) to remove particulate matter and tissue debris that would lengthen the inflammatory stage of healing or allow the growth of bacteria beyond the critical threshold. [16]

### Patient Preparation

Prior to examining, cleaning, exploring, or repairing wounds, medical procedures should be explained to patients to allay fears and to engender patient cooperation. In general, all wound care should be performed *with the patient in a supine position,* since fainting is a common occurrence once wound preparation has commenced (Fig. 36-2) . Even the most hardy or brave patient may faint at the sight of a needle, scalpel, or blood. Patient falls are a serious source of comorbidity and litigation. Likewise, relatives and

friends should be allowed to stay with the patient only after their propensity for fainting has been assessed and they have been properly cautioned. The wise physician will insist that any significant others who remain in the room to support the patient sit during the procedure and report any perceived dizziness or nausea.

## Wound Handling

Anyone cleaning, irrigating, or suturing wounds should wear protective eyewear and a mask, as virtually any patient may be seropositive for the human immunodeficiency virus (HIV). Although mucosal exposure to blood or tissue products that are contaminated by HIV is considered a relatively low risk for subsequent infection, universal precautions are currently recommended.

Thorough cleansing of bacteria, soil, and other contaminants from a wound cannot be accomplished without the patient's cooperation. Scrubbing most open wounds is painful, and the patient's natural response is withdrawal. Therefore, *local or regional anesthesia often must precede the examination and cleaning of a wound.* Approaches to wound anesthesia are discussed in detail in Chapters 31 , 32 , 33 , and 34 .

Despite adequate anesthesia, the patient may be unable to cooperate because of apprehension. The physician should explain the wound cleansing procedure to the patient and should provide assurance that everything possible will be done to minimize pain. Reassurance may not alleviate the fears of young children, and both sedation and physical restraining devices must be used. Approaches to sedation using parenteral sedative-hypnotics and narcotic agents and the use of inhaled nitrous oxide are discussed in Chapter 35 .

The two primary methods of wound cleaning are mechanical scrubbing and irrigation. Soaking a wound in a saline or antiseptic solution before the arrival of a physician

**Figure 36-2** What is wrong with this picture? Although the patient stated that blood and needles did not bother her, she fainted shortly after this picture was taken, nearly falling to the floor. The cautious physician prepares and repairs wounds only when the patient is recumbent (preferably supine).

is of little value. Indeed, soaking a wound in saline may actually increase bacterial counts. [32] The methods of scrubbing and irrigation are reviewed below.

## Mechanical Scrubbing

Initially, a wide area of skin surface surrounding the wound should be scrubbed with an antiseptic solution to remove contaminants that in the course of wound management might be carried into the wound by instruments, suture material, dressings, or the physician's gloved hand. Minimal aseptic technique requires the use of gloves during the cleaning procedure. It is important to remove all nonabsorbable particulate matter; any such material left in the dermis may become impregnated in the healed tissue and result in a disfiguring "tattoo" effect. [5] However, scrubbing the internal surface of a wound is controversial. Although scrubbing a wound with an antiseptic-soaked sponge

does remove foreign particulates, bacteria, and tissue debris, an abrasive sponge may inflict more damage on tissue and provoke more inflammation. [33] [34]

Some physicians reserve mechanical scrubbing for "dirty" wounds contaminated with significant amounts of foreign material. If irrigation alone is ineffective in removing contaminants from a wound, the wound should be scrubbed. Because the amount of damage inflicted on tissues by scrubbing is correlated with the porosity of the sponge, a fine-pore sponge (e.g., Optipore sponge [90 pores per linear inch]) should be used to minimize tissue abrasion. [33] [35] Detergents have an advantage over saline because they minimize friction between the sponge and tissue, thereby limiting tissue damage during scrubbing. Detergents also dissolve particles, helping to dislodge them from the wound surface. Unfortunately, many of the available detergents are toxic to tissues. [33] [36]

## Antiseptics During Cleaning

For many years, antiseptic solutions have been used for their antimicrobial properties in and around wounds (Table 36-1) . Studies of antiseptics in wounds demonstrate that there is a delicate balance between killing bacteria and injuring tissue. [37] Intact skin can withstand strong microbicidal agents, whereas leukocytes and the exposed cells of skin and soft tissue can be damaged by these agents. [16]

Many antiseptic solutions have been used for cleaning wounds. Povidone-iodine (Betadine) is widely available as a 10% stock solution. Although studies on the efficacy and safety of povidone-iodine solution have shown variable results, [41] it appears that dilute povidone-iodine solution in concentrations of <1% is both safe and effective for use in contaminated traumatic wounds. The precise concentration that provides the most benefit is unknown. In contrast, povidone-iodine surgical scrub (Betadine scrub) and hexachlorophene (pHisoHex) both contain anionic detergents that are harmful to tissues and that increase infection rates when used in wounds. Aqueous iodine is irritating and corrosive to tissue and should not be used in any wound. [38]

In vitro studies have demonstrated the toxicity of chlorhexidine gluconate-alcohol (Hibiclens) to the cellular components of blood. [41] Hydrogen peroxide is used by some clinicians for its effervescent effect in cleaning wounds. However, because peroxide is hemolytic, it is best to use it only to clean surrounding skin encrusted with blood and coagulum or to soak off adherent blood-soaked dressings.

| Agent | Biologic Activity | Tissue Toxicity | Systemic Toxicity * | Potential Uses | Comments |
|---|---|---|---|---|---|

**TABLE 36-1** -- Summary of Agents Used for Wound Care

| | | | | | |
|---|---|---|---|---|---|
| Povidone-iodine surgical scrub (Betadine 7.5%) | Virucidal; strongly bactericidal against gram-positive and gram-negative organisms | Detergent can be toxic to wound tissues | Painful to open wounds; other reactions extremely rare | Hand cleanser | Iodine allergy possible; systemic absorption of iodine from burns, open wounds; not routinely used in open wounds |
| Povidone-iodine solution (Betadine 10%) | Same as povidone-iodine scrub; virucidal, bactericidal | Minimally toxic to wound tissues at full strength; 1% solution has no significant tissue toxicity | Extremely rare | Wound periphery cleanser; diluted to 1% for wound irrigation | Probably the safest and most effective product currently available; iodine is active agent, povidone is carrier molecule; iodine allergy possible; systemic absorption of iodine from burns, open wounds; dilute 10:1 (saline:Betadine) if used to irrigate wounds |
| Chlorhexidine gluconate (Hibiclens) | Strongly bactericidal against gram-positive organisms, less strong against gram-negative bacteria | Ionic detergent can be toxic to tissue/cellular components; eye and inner ear toxicity | Extremely rare | Hand cleanser | Generally avoid use in open wounds; not for use in eye/ear |

| Polaxamer 188 (Shur-Clens; Pluronic F-68) | No antibacterial or antiviral activity | None known; does not inhibit wound healing | None known | Wound cleanser (particularly useful on face) | Nonionic detergent used for cleansing properties; nontoxic even with IV use; will not damage eye/cornea; lack of antibacterial properties limits use |
|---|---|---|---|---|---|
| Hexachlorophene (pHisoHex) | Bacteriostatic against gram-positive bacteria, poor activity against gram-negative bacteria | Detergent can be toxic to wound tissues | Possibly teratogenic with repeated use | Alternative hand cleanser; not used on open wounds | Systemic absorption causes neurotoxicity |
| Hydrogen peroxide | Very weak antibacterial agent | Toxic to tissue/red cells | Extremely rare | Wound cleanser adjunct; very weak antiseptic properties | Breaks down to water and oxygen; foaming activity useful to remove debris/coagulated blood |

* Based largely on in vitro studies/animal data

Peroxide should not be used on granulation tissue, because oxygen bubbles lift newly formed epithelium off the wound surface. [42] Hexachlorophene was used as an antiseptic for a time but was found to be neurotoxic and teratogenic through skin absorption. Its narrow antimicrobial spectrum makes it no more effective than ordinary soap and water. [43] Quaternary ammonium compounds are less toxic to tissue but have a limited antimicrobial spectrum; gram-positive organisms are more susceptible to these solutions than are gram-negative bacteria. Benzalkonium chloride (Zephiran) is inactivated by soaps, detergents, blood, and other organic matter. Furthermore, *Pseudomonas* has been known to proliferate in stored solutions. Consequently, use of benzalkonium chloride has fallen into disfavor. [35]

Nonantiseptic nonionic surfactants are attractive alternatives to these toxic cleansing agents. In contrast to antiseptic solutions, these preparations cause no tissue or cellular

damage, leukocyte inhibition, or impairment in wound healing. The solutions also cause no corneal injury, conjunctival irritation, or pain on contact with the wound. [41] [44] Poloxamer 188 (Pluronic F-68, Shur-Clens, and Pharma Clens) is nontoxic, even when administered intravenously, and nonallergenic. This pluronic polyol has no antibacterial activity, but scrubbing experimental wounds with poloxamer has reduced infection rates, proving its ability to cleanse a wound effectively and atraumatically. [33]

From a clinical standpoint, for most simple wounds, there may be little practical difference between many irrigation and cleaning solutions. The above cited concerns about toxicity of solutions are largely theoretical, suggested by in vitro studies, or inferred from animal data. A survey of wound practice by Howell and Chisholm suggests that a wide range of solutions and techniques are in clinical use in the United States. [45] However, it is important to distinguish

between skin antiseptics and irrigating solutions. As a general rule, commercially available antiseptics should be used *only to clean intact skin,* and one should avoid introduction of significant amounts of these products into open wounds. It is recommended that most open wounds be irrigated with copious amounts of saline or a dilute (1%) povidone-iodine solution. Pluronic polyols may be considered when the wound is near mucous membranes and dilute povidone-iodine may be particularly irritating.

**Irrigation**

Properly performed irrigation is effective in removing particulate matter, bacteria, and devitalized tissue that is loosely adherent to the edges of the wound and trapped within its depths. Rodeheaver and colleagues studied the effect of irrigating experimental wounds contaminated with 20 mg of soil. Irrigating wounds with 400 mL of fluid at 1 psi removed 48.6% of the soil, whereas increasing the pressure to 15 psi removed 84.8%, reducing the infection rate from 100% to 7%. [46] *The effectiveness of irrigation is determined primarily by the hydraulic pressure at which the irrigation fluid is delivered.*[47] [48] Bulb syringes or gravity flow irrigation devices deliver fluid at low pressures and are ineffective in ridding wounds of small particulate matter or in lowering wound bacterial counts. The flow rate of irrigation fluid delivered through IV tubing with a blood pressure cuff inflated around a collapsible plastic IV bag provides <10 psi of irrigation pressure.

The pressure that can be delivered with a syringe varies with the force exerted on the plunger of the syringe and with the internal diameter of the attached needle. A simple irrigation assembly consisting of a 19-ga plastic catheter or needle attached to a 35-mL syringe produces 25 to 40 psi when the barrel of the syringe is pushed with both hands. [48] This high-pressure irrigation system removes significant numbers of bacteria and a substantial amount of particulate matter from the wound surface (Fig. 36-3) . Commercial irrigation systems with a ring-handled syringe and a one-way valve that connects into a standard IV solution are available (Travenol pressure irrigation set, code number 2D2113, or Irrijet, Ackrad Laboratories, Garwood, NJ).

Pulsatile jet irrigation of wounds creates pressures of 50 to 70 psi but does not appear to drive significant amounts of bacteria or surface contaminants into the soft tissues of

the wound. [49] [50] Although jet irrigation can damage tissue defenses and spread fluid laterally into loose areolar tissue, [51] it is more effective in cleaning wounds, less traumatic to tissues, and less likely to produce edema than conventional scrubbing with a brush. However, this technique should generally be reserved for use in heavily contaminated wounds in which syringe irrigation proves to be ineffective. The jet irrigation system used by many investigators was a Water Pik unit (Teledyne Aquatic Corp.) with a sterile tip nozzle held approximately 4 cm from the wound. [35] [50] [51]

Minimum recommended volumes of irrigation fluid vary, but for average-sized wounds, 100 to 300 mL should be used. [35] Greater volumes may be required for larger or heavily contaminated wounds. Irrigation should continue until all visible, loose particulate matter has been removed. Approximately 20% of open, undated bottles of "sterile" saline and water are contaminated; only solutions in bottles opened within the past 24 hours should be used to irrigate wounds. [52] [53] A potential complication of wound irrigation is that infectious material can be splashed into the face of the physician, even when the tip of the irrigation device is held below the wound surface. A plastic cup device that fits on the end of a syringe (ZeroWet Splashshield) can be used to contain the splatter (Fig. 36-4) . The wound should be positioned to allow continuous drainage of fluid during irrigation by any method. [54]

**Antibiotic Solutions for Irrigation**

Antibiotic solutions have been instilled directly into wounds or used as irrigation solutions. Halasz reviewed the studies of several investigators who analyzed the technique of irrigating wounds with antibiotic solutions, including ampicillin, a neomycin-bacitracin-polymyxin combination; tetracycline; penicillin; kanamycin; and cephalothin. He concluded that "organisms in the wound can be exposed to adequate concentrations of antibiotics, and that the concentration of these drugs in the wound remains in the bactericidal range for long periods of time, far exceeding that obtainable by systemic administration." [55] The use of antibiotics in irrigation solutions in lieu of antiseptic solutions avoids the tissue destruction of the antiseptics but theoretically risks topical sensitization of the patient to the antibiotic and the development of toxic tissue levels of the antibiotic. To date, there have been no reports of these complications. Within 3 hours of injury, a proteinaceous coagulum forms within the wound, surrounding the bacteria and probably preventing their contact with topical or systemic antibiotics. Therefore, the wound should be scrubbed before irrigation with an antibiotic solution. [35] [56] The indications for antibiotic solutions in cleaning wounds have not been defined, and this practice is not considered standard, although a decrease in wound infection has been demonstrated in several studies.

**Recommendations for Cleaning the Wound**

The prerequisites of any wound-cleaning technique are a calm or sedated patient, satisfactory anesthesia, and a thorough scrub of the skin surface adjacent to the wound. The importance of ridding the wound of major contaminants and infective doses of bacteria is unquestionable. Two strategies to accomplish the goals of wound cleaning are apparent from this discussion. The contaminated or "dirty" wound can be irrigated or both scrubbed and irrigated with a 1% povidone-iodine solution (Betadine preparation,

*not* Betadine scrub). This should be followed by flushing with a 0.9% saline solution. As an alternative, the wound can be scrubbed with pluronic polyols and irrigated with an antibiotic-normal saline solution. *Only pluronic polyols or saline should be used near the eyes.* All scrubbing should be performed with a soft, fine-pore sponge, and high-pressure techniques should be used for all irrigation. The use of hydrogen peroxide on open wounds is discouraged. Gentle scrubbing with poloxamer and normal saline high-pressure irrigation both appear to be satisfactory methods for cleaning minimally contaminated wounds.

Some clinicians routinely irrigate wounds, especially extremity wounds, with tap water instead of sterile saline. The technique has not been studied extensively, but given that patients almost always irrigate their wound under the tap prior to presentation and that the practice is widespread in hospitals, it is unlikely to be of major harm. Angeras and coworkers demonstrated that tap water produced a lower infection rate than saline (5.4 vs 10.3%). [59] Even though bacteria were cultured from the faucets, these organisms did not account for a single wound infection. The obvious advantage of using tap water is the large volume of irrigant that can be quickly applied to an open wound.

**Preparation for Wound Closure**

Before debridement or wound closure, the wound must be prepared and draped. Body hair should generally be left intact, since wounds that are shaved demonstrate *higher* infection rates. For wounds in hair-bearing areas, hair should be removed by clipping only if the hair interferes with the procedure. [61] Stubborn hairs that repeatedly invade the wound during suturing can be coated with petrolatum jelly or water-soluble ointments to keep them out of the field. Eyebrows should not be shaved, because critical landmarks needed for exact approximation would be lost. Although shaved eyebrows will grow back eventually, shaving produces an undesirable cosmetic effect.

The skin surface adjacent to the wound (not the wound itself) should be disinfected with a standard 10% povidone-iodine or chlorhexadine gluconate (Hibiclens) solution. The solution is painted widely on the skin surrounding the wound but should not cover the interior of the wound itself. After hand washing, the physician and any assistants involved in the procedure must wear gloves. Visible talc or other powders on the gloves should be rinsed before touching the patient's wound. [30]

Face masks are recommended and are mandatory for any clinician with a bacterial upper respiratory infection. Because droplets of saliva may leak even from around the edges of a face mask, talking in proximity to the wound must be avoided. [63]

A single fenestrated drape or multiple folded drapes are placed over the wound site. For hand wounds, a sterile glove may be applied to the patient to provide a sterile field in lieu of a fenestrated drape. The area to be sutured can be exposed by cutting the glove, and the extremity can be placed on a sterile towel. This technique provides a clean field without the need to continually adjust the drape or to operate through a small opening. If the wound has not yet been anesthetized, anesthesia can be provided at this time (see Chapters 31 , 32 , 33 , and 34 for details).

The entire depth and the full extent of every wound should be explored in an attempt to locate hidden foreign

bodies, particulate matter, bone fragments, and any injuries to underlying structures that may require repair. The clinician should avoid the temptation to initially explore wounds with a finger in search of a foreign body or to assess wound characteristics. Embedded glass, metal fragments, or sharp pieces of bone may cut the physician, exposing him or her to contamination with the patient's blood. Exploration with a metal probe and the liberal use of radiographs, combined with direct vision and good lighting, is a much safer approach. Lacerations through thick subcutaneous (SQ) adipose tissue are treacherous, because large amounts of particulate matter can be totally obscured in deeper folds of tissue. Unless a careful search is undertaken, these contaminants may be left in the depths of a sutured wound, and infection usually follows. Some physicians are reluctant to extend lacerations to properly clean or explore them; however, opening the wound to permit adequate visualization may be needed for successful wound preparation.

### Debridement

Debridement is of undisputed importance in the management of the contaminated wound. With this technique, the physician can remove tissue impregnated with foreign matter, bacteria, and devitalized tissue that otherwise impairs the ability of the wound to resist infection and prolongs the period of inflammation. [20] Debridement also creates a tidy, sharp wound edge that is easier to repair and results in a more cosmetically acceptable scar.

If the wound already is clean and the edges are viable, sharp debridement may not improve the outcome. Irregular wounds have greater surface areas than do linear lacerations. Because skin tension is distributed over a greater length, the scar width is usually less in jagged wounds than if the wound is converted to an elliptical defect with tidy edges. If the edges are devitalized or contaminated, the wound edges must be debrided. To avoid a wide scar in this situation, the wound can be undermined.

### Excision

If significant contamination occurs in areas in which there is a laxity of tissues and if no important structures, such as tendons or nerves, lie within the wound, the entire wound may be excised. [3] This technique is the most effective type of debridement, because it converts the contaminated traumatic wound into a clean surgical wound (Fig. 36-5) . Complete excision of grossly contaminated wounds such as animal bites allows primary closure of such wounds with no greater risk of infection than in relatively uncontaminated lacerations. [35] Wounds of the trunk, the gluteal region, or the thigh are amenable to this technique. If necessary, the clinician can judge the adequacy of the excision by coloring the wound surface with a vital dye. The clinician then creates a new wound by excising all dyed tissue. [20] Most traumatic wounds can be excised with an elliptical excision. A lenticular configuration should be marked superficially around the

wound with the blade of a No. 15 scalpel by cutting only the epidermis.

If a puncture wound is being excised, the axis of the excision should parallel a wrinkle, a skin line, or a line of dependency or facial expression, and the long axis should be three to four times as great as the short axis. The clinician may plan this type of excision by premarking the skin with a surgical marking pen. Tension should be placed on the surrounding skin with a finger or a skin hook. With the clinician's hand steadied on the table or on the patient, the No. 15 blade is used to cut through the skin at right angles or at slightly oblique angles to the skin surface. If complete excision of the entire depth of the wound is not necessary, the tissue scissors may be used to cut the edge of the wound, following the path premarked in the epidermis by the scalpel blade. If a complete excision is desired, the incision on each wound edge should be carried past the deepest part of the wound (see Fig. 36-5) .

Excision should be planned carefully; excessive removal of tissue can create a defect that is too large to close. In hair-bearing areas of the face, particularly through the eyebrows, the incision should be angled parallel to the angle of hair follicles to avoid linear alopecia (Fig. 36-6) (Figure Not Available) . The wedge of excised tissue should be removed carefully, without contaminating the fresh wound surface. [64] [65]

Puncture wounds of the feet may contain foreign bodies that are difficult to remove. Contaminated punctures or those likely to contain foreign bodies (e.g., nail punctures through shoes) can be excised by removing a small cone of surrounding tissue with a scalpel or with a 4-mm disposable punch biopsy and the wound irrigated a second time. [66] [67]

**Figure 36-6** (Figure Not Available) Excision through an eyebrow. Use an angled incision to remove tissue in the eyebrow, thus avoiding further injury of hair follicles. *(From Dushoff IM: A stitch in time. Emerg Med 5(1):2, 1973. Reproduced by permission.)*

**Selective Debridement**

Complete excision is impossible for most wounds because of insufficient skin elasticity, and selective debridement must be used. [3] [20] Simple excision of a wound of the palm or the dorsum of the nose will make approximation of the resulting surgical wound edges difficult. Stellate wounds and wounds with an irregular, meandering course have greater surface areas and less skin tension per unit length than do linear lacerations. In some cases excision of an entire wound would result in the loss of too much tissue (i.e., produce a gaping defect and excessive tension on the wound edges when closed). This problem can be avoided with selective debridement and approximation of the irregular wound edges. This technique involves sharp debridement of devitalized or heavily contaminated tissue in the wound piece by piece and eventual matching of one edge of the wound with the other. Selective debridement is time consuming but preserves more surrounding tissue.

Identifying devitalized tissue in a wound remains a challenging problem. Tissue with a narrow pedicle or base, especially distally based, narrow flaps on extremities, is unlikely to survive and should be excised. Sometimes a sharp line of demarcation distinguishes

devitalized skin and viable skin, but in most wounds there is usually only a subtle bluish discoloration. The comparison of capillary refill in wounded tissue with that in adjacent skin is probably the most practical test for tissue viability available to the emergency physician. [68] If circulation is adequate, viable tissue becomes hyperemic following the release of a proximal tourniquet.

In heavily contaminated wounds, especially those with abundant adipose tissue, all exposed fat and all fat impregnated with particulate matter should be removed. The SQ adipose tissue attached to large flaps or to avulsed viable skin should be debrided before reapproximation of the wound; removal of this fatty layer allows better perfusion of the flap or the graft.

Contaminated bone fragments, nerves, and tendons are almost never removed. Every effort should be made to clean these structures and return them to their place of origin, because they may be functional later. [69]

Instruments usually required for debridement include two fine single- or double-pronged skin hooks, a scalpel with a No. 15 blade, tissue scissors, hemostats, and a small tissue forceps. The jagged wound edges are stabilized with skin hooks or forceps, and the scalpel or scissors are used to cut away devitalized tissue from one end of the wound to the other. Fascia and tendons perform important functions despite potential loss of viability. If they can be cleaned adequately, these tissues should not be debrided. They may be left in wounds as free grafts and covered by viable flaps of tissue. [70]

Following debridement or excision, the wound should be irrigated again to remove any remaining tissue debris.

**Control of Hemorrhage**

Wound exploration or cleaning sometimes induces bleeding. Hemostasis is essential at any stage of wound care. Not only does persistent bleeding obscure the wound and hamper wound exploration and closure, but also hematoma formation in a sutured wound separates wound edges, impairs healing, and risks dehiscence or infection. If bleeding is not a problem before wound debridement, it frequently becomes a complication once the wound edges are excised.

Several practical methods of achieving hemostasis are available to the emergency physician. Sustained direct pressure with gloved fingers, gauze sponges, or packing material, combined with elevation, is usually effective in immediately controlling a single bleeding site or a small number of sites until cut ends of vessels constrict and coagulation occurs. In a patient with multiple injuries and several urgent problems, hemorrhage can be controlled temporarily with a compression dressing. Several absorptive sponges are applied directly over the bleeding site, and these are secured in place with an elastic bandage (e.g., Ace wrap) or elastic adhesive tape (Elastoplast). Pressure is provided by the elasticity of the bandage. The bleeding part should be elevated. Wound care can then be deferred while the physician attends to more

pressing matters.

Although simply crushing and twisting the end of a small vessel with a hemostat avoids the introduction of suture material into the wound, this method provides unreliable hemostasis. Ligation of the vessel with fine absorbable suture material is preferred. Bleeding ends of vessels are clamped with fine-point hemostats, providing immediate hemostasis. Because nerves often course with these vessels, all clamping should be done under direct visualization. The tip of the hemostat should project beyond the vessel to hold a loop of a ligature in place (Fig. 36-7) . While an assistant lifts the handle of the hemostat, a synthetic absorbable 5-0 or 6-0 suture is passed around the hemostat from one hand to the other (Fig. 36-8) (Figure Not Available) . The first knot is tied beyond the tip of the hemostat. Once the suture is securely anchored on the vessel, the hemostat is released. [65] [71]

In practice, the emergency physician seldom has an assistant available to ligate vessels by this method. MacDonald describes a technique that enables a single operator to maintain tension on the ligature while removing the hemostatic clamp. [72] A needle holder is used to grasp one tail of the ligature; the other end is held by the third, fourth, and fifth fingers of the left hand. As the clamp held in the right hand is removed from the vessel, the needle holder is moved

away from the left hand by extending the thumb and the index finger, maintaining tension on the ligature. The right hand can discard the clamp, grasp the needle holder, and complete the tie (Fig. 36-9) (Figure Not Available) . [72] Three knots are sufficient to hold the ligature in place. The ends of the suture should be cut close to the knot to minimize the amount of suture material that is left in the wound.

Physicians can make the mistake of spending excessive time attempting to tie off small bleeding vessels while the patient slowly exsanguinates. In highly vascular areas, such as the scalp, it is sometimes best to suture the laceration following wound exploration and irrigation, despite active bleeding; the pressure exerted by the closure will usually stop the bleeding. If bleeding is too brisk to permit adequate wound evaluation and irrigation, hemorrhage can often be controlled by clamping and everting the galea or dermis of each wound edge using hemostats. Lemos and Clark propose the use of scalp clips as an alternative. [71]

Cut vessels that retract into the wall of the wound may frustrate attempts at clamping and ligation. Bleeding should be controlled first by downward compression on the tissue. A suture is passed through the tissue twice, using a figure-of-eight or horizontal mattress stitch, and then tied. The double thread will constrict the tissue containing the cut vessel (Fig. 36-10) . The disadvantage of this method is that the tissue constricted by the ligature may necrose and leave devitalized tissue in the wound.

Vessels with diameters greater than 2 mm should be ligated. Those smaller than 2 mm that bleed despite direct pressure can be controlled by pinpoint electrocautery. A dry field is required for an effective electrical current to pass through the tissues; if sponging does not dry the field, a suction-tipped catheter should be used. Trauma is minimized by using fine-tipped electrodes to touch the vessel or by touching the active electrode of

the electrocautery unit to a small hemostat or fine-tipped forceps gripping the vessel. [1] The power of the unit should be kept to the minimum level required for vessel thrombosis. Bipolar coagulation (such as that provided by the Bovie unit) is preferred over monopolar coagulation because it produces approximately one third less necrosis of surrounding tissue. [35] If the amount of tissue cauterized is kept to a minimum, wound healing is no more compromised by this technique than by ligation. Cauterization of medium- and small-sized vessels can quickly provide hemostasis. Self-contained, sterilizable, battery-powered coagulation units also are available. Vessels are cauterized by the direct application of a heated wired filament. Although these units may damage more surrounding tissue than electrocautery units, they are compact and simple and thus well suited for use in the emergency center (Fig. 36-11) .

Epinephrine is an excellent vasoconstrictor. Topical epinephrine (1:100,000) on a moistened sponge can be applied to a wound to reduce the bleeding from small vessels. Combined with local anesthetics, concentrations of 1:100,000 and 1:200,000 prolong the effect of the anesthetic and provide some hemostasis in highly vascular areas. Because vasoconstrictors theoretically may increase the risk of wound infection, they should be restricted to situations in which widespread small vessel and capillary hemorrhage in a wound is not controlled by direct pressure or cauterization.

Fibrin foam, gelatin foam, and microcrystalline collagen may be used as hemostatic agents. Their utility is limited in that vigorous bleeding will wash the agent away from the bleeding site. Their greatest value may be in packing small

**Figure 36-9** (Figure Not Available) *A,* Ligature tension is maintained with one hand by grasping one tail of the suture with a clamp and keeping its base between the thumb and the forefinger. *B,* As the pedicle clamp is removed with the other hand, the ligature is tightened by extending the flexed thumb and index finger to the desired tension. Then the pedicle clamp is discarded from the right hand, and further knots are applied in the usual fashion. *(Modified from MacDonald RT: Maintenance of ligature tension by a single operator with simultaneous removal of a hemostatic clamp. Am J Surg 143:770, 1982. Reproduced by permission.)*

cavities from which there is a constant oozing of blood. [65] In most simple wounds with persistent but minor capillary bleeding, apposition of the wound edges with sutures provides adequate hemostasis.

**Tourniquets**

If bleeding from an extremity wound is refractory to direct pressure, electrocauterization, or ligation, or if the patient presents with exsanguinating hemorrhage from the wound, a tourniquet can be used to control the bleeding temporarily. Tourniquets also are helpful in examining extremity lacerations by providing a bloodless field. However, they can cause injury in three ways:

**Figure 36-10** Ligation of a retracted, bleeding vessel. *A,* Horizontal mattress technique. *B,* Figure-of-eight technique.

1. They can produce ischemia in an extremity.

2. They can compress and damage underlying blood vessels and nerves.
3. They can jeopardize the survival of marginally viable tissue.Although problems rarely develop from tourniquets used in routine wound care, potential problems can be minimized if (1) there is a limit placed on the total amount of time that an extremity is confined by a tourniquet, and (2) excessive tourniquet pressures are avoided. It is also imperative that all tourniquets be removed prior to releasing the patient. A tourniquet may be overlooked if a bulky dressing is applied over the tourniquet.A single-cuff tourniquet (sphygmomanometer cuff) placed around an arm or a leg effectively stops distal venous or arterial bleeding without crushing underlying structures. The length of time that a tourniquet may remain in place is

**Figure 36-11** Battery-powered cautery.

limited by the development of pain underneath and distal to the tourniquet. This occurs within 30 to 45 minutes in a conscious patient, well within the limits of safety. [73] Before application of the tourniquet, the injured extremity should be elevated and then manually exsanguinated to prevent bothersome venous bleeding. An elastic bandage (e.g., Ace wrap or Esmarch) may be wrapped circumferentially around the extremity, starting distally and moving in a proximal direction. A cuff that is 20% wider than the diameter of the limb is placed around the arm proximal to the wound and inflated to 250 to 300 mm Hg, and the tubing is clamped; the bandage is then removed and the extremity lowered. [74] Some experts recommend a cuff pressure 70 mm Hg higher than the patient's systolic blood pressure. [75] Because tourniquets impair circulation and may produce neurapraxia, their use in the emergency department should be limited to a maximum of 1 hour.Tourniquets on digits have a greater potential for complications. The maximum tourniquet time that is safe for a finger may easily be exceeded inadvertently. Also, finger tourniquets can exert excessive pressures over a small surface area at the base of the finger and injure digital nerves or cause pressure necrosis of digital vessels. For this reason, rubber bands should *not* be used as tourniquets. Tourniquet pressures up to 250 to 300 mm Hg are safe in digits, but pressures of only 150 mm Hg are needed for hemostasis.A 0.5-inch Penrose drain placed around the base of a finger and stretched to no more than two thirds of its circumference provides safe and effective hemostasis. Some physicians wrap the entire finger with a Penrose drain in the fashion of a miniature Esmarch bandage to exsanguinate the digit. The wrap is unraveled from distal to proximal, leaving 2 or more turns around the proximal part of the finger to serve as a tourniquet. This technique generates excessive pressures, ranging from a minimum of 300 mm Hg to >800 mm Hg. [76] A finger can be exsanguinated with a Penrose drain, but a separate drain should be used as a tourniquet (Fig. 36-12) . A few millimeters of difference in total stretch makes a large difference in the pressure applied by this type of tourniquet. [76] Alternatively, a finger can be exsanguinated with a moistened piece of gauze opened to its fullest length, folded in half, and rolled tightly around the elevated finger from tip to base. A Penrose drain is stretched around the base of the finger and secured with a hemostat, and the gauze is removed.A latex rubber surgical glove placed over a patient's hand also can serve as a finger tourniquet. The tip of the glove covering the injured digit is removed, and the latex rubber is then rolled proximally along the patient's finger to form a constricting band at the base (Fig. 36-13) . Another advantage of this technique is that contamination of the wound during closure is less likely. Rolled surgical gloves produce pressures ranging from 113 to 363 mm Hg, depending on the

thickness, the amount of glove finger removed, the number of rolls, and the size of the glove in relation to the size of the patient's hand. [76] Pressure under a Penrose drain ranges between 100 and 650 mm Hg, but it can be more easily controlled. [77] Commercial ring-shaped exsanguinating digit tourniquets are available (Tourni-cot [Mar-Med Company]) (Fig. 36-14) . There is a danger of forgetting to remove such a small tourniquet and of accidentally incorporating it in the dressing.These techniques provide bloodless fields in which to examine, clean, and close extremity wounds. The maximum tourniquet time on a finger should not exceed 20 to 30 minutes. [76] [77] Debridement of questionably devitalized tissue in a wound is best accomplished *without* a tourniquet or pharmacologic vasoconstriction, because bleeding from tissues is often an indication of their viability.

# CLOSURE

The various techniques of wound closure are presented in Chapter 37 . The remainder of this chapter addresses issues related to wound management (e.g., secondary closure, wound dressings, antibiotic use, aftercare instructions, and suture removal).

### Open Vs Closed Wound Management

Wounds that heal spontaneously (i.e., by secondary intention) undergo much more inflammation, fibroplasia, and contraction than those whose edges are reapproximated by wound closure techniques. [5] [78] During wound healing, contraction covers the defect, yet it may have undesirable consequences--notably, deformity (contracture) or loss of function. Left to itself, the healing process may be unable to close a defect completely in areas in which surrounding skin is immobile, such as on the scalp or in the pretibial area.Exposed tendons, bone, nerves, or vessels may desiccate in an open wound. If the patient is careless with an otherwise adequate dressing that covers an open wound, the wound may be further contaminated. [79] The advantages of surgical closure of wounds are apparent: this procedure minimizes inflammation, fibroplasia, contracture, scar width, and contamination.

On the other hand, risks are incurred when wounds are closed. Closure of contaminated wounds increases the probability of wound infection, with impaired healing, dehiscence, and sepsis as possible complications. After cleaning and debridement, wounds left unsutured appear to have a higher resistance to infection than do closed wounds.

Sutures in themselves are detrimental to healing and increase the risk of infection. Each suture inflicts an intradermal incision, damaging surface epithelium, dermis, SQ fat, blood vessels, small nerves, lymphatics, and epithelial appendages such as hair follicles, sweat glands, and ducts. These appendages, once divided and separated by a stitch, usually undergo inflammation and resorption.  Each suture is another piece of foreign material that provokes inflammation. [5] When a suture is removed, bacteria that have settled on the exposed portion of the suture are pulled into the suture track and deposited there. [82] Raised pretibial flap lacerations in elderly patients often necrose when sutured but survive and heal well by secondary intention if taped back into

position. [84]

If the wound is judged to be clean or is rendered clean by scrubbing, irrigation, and debridement, it may be closed. If the wound remains contaminated despite the best of efforts, it must be left open to heal by secondary intention. If the status of the wound is uncertain, the physician must make an educated guess about the risk of infection. Another option available is delayed primary closure.

## Delayed Primary or Secondary Closure

There is a common misconception that all wounds must either be sutured within a few hours or be left open and

relegated to slow healing and an unsightly scar. If there is a substantial risk that closure of a particular wound might result in infection, the decision to close or to leave the wound open can be postponed (Fig. 36-15) (Figure Not Available) . The condition of the wound after 3 to 5 days will then determine the best strategy. Although cleaning and debridement should be accomplished as rapidly as possible, there is no urgency in closing a wound. Edlich and coworkers point out that "the fundamental basis for delayed primary closure is that the healing open wound gradually gains sufficient resistance to infection to permit an uncomplicated closure." [18] Despite its effectiveness, delayed primary closure is a technique that is unappreciated and likely underused by most physicians.

Open wound management is usually an outpatient procedure. The technique consists of the usual careful cleaning and meticulous debridement, followed by packing of the wound with sterile, saline-moistened, fine-mesh gauze. The packed wound is covered by a thick, absorbent, sterile dressing. Depending on the specifics of the wound and the ability of the patient to perform his or her own wound care, the packing may be changed daily at home or in the emergency department, or the wound may be left undisturbed for several days. Sterile saline-soaked packing is standard, and there is no need to impregnate wounds with antiseptics. Prophylactic antibiotics are occassionally prescribed, but their use is neither mandatory nor of proven benefit. On the fourth postoperative day, the wound is reevaluated for closure. If no evidence of infection is present, the wound margins can be approximated (delayed primary closure), or the wound can be excised and then sutured (secondary closure) with minimal risk of infection. Because the wound is closed before the proliferative phase of healing, there is no delay in final healing, and the results are indistinguishable from those of primary healing.

Certain wounds should almost always be managed open or by delayed closure. These include wounds that are already infected and those heavily contaminated by soil, organic matter, or feces. Also included in this category are wounds associated with extensive tissue damage (e.g., high-velocity missile injuries, explosion injuries of the hand, or complex crush injuries) and most bite wounds. Physicians disagree as

**Figure 36-15** (Figure Not Available) Incidence of wound infection over time when delayed closure is performed. Delayed closure is best accomplished on the fourth or fifth day to avoid infection. *(From Edlich*

to which bite wounds may be closed initially. Most would suture cosmetically deforming injuries, including facial bites, and bite wounds that can be completely excised. [35] Others would suture nonextremity dog bites. [85] In severe soft tissue injuries, delayed closure allows time for nonviable tissue to demarcate from uninjured tissue. Debridement can then be accomplished with maximal preservation of tissue.

# PROTECTION

## Dressings

At the conclusion of wound repair, dried blood on the skin surface should be wiped away gently with moistened gauze, and the wound should be covered with a dressing. Depending on the specifics of the wound and the type of repair, a dressing can consist of a simple dry gauze pad or a complex multilayer dressing. Some wounds, such as sutured scalp lacerations, do not routinely require any dressing. Although a variety of specialized (and expensive) dressings are available, there are little hard data to support their use over readily available, properly applied gauze dressings. Therefore, much of the following discussion is theoretical.

### Function of Dressings

Dressings serve a variety of functions. They protect the wound from contamination and trauma, absorb secretions from the wound, immobilize the wound and the surrounding area, exert downward pressure on the wound, and improve the patient's comfort. Occlusive dressings on burns or abrasions prevent painful exposure of the wound to the air and dehydration of the wound surface. [88] Sutured wounds are susceptible to infection from surface contamination during the first 2 days after wound repair. Dressings effectively protect the wound from contamination during this vulnerable period.

One of the primary functions of a gauze dressing is to absorb the serosanguineous drainage that exudes from all wounds. Absorbent dressings also reduce the development of stitch abscesses to some extent. Surface sutures produce small indentations at their points of entrance; tiny blood clots and debris overlie these indentations, allowing bacterial growth at the site. Small "stitch abscesses" can develop; these are initially undetectable but are nevertheless destructive to epithelium. Stitch abscesses rarely infect the entire wound but can slightly increase the width of the scar and produce noticeable, punctate suture marks. [13]

The most common type of dressing is constructed in three layers: a nonadherent contact layer, an absorbent layer, and an outer wrap. [89] Ideally, this dressing provides nonadherence without maceration.

**Contact Layer: Dry, Semiocclusive, and Occlusive Dressings**

Petrolatum gauze (e.g., Adaptic, Xeroform, Betadine, Aquaflo) can be applied next to the wound surface to prevent the wound from sticking to the dry gauze in the absorbent layer and to protect the regenerating epithelium (Table 36-2) . (Nonadherent material should always be used to cover skin grafts.)

Coarse weaves of gauze, usually available in the form of multilayered pads, absorb blood and exudate, but the dressing

| **TABLE 36-2** -- Advantages of Occlusive Dressings<br>*Eaglstein WH: Effect of occlusive dressings on wound healing. Clin Dermatol 2:107, 1984.* |

| 3. Better cosmetic results |
| 4. Fewer dressing changes |
| 5. Better protection from bacteria |

will adhere if the interstices of the fabric are relatively large. Capillaries, fibrin, and granulation tissue will penetrate and become enmeshed in the material. If the proteinaceous exudate from the wound dries by evaporation, the scab usually clings to the dressing. [89] [90] Some clinicians use this effect to "debride" the wound when the gauze is removed. However, it also destroys healing tissue, particularly the new epithelium. Debridement of the wound with wet-to-dry dressings is quick, but debridement with surgical instruments is more controlled and less traumatic.

Adherence to the wound can be avoided if the dressing is nonabsorbent, occlusive, or finely woven. Some physicians use fine mesh gauze (41 to 47 warp threads per square inch) rather than petrolatum gauze on abrasions, especially on those wounds that are

heavily contaminated, because removal of this type of dressing debrides only the small tufts of granulation tissue that become fixed in the mesh pores, leaving a clean, even surface. Once a healthy, granulating surface is present and re-epithelialization is proceeding, nonporous dressings can be used. [90] Fine mesh gauze also is used next to exposed tissue in wounds being considered for delayed primary closure; a protective and absorptive bulky dressing is placed on top of the wound.

Wounds covered with permeable dressings such as plain gauze tend to dry out. Drying of the wound surface damages a shallow layer of exposed dermis, which impedes epidermal resurfacing of abrasions, burns, and incisions. [87] Wound desiccation results in further epidermal necrosis, crust formation, and increased inflammation. [90] [91] If the wound is kept moist by covering it with an occlusive film soon after wound management and if the film is left in place for at least 48 hours, the epidermis will migrate over the surface of the dermis up to 100% faster than when a dry scab is allowed to form. [92] [93] [94] In one study, the occluded half of a surgical incision produced a more linear, less pigmented scar. [95] Protection of wounds that are healing by secondary intention with occlusive or semiocclusive dressings has several advantages, [6] including more rapid healing, less pain from air exposure, better cosmetic result, few dressing changes, and protection from bacteria.

This occlusive effect is achieved with various polyurethane-derived membranes, such as Epilock (Derma-Lock Medical Corporation), Op-Site (Smith and Nephew, Ltd.), Tegaderm (3M), Bioclusive (Johnson & Johnson), and Primaderm (ACCO, Inc.); those with soluble collagen or gelatin backing, such as DuoDerm (Convatec) and Biobrane (Woodroof Laboratories); and products with hydrogels, such as Vigilon.

One of the fears of using occlusive dressings is that microorganisms will proliferate in the moist environment beneath the occlusive film and increase wound infection rates. Occlusive dressings such as DuoDerm actually serve more as a barrier to external pathogenic bacteria [97] ; although *surface* bacteria under occlusive dressings can multiply, [98] chronic wounds, usually contaminated with large numbers of bacteria, are routinely treated with occlusive dressings successfully. [99]

A paint-on collodion dressing over a wound closed with a buried subcuticular stitch provides considerably greater resistance to infection than wounds closed by the same technique but with no dressing. The use of collodion obviates the need for a gauze dressing, frequent dressing changes, and uncomfortable dressings in areas such as the groin, the axilla, and the neck. [100] However, the collodion does not allow drainage of the wound and so is rarely used.

Another concern of physicians is that occlusive dressings will macerate underlying skin. Optimal wound appearance under a dressing is a moist red surface with capillary and epithelial growth. Collagen sponge dressings provide this appearance (if they are not accidentally dislodged), whereas both DuoDerm and Op-Site adhere to the wound site, macerate it, and produce a thick eschar that may be difficult to remove. However, underneath the eschar the surface is epithelialized. [101] Wounds covered with certain occlusive dressings or with silver sulfadiazine (Silvadene [Marion Laboratories]) applications appear to be blanketed with pus; this exudate actually represents the

beneficial proliferation of macrophages and polymorphonuclear leukocytes. [94] [102]

Adhesive-backed dressings (e.g., DuoDerm and Op-Site) have a tendency to adhere to and remove new epidermis, and they do not allow exudate to drain out the edges of the dressing. Between dressing changes, the wound should be coated with petrolatum or an antibiotic ointment before these products are applied. [6] Epilock has the advantage of thermally insulating the wound by virtue of its thickness, but unlike Tegaderm and Op-Site, it is opaque and does not allow inspection of the underlying wound surface. [102] Because Epilock allows drainage of exudate, it is better tolerated by patients if the overlying gauze bandage is changed daily.

Other nonadherent-type dressings include Adaptic, Xeroform, Betadine, Dermicel, and the nonabsorbent Telfa. Petrolatum gauze does not appear to enhance epidermal healing. [103]

### Absorbent Layer

In dressing wounds with considerable drainage, sufficient gauze should be used to cover the wound and to absorb all of the drainage. Dressings on such wounds can be changed daily, which is frequent enough to avoid bacterial overgrowth beneath the dressing. [5] [90] Once a dressing becomes moist, pathogens can pass through the dressing to the underlying wound. [87] Any dressing should be changed whenever it becomes soiled, wet, or saturated with drainage. Fluid accumulating under an occlusive dressing should be aspirated or the dressing changed every 1 to 2 days during the first week or until the exudate no longer accumulates. [104] A dressing that is used to absorb exudate or debride the wound must be changed more frequently than one designed solely to occlude.

### Outer Layer

Dressings and bandages can serve as surface splints (as can surgical tape) by reducing mechanical stresses on the wound during the early phases of healing. Even when subcuticular stitches have been placed, these "external splints" are useful

in relieving tension across the wound. They are most needed between the 7th and 42nd days, the time of collagen synthesis and remodeling. [13]

Compressive dressings may be helpful in preventing hematoma formation and eliminating dead space within a wound. They are particularly useful in wounds that have been undermined extensively and in facial wounds, in which SQ capillary bleeding and swelling can exert tension on fine skin sutures and jeopardize skin closure (Fig. 36-16) . Pressure dressings should be used to immobilize skin grafts. Surgical tape can serve as a pressure dressing in areas such as fingertips on which bandages cannot be easily applied. However, a pressure dressing should not be used as a substitute for good hemostasis. [5]

Pressure dressings should be applied to all ear lacerations to prevent hematoma

formation and subsequent deformation and destruction of cartilage. The ear should be enveloped in the dressing so that pressure from the outer bandage is distributed evenly across the irregular surface of the pinna. Moistened cotton is packed into the concavities of the pinna until the cotton is level with the most lateral aspect of the helical rim. Square pieces of gauze cut to fit the curvature of the ear are placed *behind* (medial to) the pinna. Several more gauze squares are placed on the lateral surface of the ear; the packing is then secured in place with a circumferential head bandage. The bandage must not encompass the opposite ear, because it would just as easily cause pressure necrosis of that ear if left unprotected. Application of a pressure dressing for the ear is discussed further in Chapter 68

Traumatic wounds are bandaged to compress or immobilize the wound or to secure and protect the underlying dressing. Most bandaging is performed on extremities, on which dressings are difficult to secure with tape alone. Rolls of cotton (Kerlix; Kling stretch gauze) are well suited for this purpose. The bandage is wound around the extremity, advancing proximally with circular, overlapping turns. Care should be taken to avoid allowing wrinkles in the bandage, which will later create pressure points, or making loose turns that shorten the effective life of the dressing. When joint surfaces are crossed, the cotton is anchored distally with several turns, unrolled obliquely across the joint several times in a figure-of-eight pattern, and anchored proximally by two complete turns. This process is repeated until the bandage is securely in place. The ends of the bandage are fastened to the skin by strips of adhesive tape.

Bandages over the forearm and the lower extremities are particularly prone to slippage because of the constant motion of these parts and because of the marked changes in extremity diameter over a short distance. The roll of bandage can be rotated 180° after each circular turn, producing a reverse spiral and reducing the bandage's mobility (Fig. 36-17) (Figure Not Available) . A "tube" of elastic cotton netting (e.g., Surgifix, Tubex, Surgitube, HygiNet) pulled over the bandage or unrolled from a metal applicator frame effectively stabilizes the entire dressing in these areas (Fig. 36-18) (Figure Not Available) . Another useful technique consists of placing strips of tape on opposite sides of the extremity, leaving the ends free. The bandage is wrapped around the dressing, covering the portions of the tape that are attached to the skin. The free ends of tape are then incorporated in the bandage (Fig. 36-19) (Figure Not Available) . [105]

Certain chemically treated wide-mesh weaves have the properties of cling and stretch, holding snugly in place but expanding if edema develops. [89] An elastic cotton roll (Kerlix) allows the bandage to conform to body contours, provides some mobility to bandaged joints, and permits the wound to swell without the circumferential bandage constricting the extremity. The inelastic Kling bandage better immobilizes the part. Rigid immobilization with plaster splints or braces is needed to protect wounds in mobile areas, such as around large joints.

Most scalp wounds do well when left uncovered. If a dressing is necessary, it must be held in place by a bandage. There are many techniques for bandaging heads. Stavrakis described the following method:

The assistant tightly holds a strip of bandage three inches wide and three feet long over

the patient's head in a frontal plane [Fig. 36-20 (Figure Not Available) *A*]. While one person maintains tension on the first strip of bandage, the second person starts bandaging the head with the main bandage at the forehead level in a horizontal plane, using a full-length gauze bandage [see Fig. 36-20 (Figure Not Available) *B*]. (The 'Kling'-type bandage is preferred.) After several turns are made to stabilize the main bandage, it is passed near the patient's ear, then wrapped around the short strip of bandage in a full turn [see Fig. 36-20 (Figure Not Available) *C*]. The main bandage is then taken across the front of the head, wrapped full-turn around the other side of the short bandage, then brought around the back of the head and wrapped around the first side again. This maneuver is repeated, alternating front and back until the head is covered by overlapping passes of bandage [see Fig. 36-20 (Figure Not Available) *D*]....Several turns of the bandage across the forehead in a horizontal plane stabilize the dressing. The dressing is...secured by tying the ends of the short strip under the chin [see Fig. 36-20 (Figure Not Available) *E*]. Removal of this dressing can be accomplished easily by untying the chin straps and gently pulling both ends upward. [106]

Methods of bandaging wounds in other locations of the body are described in detail in other texts. [68] [86]

Dressings vary in their absorbency, adhesiveness, occlusiveness, opacity, and insulating properties. Further research may identify types of dressings best suited for different phases of the healing wound. Currently, a two- or three-layer dressing is used for most traumatic wounds; the choice of material for the contact layer is determined by the characteristics of the individual wound. [107]

**Splinting and Elevation**

Although splints are readily applied to orthopedic or soft tissue injuries, immobolization of wounds and sutured lacerations is often neglected, despite the fact that these techniques

**Figure 36-20** (Figure Not Available) *A- E,* Technique for bandaging the head. *(From Stavrakis P: A better head dressing. Res Staff Physician 26:88, 1980. Reproduced by permission.)*

may enhance healing and provide patient comfort. Immobilization of an injured extremity promotes healing by protecting the closure and by limiting the spread of contamination and infection along lymphatic channels. Wounds overlying joints are subjected to repeated stretching and movement, which delays healing, widens the scar, and could possibly disrupt the sutures. [18] Splints are almost always required for lacerations that overlie joints and are frequently necessary for protection of wounds involving fingers, hands, wrists, the volar aspects of forearms, the extensor surfaces of elbows, the posterior aspects of legs, the plantar surfaces of feet, and the extremities when skin grafts have been applied. Splinting is often underused by the emergency physician in the treatment of lacerations.

A plaster or aluminum splint may be incorporated into a bandage to reduce the mobility of the part. Splinting techniques for extremities are explained more fully in Chapters 51 ,

Elevation of injured extremities is important in all but trivial injuries. Elevation limits edema formation, an expected sequela of trauma and inflammation, and allows more rapid healing. [18] Elevation also reduces throbbing pain. Patients given this information are often more motivated to elevate the extremity as instructed. Slings can be used to elevate wounds involving the forearm or the hand.

## Ointments

The safety and efficacy of topical antibiotic preparations used on wound surfaces are still debated. Some investigators warn of skin sensitization by preparations containing neomycin [83] and others, of the emergence of resistant strains of bacteria with any topical antibiotic. [108] Other studies have shown that use of a triple-antibiotic preparation containing neomycin, bacitracin, and polymyxin provides a broad spectrum of protection against infection in *abrasions* without systemic absorption and toxicity or the emergence of resistant strains of bacteria. Unless this topical antibiotic ointment is used repeatedly or on inflamed skin, there is a relatively low risk of allergic sensitization. [109] There is evidence that the active agents in Neosporin ointment and Silvadene cream, as well as their inert bases and vehicles, improve wound healing. In a prospective, randomized, double-blind study, Dire and colleagues found that bacitracin and Neosporin ointments reduced the infection rate over that seen with plain petrolatum ointment. [112]

Ointments can be used to reduce the formation of a crust that covers and separates the edges of the wound. Lacerations surrounded by abraded skin are especially predisposed to coagulum formation. In such cases the patient can be instructed to cleanse the wound frequently and to follow the cleansing with an application of ointment during the first few days. [18] Ointments also prevent the dressing from adhering to the wound. [3] Some researchers recommend using bacitracin applied in a thin coating, not for protection against infection, but for prevention of these mechanical problems.

Note that the stronger topical corticosteroids have detrimental effects on healing. Application of 0.1% triamcinolone acetonide in an ointment retards healing in wounds by as much as 60%, whereas hydrocortisone probably does not interfere with epithelialization. [93] [103] Some physicians believe that single and low doses of oral corticosteroids probably have no effect on wound healing but that repeated, large doses of steroids (40 mg of prednisone per day) inhibit healing, particularly if used before the injury or during the first 3 days of the healing phase. There is some evidence that topical vitamin A may reverse some of the anti-inflammatory and immunosuppressive effects of corticosteroids. [115] The exact value of ointments in the treatment of lacerations has yet to be determined. However, their routine use after wound cleaning does encourage patient inspection of the wound.

## Systemic Antibiotics

Most traumatic soft tissue injuries sustain a low level of bacterial contamination. [79] The standard wound infection rate in unselected emergency department wounds is 2 to 5%. In a number of clinical studies of traumatic wounds, prophylactic antibiotics administered

orally and intramuscularly in a variety of regimens did not reduce the incidence of infection.

In experimental models of contaminated incisions, antibiotics have no therapeutic value >3 hours after the injury. [121] [122] When the wound is contaminated with greater than $10_9$ bacteria per gram of tissue (such as wounds in contact with pus or feces,) infection will develop despite antibiotic treatment. [35] Most clinical investigations of antibiotic use in emergency patients have omitted heavily contaminated wounds in their series. Studies of antibiotic prophylaxis for animal bite wounds have produced variable results, and no large study providing stratification of the many prognostic factors has been done. [123]

Indications for antibiotics vary among physicians, and

because of limited scientific data, there is no clear practice standard. In most soft tissue wounds where the level of bacterial contamination after cleaning and debridement is low, antibiotics have not been proven beneficial. Antibiotics may have marginal benefit when the level of contamination is overwhelming or if the amount of questionably viable tissue left in the wound is considerable (e.g., with crush wounds). Antibiotics should be considered for extremity bite wounds, puncture-type bite wounds in any location, intraoral lacerations that are sutured, orocutaneous lip wounds, wounds that cannot be cleaned or debrided satisfactorily, and highly contaminated wounds (e.g., those contaminated with soil, organic matter, purulence, feces, saliva, or vaginal secretions). They also should be considered for wounds involving tendons, bones, or joints; for wounds requiring extensive debridement in the operating room; for wounds in lymphedematous tissue; for distal extremity wounds when treatment is delayed for 12 to 24 hours; for patients with orthopedic prostheses; and for patients at risk of developing infective endocarditis. [18] [117] If systemic antibiotics are considered necessary, they should be given intravenously or intramuscularly in the earliest stages of wound management.

The choice of antibiotic, particularly for bite wound prophylaxis, is as controversial as the indications for usage. Many species of bacteria cause bite wound infections, making complete coverage impossible. [28] [124] [125] Some of the antibiotic regimens that have been recommended for bite wounds include dicloxacillin or cephalexin for high-risk dog bite wounds, dicloxacillin or cephalexin plus penicillin for human or cat bite wounds, and amoxicillin-clavulanic acid or cefuroxime for any domestic animal bite. Irrigation with topical antibiotics may be of benefit in these situations. The duration of antibiotic prophylaxis also is in question. It is common practice to provide antibiotics for 72 hours, although data from surgical studies indicate that antibiotics administered beyond the first postoperative day provide no additional protection. [126] Short courses of antibiotics do not seem to increase the incidence of resistant strains of organisms. [127] In all cases, the use of antibiotics should remain subordinate to careful cleaning and debridement. If the infection risk is high enough to warrant antibiotics, secondary closure should be considered.

It is often difficult for physicians to accept that there are *no data to support the routine use of prophylactic antibiotics for the majority of wounds encountered in the emergency department*. [128] Although the theoretical arguments for antibiotic use have been

outlined above, hard data demonstrating benefit are generally lacking. Antibiotics should not be used as a substitute for proper wound preparation or a measure to overcome factors suggesting delayed wound closure. The downsides of antibiotic use include needless expense; potential side effects (e.g., rash, anaphylaxis, diarrhea, vomiting); and the development of resistant bacteria, both in the wound and in general. If antibiotics are used, they should be given as soon as possible after wounding and continued for only 2 to 3 days in the absence of a developing infection.

## Immunoprophylaxis

Although tetanus is rare, it still occurs in the United States (about 50 cases per year) and is a preventable disease. Therefore, any wound should be assessed for its potential to cause tetanus, and prophylaxis should be considered in the emergency department. Gergen and colleagues demonstrated that about 70% of Americans >6 years of age had protective levels of tetanus antibodies. [130] Levels declined as age increased, and elderly women had the lowest levels of protection. Hispanics (and likely other immigrants) were most likely to have inadequate immunity. Hence, efforts at preventing tetanus should be especially addressed in immigrants and the elderly.

Recommendations for tetanus prophylaxis have evolved since the 1980s. The guidelines published by the Public Health Services Advisory Committee on Immunization Practices, Centers for Disease Control and Prevention, differ slightly from those of the American College of Surgeons in the use of tetanus immune globulin.

Many cases of tetanus develop despite prior immunization; tetanus frequently results from chronic skin lesions and apparently minor or clean wounds. [132] In 10 to 20% of cases, a precedent wound cannot be identified. Patients' recall of past immunizations is imperfect, and immunity may rarely be inadequate after a complete series of tetanus toxoid. [133] Furthermore, there is no precise consensus on the definition of a "tetanus-prone wound," yet treatment decisions are based on the differentiation between clean and contaminated wounds. Some investigators warn of overtreatment, and others maintain that the risk of therapy is minimal compared with the danger of tetanus.  After comparing those risks and benefits, most clinicians would agree that a certain amount of overtreatment is acceptable.

Tetanus-prone wounds include injuries >6 hours old; wounds contaminated by feces, saliva, purulent exudate, or soil; wounds with retained foreign bodies or containing devitalized or avascular tissue; established wound infections; penetrating abdominal wounds involving bowel; deep puncture wounds; and wounds caused by crush, burns, or frostbite (Fig. 36-21) . When patients are questioned about their tetanus immunization status, they should be asked if they completed the primary immunization series, and if not, how many doses have been given.

Patients who have not completed a full primary series of injections may require both tetanus toxoid and passive immunization with tetanus immune globulin. The preferred preparation for active tetanus immunization in patients 7 years of age and older is 0.5 mL of tetanus toxoid (plus the lower, adult dose of diphtheria toxoid); the dose of tetanus immune globulin is 250 to 500 units given intramuscularly. [130] Mild local

reactions consisting of erythema and induration are common after tetanus toxoid injections. Some patients with high antibody levels develop a hypersensitivity reaction of tenderness, erythema, and swelling, or serum sickness. Generalized urticarial reactions and peripheral neuropathy have also been reported. A significant percentage of elderly patients fail to develop protective antitoxin antibody titers after 14 days when given tetanus toxoid boosters.

Because protective levels of tetanus antibodies tend to parallel levels of antibodies to diphtheria, it has been recommended that both immunizations be given simultaneously. Both tetanus and diphtheria immunization have been implicated as a cause of adverse reactions. Tetanus and diphtheria toxoid are products of human antisera, and serious reactions are rare. [138] The most common reaction is a painful, indurated, tender eruption at the injection site, occasionally accompanied by a fever and mild systemic symptoms. This is a hypersensitivity reaction (arthus-type reaction), not an infection or immunoglobulin E (IgE)-mediated allergy. As such, this reaction does not require drainage or antibiotics, nor does it represent an absolute contraindication to further immunizations. Local reactions are more common in patients who have been given multiple immunizations, so it is unwise to give excessive immunizations "just to be safe." In tetanus-prone injuries, "hyperreactors" can be given tetanus immune globulin. A minor febrile illness, such as an upper respiratory infection, is not a reason to delay immunization. The only absolute contraindication to tetanus toxoid is a history of anaphylaxis or a neurologic event. In such cases, tetanus immune globulin can be safely given. Pregnancy is not a contraindication to either toxoid or immune globulin, although some suggest that the toxoid be used with caution during the first trimester. Given the excellent amnestic response to the toxoid, it is likely that the primary immunization series, coupled with intermittent boosters, conveys immunity for most of one's life.

When a wound results from the bite or scratch of a wild or domestic animal, prophylaxis against rabies also must be considered (Tables 36-3 and 36-4) . Further discussion of the prevention of rabies is provided elsewhere. [139]

## PATIENT INSTRUCTIONS

Successful wound healing is partly dependent on the care given to the wound once the patient leaves the emergency center. Patient satisfaction depends not only on the cosmetic result, but also on the expectation of that result. [6] Therefore, the patient should receive thorough and understandable instructions.

The patient should be informed that no matter how skillful the repair, any wound of significance produces a scar. Most scars deepen in color and become more prominent before they mature and fade. The final appearance of the scar cannot be judged before 6 to 12 months after the repair. [83]

Patients may experience dysesthesias in or around a scar, particularly about the midface. Gentle rubbing or pressing on the skin may relieve the symptoms. If wounds extending to SQ levels lacerate cutaneous nerves, patients may be bothered by hypoesthesia distal to the wound. Dysesthesia and anesthesia usually resolve in 6

months to 1 year. [6]

Because the wound edges are rapidly sealed by coagulum and bridged by epithelial cells within 48 hours, the wound is essentially impermeable to bacteria after 2 days. [13] [140] The patient should be instructed to keep the wound protected by keeping the dressing clean and dry for 24 to 48 hours. In this initial period the dressing should be changed only if it becomes externally soiled or soaked by exudate from the wound. If possible, the injured part should be kept elevated. There is a tendency on the part of most patients to avoid getting sutures wet. *There is no proven harm in exposing sutured wounds to soap and tap water for short periods*, and many physicians routinely allow patients to bathe with sutures in place. Some advise patients to wash wounds daily to remove dried blood and exudate, especially on areas such as the face or the scalp.

After 48 hours, the patient may remove the dressing in uncomplicated wounds and check for evidence of infection: redness, warmth, increasing pain, swelling, purulent drainage, or the "red streaks" of lymphangitis. Not all patients are able to identify these signs of infection; it is prudent to have patients with complicated or infection-prone wounds examined in 2 days by a physician or nurse. [141] Interestingly, patients may be more likely to fail to recognize a bona fide infection than to overdiagnose an infection when it is absent. [140] If there is no sign of infection after 48 hours, the patient can care for the wound until it is time for removal of the sutures. A daily gentle washing with mild soap and water to remove dried blood and exudate is beneficial. [139] [141] Undiluted hydrogen peroxide may destroy granulation tissue and newly formed epithelium, and it should not be used as

| **TABLE 36-3** -- Rabies Postexposure Prophylaxis Guide--July 1984 [139] *From Leads from the Mortality and Morbidity Weekly Report. JAMA 252:883-887, 1984.* | | |
|---|---|---|
| **The following recommendations are only a guide. In applying them, take into account the animal species involved, the circumstances of the bite or other exposure, the vaccination status of the animal, and presence of rabies in the region. Local or state public health officials should be consulted if questions arise about the need for rabies prophylaxis.** | | |
| **Animal Species** | **Condition of Animal at Time of Attack** | **Treatment of Exposed Person A** |
| *Domestic* | | |

| Dog and cat | Healthy and available for 10 days of observation | None, unless animal develops rabies [D] |
|---|---|---|
| | Rabid or suspected rabid | HRIG [I] and HDCV |
| | Unknown (escaped) | Consult public health officials. If treatment is indicated, give HRIG [I] and HDCV |
| *Wild* | | |
| Skunk, bat, fox, coyote, raccoon, bobcat, and other carnivores | Regard as rabid unless proven negative by laboratory tests [T] | HRIG [I] and HDCV |
| *Other* | | |
| Livestock, rodents, and lagomorphs (rabbits and hares) | Consider individually. Local and state public health officials should be consulted on questions about the need for rabies prophylaxis. Bites of squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice, other rodents, rabbits, and hares almost never call for antirabies prophylaxis. | |

*All bites and wounds should immediately be thoroughly cleansed with soap and water.* If antirabies treatment is indicated, both human rabies immune globulin (HRIG) and human diploid cell rabies vaccine (HDCV) should be given as soon as possible, *regardless* of the interval from exposure. Local reactions to vaccines are common and do not contraindicate continuing treatment. Discontinue vaccine if fluorescent antibody tests of the animal are negative.

During the usual holding period of 10 days, begin treatment with HRIG and HDCV at first sign of rabies in a dog or cat that has bitten someone. The symptomatic animal should be killed immediately and tested.

If HRIG is not available, use antirabies serum, equine (ARS). Do not use more than the recommended dosage.

The animal should be killed and tested as soon as possible. Holding for observation is not recommended.

a cleaning agent on the scar itself. [42] Generally, a wound should be protected with a dressing during the first week, and the dressing should be changed daily. If the wound is unlikely to be contaminated or traumatized, it may be left uncovered. Although it is

generally recommended that uncovered scalp wounds can be washed after 1 to 2 days, a gentle rinse with water in the first few hours after wound closure is unlikely to be harmful. Vigorous scrubbing of wounds should be discouraged.

Patients should be informed that sutures themselves do not cause pain. A painful wound is often a sign of infection or suture reaction, and pain should prompt a wound check.

| TABLE 36-4 -- Rabies Postexposure Prophylaxis Schedule, United States *From the Recommendations of the Immunization Practices Advisory Committee, MMWR 40(RR-3):1, 1991.* | | |
|---|---|---|
| **Vaccination Status** | **Treatment** | **Regimen** [*] |
| Not previously vaccinated | Local wound cleansing | All postexposure treatment should begin wih immediate thorough cleansing of all wounds with soap and water |
| | HRIG | 20 IU/kg of body weight; if anatomically feasible, up to half the dose should be infiltrated around wounds and rest administered IM in gluteal area; HRIG should not be administered in same syringe or into same anatomic site as vaccine; because HRIG may partially suppress active production of antibody, no more than recommended dose should be given |
| | Vaccine | HDCV or RVA, 1 mL, IM (deltoid area ), one each on days 0, 3, 7, 14, and 28 |

| Previously vaccinated | Local wound cleansing | All postexposure treatment should begin with immediate thorough cleansing of all wounds with soap and water |
| --- | --- | --- |
| | HRIG | HRIG should not be administered |
| | Vaccine | HDCV or RVA, 1 mL, IM (deltoid area ), one each on days 0 and 3 |

*These regimens are applicable for all age groups, including children.
The deltoid area is the only acceptable site of vaccination for adults and older childen. For younger children, the outer aspect of the thigh may be used. Vaccine should never be administered in the gluteal area.
Any person with a history of preexposure vaccination with HDCV or RVA, prior postexposure prophylaxis with HDCV or RVA, or previous vaccination with any other type of rabies vaccine and a documented history of antibody response to the prior vaccination. HDCV, human diploid cell rabies vaccine; HRIG, human rabies immune globulin; RVA, rabies vaccine, adsorbed.

Some wounds heal with wide, unattractive scars despite the physician's best efforts. These include wounds that cross perpendicular to joints, wrinkle lines, or lines of minimum tension (Kraissel's lines); wounds that retract >5 mm; and wounds that are over convexities or in certain anatomic locations (e.g., back, shoulders) where hypertrophic scars are common. A wound crossing a concave surface may result in a bowstring deformity; one crossing a convexity may leave a scar depression. To avoid these complications, a Z-plasty procedure can be done at the time of initial wound management, or the scar can be revised later. The patient should be told to expect suboptimal outcomes in these situations. [30]

If an injured extremity or finger is protected by a splint, it should be left undisturbed until the sutures are removed. Patients with intraoral lacerations should be instructed to use warm salt water mouth rinses at least three times a day.

Patients may ask about the efficacy of various creams and lotions (e.g., vitamin E, cocoa butter) in limiting scar formation. At this time there are no data to evaluate the use of these substances. Patients should be told to avoid aspirin, as it has been shown to decrease the development of tensile strength and increase the likelihood of hematoma formation.

## SECONDARY WOUND CARE

### Reexamination

Patients with simple sutured wounds may be released with appropriate instructions for home care and told to return for suture removal at an appropriate time. Selected wounds should be examined in 2 to 3 days for signs of infection. All wounds should be inspected if the patient experiences increasing discomfort or develops a fever. [143] Bite wounds and other infection-prone wounds should be inspected in 2 days. Wounds being considered for delayed primary closure are evaluated in 4 to 5 days. [78]

Wounds in which extensive dissection of SQ tissue has been performed may develop a low-grade, localized cellulitis. It is rarely necessary to open these wounds. The removal of 1 or 2 stitches may relieve some of the tension caused by mild swelling. With daily cleansing using water and a mild soap and with application of warm compresses, this type of wound reaction should subside within 24 to 48 hours. [143]

*A wound that has become infected should be evaluated for the presence of a retained foreign body.* Also, in most sutured wounds that become infected, the sutures must be removed to allow drainage. If a wound exhibits a minor infection, a few sutures, or all of them, may be removed, but grossly infected wounds should be packed open to allow for further drainage. The presence of sutures in a contaminated wound considerably limits the activity of various antibiotics. [144] Infection around a suture can lead to the formation of a stitch mark. [64] Infected wounds should be treated with daily cleansing, warm compresses, and antibiotics. Wounds that have been opened should be left to heal by secondary intention, which involves wound contraction, granulation tissue formation, and epithelialization.

**Suture Removal**

Because wounds do not heal at a standard rate, no strict guidelines can be set for time of suture removal. The optimal time for suture removal varies with the location of the wound, the rate of wound healing, and the amount of tension on the wound. Certain areas of the body such as the back of the hand heal slowly, whereas facial or scalp wounds heal rapidly. Speed of wound healing is affected by systemic factors such as malnutrition, neoplasia, or immunosuppression. At the time that suture removal is being considered, 1 or 2 sutures may be cut to determine whether the skin edges are sufficiently adherent to allow removal of all the sutures. [3] Removing sutures too early invites wound dehiscence and widening of the scar, whereas leaving sutures in longer than necessary may result in epithelial tracts, infection, and unsightly scarring. [145]

Small stitch abscesses are common in wounds in which sutures have been left in place for longer than 7 to 10 days. Localized stitch abscesses generally resolve following removal of the sutures and application of warm compresses. There is usually no need for antibiotic therapy with localized stitch abscesses.

Percutaneous sutures stimulate an inflammatory reaction along the suture track. Factors that determine the severity of stitch marks include the length of time skin stitches are left in place, skin tension, the relationship of the suture to the wound edge, the region of the body, infection, and tendency for keloid formation. [64] [146] The skin of the eyelids, palms, and soles and the mucous membranes seldom show stitch marks. In contrast, oily skin

and the skin of the back, the sternal area, the upper arms, the lower extremities, the dorsum of the nose, and the forehead are likely to develop the permanent imprints of suture material on the skin surface. [64]

If sutures are removed within 7 days, generally no discernible needle puncture or stitch mark will persist. [146] However, at 6 days, the wound is held together by a small amount of fibrin and cells and has minimal strength (see Fig. 36-1) . [82] The tensile strength of most wounds at this time is adequate to hold the wound edges together, but only if there are no appreciable dynamic or static skin forces pulling the wound apart. [3] Minimal trauma to an unsupported wound at this point could cause dehiscence. The physician should decide on the proper time of suture removal after weighing these various factors. If early suture removal is necessary, wound repair can be maintained with strips of surgical skin tape. The key to wound tensile strength after suture removal is an adequate deep tissue layer closure.

There are some general guidelines for suture removal. Sutures on the face should be removed on the fifth day following the injury, or alternate sutures should be removed on the third day and the remainder on the fifth day. On the extremities and the anterior aspect of the trunk, sutures should be left in place for approximately 7 days to prevent wound disruption. Sutures on the scalp, back, feet, and hands and over the joints must remain in place for 10 to 14 days, even though permanent stitch marks may result. [64] Some physicians recommend the removal of sutures in eyelid lacerations in 48 to 72 hours to avoid epithelialization along the suture tract, with subsequent cyst formation. [147]

Removing sutures is relatively simple. The wound should be cleansed, and any remaining crust overlying the wound surface or surrounding the sutures should be removed. The skin is wiped with an alcohol swab. Each stitch is cut with a scissors or the tip of a scalpel blade (No. 11 Bard-Parker) at a point close to the skin surface on one side.

**Figure 36-22** (Figure Not Available) Technique for suture removal. Pull should be toward the wound line *(A)* rather than away from it *(B),* which causes the wound to tear apart. *(Modified from Stuzin J, Engrav LH, Buehler PK: Emergency treatment of facial lacerations. Postgrad Med 71(3):81, 1982.)*

The suture is grasped on the opposite side with forceps and is pulled across the wound (Fig. 36-22) (Figure Not Available) . The amount of exposed suture that is dragged through the suture tract is thereby minimized. It is difficult to remove sutures with very short ends. At the time of suture placement, the length of the suture ends should generally equal the distance between sutures to permit easy grasping of the suture during subsequent removal yet avoiding entanglement during the knotting of adjacent sutures.

Once the skin sutures are removed, the width of the scar increases gradually over the next 3 to 5 weeks unless it is supported. Support is provided by previously placed SQ stitches that brought the skin edges into apposition, by a previously placed subcuticular stitch, or by the application of skin tape (Fig. 36-23) . A nonabsorbable subcuticular suture can be left in place for 2 to 3 weeks to provide continued support for the wound. Although complications such as closed epithelial sinuses, cysts, or internal tracts can

occur from prolonged use of this stitch, they are unusual and can be avoided by the placement of a buried subcuticular stitch using an absorbable suture. [13]

If a subcuticular stitch with reliefs has been used, the suture is cut at the midpoint of the relief. Half of the suture is removed at the original point of entry into the skin and the other half through the original exit point (Fig. 36-24) (Figure Not Available) . [148] If a nonabsorbable subcuticular suture cannot be removed or a portion of it ruptures during removal, the protruding end should be grasped with a hemostat, pulled taut, and cut with scissors as close to the skin as possible so that the end of the suture retracts under the skin.

If time and effort have been invested in a cosmetic closure of the face, the repair should be protected with skin tape after the skin sutures have been removed. Wound contraction and scar widening continue for 42 days after the injury. [82] Because the desired result is a scar of minimal width, the tape should be used for 5 weeks following suture removal. With exposure to sunlight, scars in their first 4 months redden to a greater extent than surrounding skin. In exposed cosmetic areas and when prolonged exposure to the sun is anticipated, this should be prevented with the use of a sunscreen containing para-amino benzoic acid (PABA).

## COMPLICATIONS

Infection is probably the most common cause of dehiscence. If the patient is careless or unlucky, reinjury can reopen a wound despite the protection of a thick dressing. If the suture size is too small, the stitch may break. A stitch that is too fine or tied too tightly may cut through friable tissue and pull out. Knots that have not been tied carefully may unravel. The suture material may be extruded or absorbed too rapidly. Finally, if a stitch is removed too early (i.e., before tissues regain adequate tensile strength), the wound

**Figure 36-24** (Figure Not Available) At the time of suture removal, the suture is cut at the midpoint of the relief *(A).* The proximal portion is removed at the point of original entry into the skin *(B),* and the distal portion is removed through the original exit point *(C).* (From Grimes DW, Garner RW: "Reliefs" in intracuticular sutures. Surg Rounds 1:48, 1978. Reproduced by permission.)

loses needed support and falls open. If the wound edges show signs of separating at the time of suture removal, alternate stitches can be left in place and the entire length of the wound supported by strips of adhesive tape.

There are several reasons why wounds fail to heal; some are related to decisions made at the time of wound closure, and others are consequences of later events. Some of the impediments to healing include ischemia or necrosis of tissue, hematoma formation, prolonged inflammation caused by foreign material, excessive tension on skin edges, and immunocompromising systemic factors. In attempting to repair wounds, physicians sometimes inadvertently retard the healing process (e.g., with premature closure of contaminated wounds). With the development of new methods and solutions for cleansing wounds and the discovery of the optimal concentrations of solutions currently in use, tissue-toxic antiseptic solutions can be abandoned. Better suture materials are replacing the reactive sutures that often served as foreign bodies rather than tissue

supports. Improved materials used for dressing wounds enhance wound healing.

One of the primary causes of delayed healing is wound infection. Wound cleaning and debridement, atraumatic and aseptic handling of tissues, and the use of protective dressings minimize this complication. Inversion of the edges of a wound during closure produces a more noticeable scar, whereas skillful technique can convert a jagged, contaminated wound into a fine, inapparent scar. However, the patient's actions also affect wound healing. Delay in seeking treatment for an injury may significantly affect the ultimate outcome of the wound. Furthermore, in the first few days following an injury, the patient must take responsibility for protecting the wound from contamination, further trauma, and swelling.

The final appearance of a scar is determined by several factors. Infection, tissue necrosis, and keloid formation widen a scar. Wounds located in sebaceous skin or oriented 90° to dynamic or static skin tension lines result in wide scars.

## CONCLUSION

The objective of traumatic wound management is the restoration of tissue continuity and strength in the least possible time, with maximal preservation of tissues and minimal scar formation, deformity, or loss of function.

It is important that physicians follow the basic principles of wound care when cleaning, debriding, closing, and protecting wounds and continue to refine their management of wounds as further improvements in techniques and materials become available.

# Chapter 37 - Methods of Wound Closure

**Richard L. Lammers, Alexander T. Trott**

Once the decision to close a wound has been made, the physician must select the closure technique best suited for the location and configuration of the wound. Available techniques include hair tying (in the scalp) and use of tape, tissue adhesive, metal staples, and sutures. All traumatic wounds should be cleaned, and wounds containing devitalized tissue should be debrided prior to closure (see Chapter 36) .

## HAIR TYING OF SCALP WOUNDS

Scalp wounds that gape have traditionally been closed with suture material or skin staples. One "folk method" of scalp wound closure that has received limited discussion [1] and study [2] is the technique of tying together "roped" strands of hair from opposite sides of the wound.

The advantages of this technique are that no surgical instruments are required; no foreign material is placed in the wound; and it is relatively painless, because a local anesthetic injection is not needed. This technique may be of particular value in wilderness settings when wound repair equipment is unavailable and the wound is relatively clean. In certain superficial scalp wounds in children, this technique offers a particularly humane method of wound closure.

### Indications and Contraindications

Closure by hair tying can be performed on small scalp wounds (i.e., 1 to 2 cm in length). Davies suggests the following 6 criteria for consideration of this technique [2] :

1. The patient's hair must be of adequate length to form "roped" strands that can be tied across the wound.
2. The wound edges should not be contused.
3. There should be no gross wound contamination.
4. There must be good wound hemostasis.
5. The galea (occipitofrontalis aponeurosis) must not be divided.
6. There must be no underlying skull fracture.When these conditions cannot be met, the technique should not be undertaken. If local anesthesia must be used to permit evaluation of the deep structures of the wound, it may be best to simply repair the wound with sutures or staples.

### Procedure

When possible, the area surrounding the wound should be cleansed with mild disinfectant, avoiding contact with the unanesthetized wound. The wound should be irrigated with normal saline. The wound should be gently explored using a gloved hand or cotton-tipped applicator to verify that the galea is not compromised and that no

foreign material remains in the wound.

Hair on each side of the laceration is then twisted to form "ropes" of hair (Fig. 37-1 *A*). These "roped" strands are tied across the wound in a surgical knot, with several additional throws (Fig. 37-1 *B*) to tightly appose the skin edges. Davies recommends spraying the knot with a plastic sealant to avoid loosening of the knot. [2]

Postclosure wound care is similar to that for routine scalp closure. The patient may gently shampoo the hair, but *vigorous* hair massage or combing in the area should be avoided. The knot is allowed to grow away from the wound edge and can be cut free in 2 to 4 weeks.

### Complications

In 1 series of 25 children under 8 years of age whose scalp wounds were closed by hair tying, 48-hour follow-up showed no evidence of wound infection and 2 cases of mild (2 to 4 mm) wound separation. [2] The investigators noted that some of the children complained of the sensation that their hair was "being pulled" during wound closure, but all cooperated without restraints or anesthesia. The most common complaint noted at follow-up was that the hair-tie knot was untidy.

### Conclusion

Closure of scalp wounds by hair tying offers an attractive alternative for closure of small, superficial scalp wounds in children and for clean scalp wound repair in wilderness settings.

## WOUND TAPE

The use of surgical tape strips to close simple wounds has become routine in recent years. Tape strips can be applied by health care personnel in many settings, including emergency departments, operating rooms, clinics, and first-aid stations. Advantages of tape strips include ease of application, reduced need for local anesthesia, more evenly distributed wound tension, no residual suture marks, minimal skin reaction, no need for suture removal, superiority for some grafts and flaps, and suitability for use under plaster casts. One of the main advantages of wound tapes is their greater resistance to wound infection compared with standard sutures and wound staples.

### Background and Tape Comparisons

Tape closure of wounds has been reported since 1600 B.C. [7] It was not until the late 1950s, however, with the introduction of woven tapes and nonsensitizing adhesive, that tapes gained widespread acceptance in the United States. [8] Since then, there have been rapid advances in the manufacture of tapes with increased strength, improved adhesiveness, and presterilized packaging.

Currently there are several brands of tapes with differing porosity, flexibility, strength, and configuration. Steri-Strips (3M Corporation, St. Paul, Minn) are microporous tapes with ribbed backing. They are porous to air and water, and the ribbed backing provides extra strength. Cover-Strips (Beiersdorf, South Norwalk, Conn) are woven in texture and have a high degree of porosity. They allow not only air and water, but also wound exudates to pass through the tape. Shur-Strip (Deknatel, Inc., Floral Park, NY) is a nonwoven microporous tape. Clearon (Ethicon, Inc., Somerville, NJ) is a synthetic plastic tape whose backing contains longitudinal parallel serrations to permit gas and fluid permeability. An iodoform-impregnated Steri-Strip (3M Corporation) is intended to further retard infection without sensitization to iodine. [3] Other tape products include Curi-Strip (Kendall, Boston), Nichi-Strip (Nichiban Co., Ltd, Tokyo), Cicagraf (Smith & Nephew, London), and Suture Strip (Genetic Laboratories, St. Paul).

Scientific studies of wound closure tapes have been limited, and because of different investigators' choices of products and methods, it is not always easy to compare results. Koehn showed that the Steri-Strip tapes maintained adhesiveness about 50% longer than Clearon tape. [9] Rodeheaver and coworkers compared Shur-Strip, Steri-Strip, and Clearon tape in terms of breaking strength, elongation, shear adhesion, and air porosity. [10] The tapes were tested in both dry and wet conditions. The Steri-Strip tape was found to have about twice the breaking strength of the other two tapes in both dry and wet conditions; there was minimal loss of strength in all tapes when wetted. The Shur-Strip tapes showed approximately two to three times the elongation of the other tapes at the breaking point, whether dry or wet. Shear adhesion (amount of force required to dislodge the tape when a load is applied in the place of contact (angle = 0°) was slightly better for the Shur-Strip tape than for the Steri-Strip tape and approximately 50% better than for the Clearon tape. Of these three wound tapes, the investigators considered Shur-Strips to be superior for wound closure.

One comprehensive study of wound tapes compared Curi-Strip, Steri-Strip, Nichi-Strip, Cicagraf, Suture Strip, and Suture Strip Plus. [11] All tapes were 12 mm wide except for Nichi-Strip, which was 15 mm. Each tape was compared for breaking strength, elongation under stress, air porosity, and adhesiveness. Curi-Strip, Cicagraf, and Steri-Strip exhibited equivalent dry breaking strengths. However, when wet (a condition that can occur in the clinical setting), Cicagraf outperformed all tapes. All of the tested tapes had similar elongation-under-stress profiles with the exception of Suture Strip Plus. This tape did not resist elongation under low or high forces. Excessive elongation may allow wound dehiscence. Nichi-Strip was the most porous to air, and Cicagraf was almost vapor impermeable. Nichi-Strip and Curi-Strip had the best adherence to untreated skin. When the skin was treated with tincture of benzoin, however, Steri-Strip dramatically outperformed all other products. When all of the study parameters were considered, Nichi-Strip, Curi-Strip, and Steri-Strip achieved the highest overall performance rankings.

**Indications**

The primary indication for tape closure is a superficial straight laceration under little tension. If necessary, tension can be reduced by undermining or placing deep closures.

Areas particularly suited for tape closure are the forehead, chin, malar eminence, thorax, and nonjoint areas of the extremities. Tape also may be preferred for wounds in anxious children when suture placement is not essential. In young children who are likely to remove tapes, tape closures must be protected with an overlying bandage. However, adhesive bandages (e.g., Band-Aids) should be avoided (see below).

In experimental wounds inoculated with *Staphylococcus aureus*, tape-closed wounds resisted infection better than wounds closed with nylon sutures. [6] Therefore, tape closures may be considered on wounds with potential for infection, although infection rates are generally comparable to those of sutured wounds. Tape closures work well under plaster casts when superficial suture removal would be delayed. Tape closures effectively hold flaps and grafts in place, particularly over fingers, the flat areas of the extremities, and the trunk. [3] [4] Wounds on the pretibial area are difficult to close. This area is particularly problematic in the elderly because of tissue

atrophy. One report found that wound tapes outperformed suture closure of the pretibial area with regard to time to healing and complications (Fig. 37-2 *A* and *B*). [12] Tape closures can be applied to wounds following early suture removal to maintain wound edge approximation while reducing the chance of permanent suture mark scarring. Finally, because of the minimal skin tension created by tapes, they can be used on skin that has been compromised by vascular insufficiency or altered by prolonged use of steroids.

## Contraindications

There also are disadvantages to tape closures. Tape does not work well on wounds that are under significant tension or on wounds that are irregular, on concave surfaces, or in areas of marked tissue laxity. In many cases tape does not provide satisfactory wound edge apposition without concurrent underlying deep closures. Tape does not stick well to naturally moist areas, such as in the axilla, the palms of the hands, the soles of the feet, and the perineum. Tape also has difficulty adhering to wounds that will have copious exudates.  Tape strips also can be prematurely removed by young children.

Tape closures are contraindicated in wounds that are irregular or under tension and in those that cannot be appropriately dried of blood or secretions. They are of little value on lax and intertriginous skin and in the scalp and beard areas.

Tapes should never be placed circumferentially around a digit, because they have insufficient ability to stretch or lengthen. If placed circumferentially, the natural wound edema of an injured digit can make the tape act like a constricting band, which can lead to ischemia and possible necrosis of the digit. Semicircular or spiral placement techniques should be used if digits are to be taped.

## Equipment

For a simple tape closure, the required equipment includes forceps and tape of the proper size. Most taping can be done in the emergency department with ¼-inch × 3-inch

strips. In wounds larger than 4 cm, however, ½-inch-wide strips might be desirable. Most companies manufacture strips up to 1 inch wide and up to 4 inches long.

## Procedure

Application of the tape must be preceded by proper wound preparation, irrigation, debridement, and hemostasis. Fine hair may be shaved, and the area of the tape application *is thoroughly dried to ensure proper adhesion*. Attempting to apply tapes to a wet area or over a wound that is slowly oozing blood will usually result in failure of the tapes to stick to the skin. On fingers, tapes can be applied to a wound that is kept dry by a tourniquet temporarily placed at the base of the finger.

Tincture of benzoin and Mastisol are liquid adhesives that can be applied initially to increase tape adhesion. [6] The physician should use sterile technique at all times. Wound tapes do not adhere unduly to surgical gloves, and sterile glove use allows the operator to maintain proper sterile technique. All tapes come in presterilized packages and can be opened directly onto the operating field.

The technique of applying tapes is shown in [Figures 37-3](#) *A- J.* After the wound has been dried and a liquid adhesive has been applied and has dried, the tapes, with backing attached, are cut to the desired length. Tapes should be long enough to allow for approximately 2 to 3 cm of overlap on each side of the wound. After the tape is cut to length, the end tab is removed. The tape is gently removed from the backing with forceps by pulling straight back. Do not pull to the side, because the tape will curl and be difficult to apply to the wound. One half of the tape is securely placed at the midportion of the wound. The opposite wound edge is gently but firmly apposed to its counterpart. The second half of the tape is then applied. The wound edges should be as close together as possible and at equal height to prevent the development of a linear, pitting scar. Additional tapes are applied by bisecting the remainder of the wound. A sufficient number of tape strips should be placed so that the wound is completely apposed without totally occluding the wound edges. Finally, additional cross tapes are placed to add support and prevent blistering caused by unsupported tape ends. [5]

Taped wounds are left open, without occlusive dressings. Adhesive bandages (e.g., Band-Aids) and other dressings promote excessive moisture, which can lead to premature tape separation from the wound. The bandage also may adhere to the closure tapes, causing separation of the closure tape from the skin at the time of the removal. Tapes may remain in place for approximately 2 weeks and in some cases longer. The duration of application is a decision that varies with the requirements of each wound. The patient can be allowed to clean the taped laceration gently with a moist, soft cloth after 24 to 48 hours. However, if excessive wetting or mechanical force is used, premature separation may result. Patients may be instructed to gently trim curled edges of the closure tape with fine scissors to avoid premature removal of the tape.

## Complications

Complications are uncommon with tape closure. The infection rate is approximately 5%

in clean wounds closed with tape. [5] This compares favorably with rates for other standard closures. Premature tape separation occurs in approximately 3% of cases. [10] Other complications include (1) skin blistering, which occurs if the tape is not properly anchored with the cross-stay strip or the tape is stretched excessively across the wound; and (2) wound hematoma, which results if hemostasis is inadequate.

When tincture of benzoin is used, it should be applied carefully to the surrounding uninjured skin. If spillage occurs into the wound, the wound is at higher risk for infection. [13] Benzoin vapors cause pain when applied near an open wound that has not been anesthetized. Benzoin can also injure the mucous membranes of the eye.

### Summary

Most investigators believe that the results of proper tape closure are as successful as those of suture closure. [5] [7] However, some investigators believe that tape closure leads to inferior cosmetic results. [14] In the aggregate, modern tape products and techniques serve a valuable role in minor wound management of selected patients in the emergency department. Generally, closure tapes are underused, and many wounds that are currently sutured in cosmetically unimportant areas could be adequately closed with tapes. As a general guide, tapes should be considered in those cases where sutures are not clearly required, but the wound is too wide for a simple dressing.

## TISSUE ADHESIVE

Adhesive tape can only be used on superficial wounds on relatively flat, hairless body surfaces. The tissue adhesive *N*-2-butylcyanoacrylate (Histoacryl glue) is a bonding agent that can be used on superficial wounds, even in hair-bearing areas. Tissue adhesive (also called *tissue glue*) polymerizes when it comes in contact with water. This substance is biodegradable but remains in the wound until well after healing. [15]

### Procedure

Tissue adhesive can be used to approximate wounds not requiring deep-layer closure. In preparation for closure, the wound should be anesthetized, cleaned, and debrided when indicated. Bleeding must be controlled.

A small volume of the adhesive solution is drawn into a syringe and 25-ga needle. Alternatively, the needle can be attached to the cut end of the cylindrical plastic container. As the wound edges are held together, droplets of tissue adhesive are placed over the laceration along the length of the wound. Alternatively, one can place the glue in strips perpendicular to the laceration (analogous to placement of closure tapes). The purple color of the solution facilitates placement of the droplets. The wound edges should be supported with edges approximated for at least 1 minute while the glue dries. The closure can be reinforced and protected with a bandage such as Elastoplast.

The primary advantage of tissue adhesive is the speed of closure. Wounds can be closed in as little as one sixth of the time required for repair with sutures. Although 1

animal study found that wounds closed with tissue adhesive had less tensile strength than sutured wounds at 4 days, [16] other studies testing wounds 1 week after closure found that tensile strength and overall degree of inflammation in wounds closed with adhesive were equivalent to those closed with sutures. [15] [17] Cosmetic results are similar to those obtained with suture repair. [18] [19] Although the glue should not be placed within the wound cavity, tissue adhesive does not cause a significant foreign body reaction. [17]

### Complications

Percutaneous sutures provide a more secure immediate closure than tissue adhesive. [15] Tissue adhesive should not be used near the eyes, over or near joints, or on wounds under significant static tension. If hemostasis is inadequate or an excessive amount of adhesive is applied too quickly, the patient can experience a burning sensation from the heat of polymerization.

### Summary

Tissue adhesive is currently being used in many countries, but its use remains investigational in the United States.

## WOUND STAPLES

### Background

Wound stapling devices date back to the early part of this century. Several Russian, Hungarian, and Japanese investigators pioneered various instruments, but it was not until the early 1960s that significant interest in the use of these devices developed in the United States. [20] [21] Since that time there has been a steady improvement in technology, including the introduction of automatic and disposable devices, precocking mechanisms, and optimal staple configurations.

Automatic stapling devices have become commonplace for closure of surgical incisions and are finding acceptance among clinicians for closure of traumatic wounds. Clinical studies of patients with stapled surgical incisions have consistently revealed that there is no significant difference between stapling and suturing when infection rates, healing outcome, and patient acceptance are compared. Four important studies have demonstrated that selected traumatic wounds in both adult and pediatric patients can be closed successfully with staples in the emergency department setting. Wound stapling and nylon suture closure of skin compared favorably in wound tensile strength, complication rates, patient tolerance, efficiency of closure, scar width, color, general appearance, suture or staple marks, infection rates, and cost. However, in 1 study more patients in the staple group reported discomfort with removal. [29] In animal models, staples cause less wound inflammation, preserve wound defense mechanisms, and offer more resistance to infection in contaminated wounds.

The most significant advantage of wound stapling over suturing is speed of closure. On

average, stapling is 3 to 4 times faster than suturing traumatic wounds. [27] [29] The time for actual staple application is 30 seconds or less for a laceration 3 to 5 cm in length. Cost has been cited as a disadvantage of staple closure, particularly when large, multistaple (25 to 35) surgical units are the only product available. [30] However, with the introduction of smaller devices more appropriate for the average laceration, the cost of stapling devices has been reduced significantly. [30] When physician time and cost of instruments are considered, the cost difference is minimal [27] or favors stapling. [37]

## Indications and Contraindications

Currently the indications for stapling are limited to relatively linear lacerations with straight, sharp edges located on an extremity, the trunk, or the scalp. Staples may be especially useful for superficial scalp lacerations in the agitated or intoxicated patient. Because of their superficial placement in the adult scalp (usually above the galea), staples are *not* ideal for *deep* scalp lacerations. Staples may not provide the same hemostasis that is possible with deep sutures. Also, they should not be placed in scalp wounds if computed tomography head scans are to be performed because staples produce scan artifacts. Similarly, staples should not be used if the

patient is expected to undergo magnetic resonance imaging, because the powerful magnetic fields may avulse the staples from the skin surface. As they are currently configured and manufactured, staples *should not be used on the face, neck, hands, or feet*.

## Equipment

Standard wound care should precede wound closure (see Chapter 36) . In many cases, when debridement and dermal (deep) closures are unnecessary, only tissue forceps are needed to assist in everting wounds.

Many stapling devices are commercially available. The most versatile and least expensive stapler is the Precise (3M Corporation). Different units can be purchased that hold between 5 and 25 staples. The 10-staple unit will suffice for most lacerations. Other devices include the Proximate 11 (Ethicon, Inc.), Cricket (US Surgical, Irvine, Calif), and Appose (Davis & Geck, Columbus, Ohio). These staplers have

**Figure 37-4** (Figure Not Available) The skin edges must be approximated and everted by hand or with forceps before they are secured with staples. Failure to evert the wound edges is a common error that may cause an unacceptable result. *(Adapted with permission from Edlich RF: A Manual for Wound Closure. St. Paul, Minn, 3M Medical-Surgical Products, 1979. Reproduced by permission.)*

a minimum of 15 staples and are 3 to 5 times more expensive than the Precise stapler.

## Procedure

The wound is prepared in the manner described in Chapter 36 . Whenever necessary, deep, absorbable sutures are used to close deep fascia and to reduce tension in the

superficial fascia and dermal layers. Before stapling, the wound edges should be everted, preferably by a second operator. The assistant precedes the operator along the wound and everts the wound edges with forceps or pinches the skin with the thumb and forefinger. This technique allows the staple to be precisely placed. Once the edges are held in eversion, the staple points are gently placed across the wound (Fig. 37-4) (Figure Not Available) . By squeezing the stapler handle or trigger, the staple is advanced automatically into the wound and bent to the proper configuration (Figs. 37-5 (Figure Not Available) and 37-6) (Figure Not Available) . One must take care not to press too hard on the skin surface in order to prevent placing the staple too deeply and causing ischemia within the staple loop. When properly placed, the *crossbar of the staple is elevated a few millimeters above the skin surface* (Fig. 37-7) (Figure Not Available) . Enough staples should be placed to provide proper apposition of the edges of the wound along its entire length.

After the wound is stapled, an antibiotic ointment may be applied to minimize dressing adherence, and a sterile dressing is applied. If necessary, the patient can remove the dressing and gently clean the wound in 24 to 48 hours. The interval between staple application and removal is the same as that for standard suture placement and removal.

Removal of staples requires a special instrument that is made available by each manufacturer of stapling devices. The lower jaw of the staple remover is placed under the crossbar (Fig. 37-8) (Figure Not Available) . One brings down the upper jaw by squeezing the handle (Fig. 37-9) (Figure Not Available) . This action compresses the crossbar, thereby releasing the staple points for easy removal. If the patient is referred for office removal of staples, it may be advisable to provide the patient with the staple removal device on emergency department release, because many physicians do not routinely stock the instrument. Staples should be removed under the same timetable as sutures.

**Figure 37-9** (Figure Not Available) By squeezing the handle gently, the upper jaw compresses the staple and allows it to exit the skin. *(Adapted from Edlich RF: A Manual for Wound Closure. St. Paul, Minn, 3M Medical-Surgical Products, 1979. Reproduced by permission.)*

## Complications

Complications can occur with staple-closed wounds, although the incidence is low and equivalent to that for sutured wounds. In 2 studies of traumatic wounds closed with staples, the infection rates were reported to be 0% and 5%. [29] [30] Staple acceptance and comfort have been reported to be equal to those of sutures, but in 1 study, removal of staples was somewhat more uncomfortable than removal of sutures. [29] Wound dehiscence has been reported, but the incidence is not considered significant. [29] A common error is failure to *evert* the skin edges before stapling (Fig. 37-10 *A* and *B*). Eversion avoids the natural tendency of the device to invert the closure. Eversion may be accomplished with forceps or by pinching the skin with the thumb and index finger, a procedure that requires some practice. Staples do cause marks in the skin similar to sutures. In patients who tend to scar more easily, the resulting scar from the staples may be more pronounced than that produced by sutures, especially if the staples are

left in place for prolonged periods.

## Conclusion

Overall results are favorable when staples are used for surgical incisions and traumatic lacerations of the scalp, trunk, and extremities. Wound stapling does not differ significantly from suturing in infection rates, wound healing, and patient acceptance. Stapling is clearly superior in reducing time to closure. With the introduction of new devices, the cost of wound stapling is comparable to that of suturing. Because of the increased availability and versatility of stapling instruments, they are being used more frequently in emergency department wound management.

# SUTURES

In most situations, suturing is the closure method of choice. Currently in the United States, most traumatic wounds are closed with sutures.

## Equipment

### Instruments

In addition to the instruments used for debridement, a needle holder and suture scissors are required for suturing. The size of the needle holder should match the size of the needle selected for suturing--that is, the needle holder should be large enough to hold the needle securely as it is passed through tissue, yet not so large that the needle is crushed or bent by the instrument. The mechanical performance of disposable needle holders distributed by different surgical instrument companies varies considerably. [38] Instruments used to debride a grossly contaminated wound should be discarded and fresh instruments obtained for the closure of the wound. Instruments covered with coagulated blood can be cleansed with hydrogen peroxide, rinsed with sterile saline or water, and then used for suturing.

### Suture Materials

A wide variety of suture materials are available. For most wounds that require closure of more than 1 layer of tissue, the physician must choose sutures from 2 general categories: an absorbable suture for the subcutaneous (SQ) layer and a nonabsorbable suture for skin closure.

Sutures can be described in terms of four characteristics:

1. Composition (i.e., chemical and physical properties)
2. Handling characteristics and mechanical performance
3. Absorption and reactivity
4. Size and retention of tensile strength

**Composition.**

Sutures are made from natural fibers (cotton, silk), from sheep submucosa or beef serosa (plain gut, chromic gut), or from synthetic materials such as nylon (Dermalon, Ethilon, Nurulon, Surgilon), Dacron (Ethiflex, Mersilene), polyester (Ti-Cron), polyethylene (Ethibond), polypropylene (Prolene, Surgilene), polyglycolic acid (Dexon), and polyglactin (Vicryl, coated Vicryl). Stainless steel sutures are rarely, if ever, useful in wound closure in the emergency department setting because of handling difficulty and fragmentation. Some sutures are made of a single filament (monofilament); others consist of multiple fibers braided together (Table 37-1) . [39]

**Handling and performance.**

Desirable handling characteristics

| TABLE 37-1 -- Examples of Suture Materials | |

|  | TiCron |

in a suture include smooth passage through tissues, ease in knot tying, and stability of the knot once tied. Smooth sutures pull through tissues easily, but knots slip more readily. Conversely, sutures with a high coefficient of friction have better knot-holding capacity but are difficult to slide through tissues. Smooth sutures will loosen after the first throw of a knot is made, and a second throw is needed to secure the first in place. However, the physician may want to tighten a knot further after the first throw is made. This is difficult with rougher types of sutures.

Multifilament sutures have the best handling characteristics of all sutures, whereas steel sutures have the worst. In terms of performance and handling, significant improvements have been made in the newer absorbable sutures. Gut sutures have many shortcomings, including relatively low and variable strength, a tendency to fray when handled, and stiffness despite being packaged in a softening fluid. [40] [41] Multifilament synthetic absorbable sutures are soft and easy to tie and have few problems with knot slippage. Polyglactin 910 (coated Vicryl) sutures have been improved with the application of an absorbable lubricant coating. The "frictional drag" of these coated sutures as they are pulled through tissues is less than that of uncoated multifilament

materials, and the resetting of knots following the initial throw is much easier. This characteristic allows retightening of a ligature without knotting or breakage and with smooth, even adjustment of suture line tension in running subcuticular stitches. [42] Synthetic monofilament sutures have the troublesome property of "memory"--a tendency of the filament to spring back to its original shape, which causes the knot to slip and unravel. Some nonabsorbable monofilament sutures are coated with polytetrafluorethylene (Teflon) or silicone to reduce their friction. This coating improves the handling characteristics of these monofilaments but results in poorer knot security. [41]

Three square knots will secure a stitch made with silk or other braided, nonabsorbable materials, and 4 knots are sufficient for synthetic, absorbable and nonabsorbable monofilament sutures. [43] Five knots are needed for the Teflon-coated synthetic Tevdek. [44] With the use of coated synthetic suture materials, attention to basic principles of knot tying is even more important. An excessive number of throws in a knot weakens the suture at the knot. If the physician uses square knots (or a surgeon's knot on the initial throw, followed by square knots) that lie down flat and are tied securely, knots will rarely unravel. [45]

**Absorption and reactivity.**

Sutures that are rapidly degraded in tissues are termed *absorbable*; those that maintain their tensile strength for longer than 60 days are considered *nonabsorbable* (see Table 37-1) . Plain gut may be digested by white blood cell lysozymes in 10 to 40 days; chromic gut will last 15 to 60 days. Remnants of both types of sutures, however, have been seen in wounds more than 2 years after their placement.  A newer type of catgut (Ethicon) is rapidly absorbed within 10 to 14 days but with less inflammation than that caused by chromic catgut. [47] Vicryl is absorbed from the wound site within 60 to 90 days, [40] [43] and Dexon, within 120 to 210 days. [48] [49] When placed in the oral cavity, plain gut disappears after 3 to 5 days, chromic gut after 7 to 10 days, and polyglycolic acid after 16 to 20 days. [50] In contrast, SQ silk may not be completely absorbed for as long as 2 years. [43] The rate of absorption of synthetic absorbable sutures is independent of suture size. [48]

Sutures may lose strength and function before they are completely absorbed in tissues. Braided synthetic absorbable sutures lose nearly all of their strength after about 21 days. In contrast, monofilament absorbable sutures (modified polyglycolic acid [Maxon, Davis & Geck] and polydioxanone [PDS, Ethicon]) retain 60% of their strength after 28 days. [51] [52] Gut sutures treated with chromium salts (chromic gut) have a prolonged tensile strength; however, all gut sutures retain tensile strength erratically. [40] [43] Of the absorbable types of sutures, a wet and knotted polyglycolic acid suture is stronger than a plain or chromic gut suture subjected to the same conditions. [41] [53]

Polypropylene remains unchanged in tissue for longer than 2 years after implantation. [54] In comparison testing, Hermann found that sutures made of natural fibers such as silk, cotton, and gut were the weakest; sutures made of Dacron, nylon, polyethylene, and polypropylene were intermediate in tensile strength; and metallic sutures were the strongest. [41] Kaplan and Hentz used the comparison of suture strength versus wound

strength as a measure of the usefulness of a suture. They stated that catgut is stronger than the soft tissue of a wound for no more than 7 days; chromic catgut, Dexon, and Vicryl are stronger for 10 to 21 days; and nylon, wire, and silk are stronger for 20 to 30 days. [55]

All sutures placed within tissue will damage host defenses and provoke inflammation. Even the least reactive suture impairs the ability of the wound to resist infection. [54] The magnitude of the reaction provoked by a suture is related to the quantity of suture material (diameter times total length) placed in the tissue and to the chemical composition of the suture. Among absorbable sutures, polyglycolic acid and polyglactin sutures are least reactive, followed by chromic gut. Nonabsorbable polypropylene is less reactive than nylon or Dacron. [41] [56] [57] Significant tissue reaction is associated with catgut, silk, and cotton sutures; highly reactive materials should be avoided in contaminated wounds. Adams found absorbable polyglycolic acid sutures to be less reactive than those of nonabsorbable silk. [58]

The chemical composition of sutures is an important determinant of early infection. The infection rate in experimental wounds when polyglycolic acid sutures are used is less than the rate when gut sutures are used. It is surprising that plain gut sutures elicit infection less often in contaminated wounds than do chromic gut sutures. [54] Lubricant coatings on sutures do not alter suture reactivity, absorption characteristics, breaking strength, or the risk of infection. [42] [54] Multifilament sutures provoke more inflammation and are more likely to produce infection than monofilament sutures if left in place for prolonged periods. [59] [60] Monofilament sutures elicit less tissue reaction than do multifilament sutures, and multifilament materials tend to wick up fluid by capillary action. Bacteria that adhere to and colonize sutures can envelop themselves in a glycocalix that protects them from host defenses, [61] or they can "hide" in the interstices of a multifilament suture and, as a result, be inaccessible to leukocytes. [59] Polydioxanone (PDS) provides the advantages of a monofilament suture in an absorbable form, making it a good choice as a subcuticular stitch. Polypropylene sutures have a low coefficient of friction, and subcuticular stitches with this material are easy to pull out. [62]

**Size and strength.**

Size of suture material (thread diameter) is a measure of the tensile strength of the suture; threads of greater diameter are stronger. The strength of the suture is proportional to the square of the diameter of the thread. Therefore, a 4-0 size suture of any type is larger and stronger than a 6-0 suture. The correct suture size for approximation of a layer of tissue depends on the tensile strength of that tissue. The tensile strength of the suture material should be only slightly greater than that of the tissue, because the magnitude of damage to local tissue defenses is proportional to the amount of suture material placed in the wound. [43] [63]

Synthetic absorbable sutures have made the older, natural suture materials obsolete. Polyglycolic acid (Dexon) and polyglactin 910 (coated Vicryl) have improved handling characteristics, knot security, and tensile strength. Their absorption rates are predictable, and tissue reactivity is minimal. [64] [65] The distinct advantages of synthetic

nonabsorbable sutures over silk sutures are their greater tensile strength, low coefficient of friction, and minimal tissue reactivity. [54] [64] They are extensible, elongating without breaking as the edges of the wound swell in the early postoperative period. [63] [64] In contrast with silk sutures, synthetics can be easily and painlessly removed once the wound has healed. The monofilament synthetic suture Novofil has elasticity that allows a stitch to enlarge with wound edema and to return to its original length once the edema subsides. Stiffer materials lacerate the encircled tissue as the wound swells. [66]

The suture materials most useful to emergency physicians for wound closure are Dexon or coated Vicryl for SQ layers and synthetic nonabsorbable sutures (e.g., nylon or polypropylene) for skin closure. Fascia can be sutured with either absorbable or nonabsorbable materials. In most situations, 3-0 or 4-0 sutures are used in the repair of fascia, 4-0 or 5-0 absorbable sutures in SQ closure, and 4-0 or 5-0 nonabsorbable sutures in skin closure. Lips, eyelids, and the skin layer of facial wounds are repaired with 6-0 sutures, whereas 3-0 or 4-0 sutures are used when the skin edges are

**Figure 37-11** (Figure Not Available) The eyeless, or "swaged," needle. *(From Suture Use Manual: Use and Handling of Sutures and Needles. Somerville, NJ, Ethicon, Inc, 1977, p 29. Reproduced by permission.)*

subjected to considerable dynamic stresses (e.g., wounds overlying joint surfaces) or static stresses (e.g., scalp).

**Needles**

The eyeless, or "swaged," needle is used for wound closure in most emergency centers (Fig. 37-11) (Figure Not Available) . The traditional closed-eye needle requires additional handling to enable one to thread the needle with the suture, and its increased width causes more damage when passing through tissue than does a swaged needle.

Selection of the appropriate needle size and curvature is based on the dimensions of the wound and the characteristics of the tissues to be sutured. The needle should be large enough to pass through tissue to the desired depth and then to exit the tissue or the skin surface far enough that the needle holder can be repositioned on the distal end of the needle at a safe distance from the needle point (Fig. 37-12) . While it is inviting to use the fingers to grasp the needle tip to pull the needle through the skin, this practice is an invitation for a needle stick. The clinician should either reposition the needle holder or use forceps to disengage the needle from the laceration.

In wound repair, needles must penetrate tough, fibrous tissues--skin, SQ tissue, and fascia--yet should slice through these tissues with minimal resistance or trauma and without bending. The type of needle best suited for closure of SQ tissue is a *conventional cutting needle* in a three-eighths or one-half circle (Fig. 37-13) . The use of double curvature

**Figure 37-13** One-half and three-eighths circle needles, used for most traumatic wound closures.

needles (coated Vicryl with PS-4-C cutting needles, Ethicon) may enhance the physician's ability to maneuver the needle in narrow, deep wounds. For percutaneous closure, a conventional cutting-edge needle may permit more precise needle placement and require less penetration force (Fig. 37-14) (Figure Not Available) . [67] [68]

## Suturing Techniques

### Skin Preparation

Before closing the wound, the skin surrounding it is prepared with a povidone-iodine solution and covered with sterile drapes. Some surgeons do not drape the face but prefer to leave facial structures and landmarks adjacent to the wound uncovered and within view. A clear plastic drape (Steri-Drape, 3M Corporation) can be used to provide a sterile field and a limited view of the area surrounding the wound. If no drapes are used on the face, the skin surrounding the wound should be widely cleansed and prepared. Wrapping the hair in a sheet prevents stray hair from falling into the operating field (Fig. 37-15) (Figure Not Available) . Some emergency departments keep a supply of oversized scrub hats to use as an alternative to wrapping.

### Closure Principles

Three principles apply to the suturing of lacerations in any location: (1) minimize trauma to tissues, (2) relieve tension exerted on the wound edges by undermining and layered wound closure, and (3) accurately realign landmarks and skin edges by layered closure and precise suture placement.

**Minimizing tissue trauma.**

The importance of careful handling of tissue has been emphasized since the early days of surgery. Skin and SQ tissue that has been stretched, twisted, or crushed by an instrument or strangled by a suture that is tied too tightly may undergo necrosis, and increased scarring and infection may result. When the edges of a wound must be manipulated, the SQ tissues should be lifted gently with a toothed forceps or skin hook, avoiding the skin surface.

When choosing suture sizes, the physician should select the smallest size that will hold the tissues in place. Skin

**Figure 37-15** (Figure Not Available) *A-D,* Technique for wrapping the scalp to keep stray hair from falling into the operating field. A scrub hat is an acceptable alternative.

stitches should incorporate no more tissue than is needed to coapt the wound edges with little or no tension. Knots should be tied securely enough to approximate the wound edges but without blanching or indenting the skin surface. [69]

**Relieving tension.**

Many forces can produce tension on the suture line of a reapproximated wound. Static skin forces that stretch the skin over bones cause the edges of a fresh wound to gape and also continuously pull on the edges of the wound once it has been closed. Traumatic loss of tissue or wide excision of a wound may have the same effect. The best cosmetic result occurs when the long axis of a wound happens to be parallel to the direction of maximal skin tension; this alignment brings the edges of the wound together. [66]

Muscles pulling at right angles to the axis of the wound impose dynamic stresses. Swelling following an injury creates additional tension within the circle of each suture. [69] Skin suture marks result not only from tying sutures too tightly, but also from failing to eliminate underlying forces distorting the wound. Tension can be reduced during wound closure in two ways: undermining of the wound edges and layered closure.

**Undermining.**

The force required to reapproximate the wound edges correlates with the subsequent width of the scar. [70] Wounds subject to significant static tension require the undermining of at least 1 tissue plane on both sides of the wound to achieve a tension-free closure. Undermining involves the creation of a flap of tissue freed from its base at a distance from the wound edge that is approximately equal to the width of the gap that the laceration presents at its widest point (Fig. 37-16) . The depth of the incision can be modified, depending on the orientation of the laceration to skin tension lines and the laxity of skin in the area. A No. 15 scalpel blade held parallel to the skin surface is used to incise the adipose layer or the dermal layer of the wound. The clinician also can accomplish this technique by spreading scissors in the appropriate tissue plane. Undermining allows the skin edges to be lifted and brought together with gentle traction. [71] Because undermining may harm the underlying blood supply, this technique should be reserved for relatively uncontaminated wounds. [66] Other potential complications of this procedure include injury to cutaneous nerves and creation of a hematoma under the flap. [55]

**Layered closure.**

The structure of skin and soft tissue varies with the location on the body (Fig. 37-17 *A-D*). The majority of wounds handled in an emergency department require approximation of no more than 3 layers: fascia (and associated muscle), SQ tissue, and skin surface (papillary layer of dermis and epidermis). [72]

Closure of individual layers obliterates "dead space" within the wound that would otherwise fill with blood or exudate. The presence of dead space enhances the development of infection; however, it is not necessary to close the adipose layer of soft tissue with a separate stitch. A "fat stitch" is not necessary, because little support is provided by closure of the adipose layer, and the additional suture material that is

required may enhance the possibility of infection. [6] [73]

Separate approximation of muscle and SQ layers hastens the healing and return of function to the muscle. However, *one should suture fascia, not muscle*. Muscle tissue itself is too friable to hold a suture. Layered closure is particularly important in the management of facial wounds; this technique prevents scarring of muscle to the SQ tissue and consequent deformation of the surface of the wound with contraction of the muscle. If a deep, gaping wound is closed without approximation of underlying SQ tissue, a disfiguring depression may develop at the site of the wound. Finally, layered closure provides support to the wound and considerably reduces tension at the skin surface.

There are exceptions to the general rule of multilayered closure. Scalp wounds are generally closed in a single layer. For lacerations penetrating the dermis in fingers, hands, toes, and feet, the amount of SQ tissue is too small to warrant layered closure; in fact, SQ stitches may leave tender nodules in these sensitive locations. In the sebaceous skin of the nasal tip, SQ sutures should be avoided, because they provoke inflammation and increase the risk of infection. Layered closure is not recommended in wounds without tension, those with poor vascularity, and those with moderate infection potential. With single-layer closure, the surface stitch should be placed more deeply. [55]

**Suture Placement**

Before suturing, the physician should ensure adequate exposure and illumination of the wound. The physician should assume a comfortable standing or sitting position, with the patient placed at an appropriate height. The best position for the physician is at one end of the long axis of the wound.

**SQ layer closure.**

Once fascial structures have been reapproximated, the SQ layer is sutured. Although histologically the fatty and fibrous SQ tissue (hypodermis) is an extension of (and is continuous with) the reticular layer of the dermis, [74] suturing of these layers is traditionally referred to as an "SQ closure." One approach is to close this layer in segments, placing the first stitch in the middle of the wound and bisecting each subsequent segment until the closure of the

**Figure 37-18** Technique of handling the needle holder. An alternate method is shown in Figure 37-26 (Figure Not Available) .

layer has been completed. [39] This technique is useful in the closure of wounds that are long or sinuous and is particularly effective in wounds with one elliptic and one linear side. The needle is grasped by the needle holder close to the suture end. Greater speed in suturing is possible if the fingers are placed on the midshaft of the needle holder rather than in the rings of the instrument (Fig. 37-18) .

The suture enters the SQ layer at the bottom of the

**Figure 37-19** *A* and *B,* Inverted SQ stitches.

wound (Fig. 37-19 *A*) or, if the wound has been undermined, at the base of the flap (Fig. 37-19 *B*) and exits in the dermis. Once the suture has been placed on one side of the wound, it can be pulled across the wound to the opposite side (or the wound edges pushed together) to determine the matching point on the opposite side. It is at this matching point along the opposite side of the wound that the needle is inserted. The needle should enter the dermis at the same depth as it exited from the opposite side, pass through the tissue, and exit at the bottom of the wound (or the base of the flap). The edges of the wound can be closely apposed by pulling the 2 tails of the suture in the same direction along the axis of the wound (Fig. 37-20) . Some physicians place their SQ suture obliquely rather than vertically to facilitate knot tying. When the knot in this SQ stitch is tied, it will remain inverted, or "buried," at the bottom of the wound. Burying the knot of the SQ stitch avoids a painful, palpable nodule beneath the epidermis and keeps the bulk of this foreign material away from the skin surface. The techniques of tying knots by hand and by instrument are well described and illustrated in wound care texts. [75] [76] Once the knot has been secured, the tails of the suture should be pulled taut for cutting. The scissors are held with the index finger on the junction of the two blades. The blade of the scissors is slid down the tail of the suture until the knot is reached. With the cutting edge of the blade tilted away from the knot, the tails are cut. This technique prevents the scissors from cutting the knot itself and leaves a tail of 3 mm, which protects the knot from unraveling (Fig. 37-21) (Figure Not Available) . [77] The entire SQ layer is sutured in this manner.

After the SQ layer has been closed, the distance between the skin edges indicates the approximate width of the scar in its final form. If this width is acceptable, percutaneous sutures can be inserted. [78] Despite undermining and placement of a sufficient number of SQ sutures, on rare occasions a large gap between the wound edges may persist. In such cases a horizontal dermal stitch may be used to bridge this gap (Fig. 37-22) .

**Skin closure.**

The epidermis and the superficial layer of dermis are sutured with nonabsorbable synthetic sutures. The choice of suture size, the number of sutures used, and the depth of suture placement depend on the amount of skin tension remaining after SQ closure. If the edges of the wound are apposed following closure of deeper layers, small 5-0 or 6-0 sutures can be used simply to match the epithelium of each side. If the wound edges remain retracted or if SQ stitches were not used, a larger size suture may be required. Skin closure may be accomplished with sutures placed in segments (Fig. 37-23) or from end to end. Either technique is acceptable.

Unless the wound edges are uneven, sutures should be placed in a mirror-image fashion such that *the depth and width are the same on both sides of the wound.*[43] In

general, the distance between each suture should be approximately equal to the distance from the exit of the stitch to the wound edge. [39] [75] Grabb suggests that "the number of sutures used in closing any wound will vary with the case, location of the repair, and degree of accuracy required by the physician and patient. In an area such as the face, sutures would probably be placed between 1 and 3 mm apart and 1 to 2 mm from the wound edge." [72]

Sutures act as foreign bodies in a wound, and any stitch may damage a blood vessel or strangulate tissue. Therefore, the physician should strive to use the smallest size and the least number of sutures that will adequately close the wound (Fig. 37-24) . [79] Wounds with greater tension should have skin stitches placed closer to each other and closer to the wound edge; layered closure is important in such wounds. If sutures are tied too tightly around wound edges or if individual stitches are under excessive tension, blood supply to the wound may be impeded, increasing the chance of infection, and suture marks may form even after 24 hours. [43] [80]

When suturing the skin, right-handed operators should pass the needle from the right side of the wound to the left. The needle should enter the skin at an oblique angle to produce an everting, bottle-shaped stitch that is *deeper than it is wide* (Fig. 37-25) (Figure Not Available) . If the skin stitch is intended to produce some eversion of the wound edges, the stitch must include a sufficient amount of SQ tissue. However, encompassing too much tissue with a small needle is a common error. Forcefully pushing or twisting the needle in an effort to bring the point out of the tissue may bend or break the body of the needle. Using a needle of improper size will defeat the best suturing technique. The needle should be driven through tissue by flexing the wrist and supinating the forearm; the course taken by the needle should result in a curve identical to the curvature of the needle itself (Fig. 37-26) (Figure Not Available) . The angle of exit for the needle should be the same as its angle of entrance so that an identical volume of tissue is contained within the stitch on each side of the wound.

Once the needle exits the skin on the opposite side of the wound, it is regrasped by the needle holder and is advanced through the tissue; care should be taken to avoid crushing the point of the needle with the instrument. Forceps are designed for handling tissue and thus should not be used to grasp the needle. The forceps can stabilize the needle by holding the needle within the tissue through which the needle has just passed. Excess thread can be kept clear of the area being sutured by an assistant, or the excess can be looped around the operator's fingers. If the point of the needle becomes dulled before all of the attached thread has been used, the suture should be discarded.  If these techniques are applied to most wounds, the edges of the wound will be matched precisely in all three dimensions.

**Eversion techniques.**

If the edges of a wound invert or if one edge rolls under the opposite side, a poorly formed, deep, noticeable scar will result. Excessive eversion that exposes the dermis of both sides also will result in a larger scar than if the skin edges are perfectly apposed, but inversion produces a more visible scar than does eversion. Because most scars undergo some flattening with contraction, optimal results are achieved when the

epidermis is slightly everted without excessive suture tension (Fig. 37-27) (Figure Not Available) . Wounds over mobile surfaces, such as the extensor surfaces of joints, should be everted; in time, the scar will be flattened by the dynamic forces acting in the area.

A number of techniques can be used to avoid inversion of the edges of the wound. If the clinician angles the needle away from the laceration, percutaneous stitches can be placed so that their depth is greater than their width. [71] Converse described this method as follows: "The needle penetrates the skin close to the incision line, diverging from the edge of the wound in order to encircle a larger amount of tissue in the lower depths of the skin than at the periphery." [81] The edge of the wound can be lifted and everted with a skin hook or fine-tooth forceps before insertion of the needle on each side (Fig. 37-28) . Eversion can also be

**Figure 37-26** (Figure Not Available) Motion of the needle holder. *(From Anderson CB: Basic surgical techniques. In Klippel AP, Anderson CB: Manual of Outpatient and Emergency Surgical Techniques. Boston, Little, Brown, 1979. Reproduced by permission.)*

obtained simply by slight retraction of the wound with the thumb (Fig. 37-29) (Figure Not Available) . This technique puts the operator at risk for a needle stick; eversion may be done more safely by applying slight pressure on the wound edge with a closed forceps. Each of these methods also serves to steady the skin against the force of the needle. [75] [81] Vertical mattress sutures are particularly effective in everting the wound edges and can be used exclusively or alternated with simple interrupted sutures (Fig. 37-30) (Figure Not Available) . [81] In wounds that have been undermined, an SQ stitch placed at the base of the flap on each side can in itself evert the wound (Fig. 37-31) (Figure Not Available) .

**Interrupted stitch.**

The simple interrupted stitch is the most frequently used technique in the closure of skin. It consists of separate loops of suture individually tied. Although the tying and cutting of each stitch are time consuming, the advantage of this method is that if one stitch in the closure fails, the remaining stitches continue to hold the wound together (Fig. 37-32) (Figure Not Available) .

**Continuous stitch.**

In a continuous, or "running," stitch, the loops are the exposed portions of a helical coil that is tied at each end of the wound. A continuous suture line can be placed more rapidly than a series of interrupted stitches. The continuous stitch has the additional advantages of strength (with tension being evenly distributed along its entire length), fewer knots (which are the weak points of stitches), and more effective hemostasis. The continuous technique is useful as an epithelial stitch in cosmetic closures; however, if the underlying SQ layer is not stabilized in a separate closure, the continuous surface stitch tends to invert the wound edges.

The continuous suture technique has other disadvantages. This technique cannot be

used to close wounds overlying joints. If a loop breaks at 1 point, the entire stitch may unravel. Likewise, if infection develops and the incision must be opened at 1 point, cutting a single loop may allow the entire wound to fall open. There is also the theoretical problem of impeded blood supply to the wound edges, particularly if the suture is interlocked. [43] Speer found that wounds closed with an interrupted stitch had 30% to 50% greater tensile strength, less edema and induration, and less impairment in the microcirculation at the wound margin than did wounds closed with a continuous stitch. [82] The simple continuous stitch has a tendency to produce suture marks if used in large wound closures and if left in place for more than 5 days. [69] However, if all tension on the wound can be removed by SQ sutures, stitch marks are seldom a problem.

Among the variations of the continuous technique, the simple continuous stitch is the most useful to emergency physicians (Fig. 37-33) (Figure Not Available) . An interrupted stitch is placed at one end of the wound, and only the free tail of the suture is cut. As suturing proceeds, the stitch encircles tissue in a spiral pattern. After each passage of the needle, the loop is tightened slightly, and the thread is held taut in the physician's nondominant hand. The needle should travel perpendicularly across the wound on each pass. The last loop is placed just beyond the end of the wound, and the suture is tied, with the last loop used as a "tail" in the process of tying the knot (Fig. 37-34) . A locking loop may be used in continuous suturing to prevent slippage of loops as the suturing proceeds (Fig. 37-35) (Figure Not Available) . The interlocking technique allows the use of the continuous stitch along an irregular laceration.  A continuous stitch is an effective method for closing relatively clean wounds that are under little or no tension and are on flat, immobile skin surfaces in patients who have no medical conditions that would impair healing.

**Continuous subcuticular stitch.**

Nonabsorbable sutures used in percutaneous skin closure outlast their usefulness and must be removed. On occasion, wounds require an extended period of support, longer than that provided by surface stitches. Some patients with wounds that require skin closure are unlikely or unwilling to return for suture removal. Some sutured wounds are covered by plaster casts. On occasion, the patient (child or adult) is likely to be as

**Figure 37-35** (Figure Not Available) Continuous interlocking stitch. *(Modified from Suture Use Manual: Use and Handling of Sutures and Needles. Somerville, NJ, Ethicon, Inc, 1977. Reproduced by permission.)*

frightened and uncooperative for suture removal as for suture placement. The continuous subcuticular (or "dermal") suture technique is ideal for these situations; the wound can be closed with an absorbable subcuticular stitch, obviating the need for later suture removal. In patients prone to keloid formation, the subcuticular technique can be used in lieu of percutaneous stitches, and disfiguring stitch marks can thereby be avoided. (Because children's skin is under greater tension than that of adults, percutaneous sutures are more likely to produce stitch marks in children.) Because stitch marks are avoided, a nonabsorbable subcuticular suture can be left in place for a

longer period than a percutaneous suture. [81]

Although this technique is commonly used in cosmetic closures, some researchers believe that closure of the subcuticular layer alone does not alter the scar width. [83] This technique does not allow for perfect approximation of the vertical heights of the 2 edges of a wound, [84] and in cosmetic closures it is often followed by a percutaneous stitch. Although theoretically the large amount of suture material left in the wound might increase the risk of infection, some investigators report a lower infection rate with the subcuticular technique. [83] [85] Buried, absorbable subcuticular stitches do not appear to provoke more inflammation than percutaneous running stitches with monofilament nylon. [86]

The subcuticular stitch requires a 4-0 or 5-0 suture that is made of either absorbable material or nonabsorbable synthetic monofilament. An absorbable suture can be "buried" within the wound, whereas a nonabsorbable suture is used for a "pullout" stitch. The absorbable synthetic monofilament suture polydioxanone (PDS, Ethicon) is designed for subcuticular closure. It passes through tissues as easily as nonabsorbable monofilament sutures and is absorbed if left in the wound.

Before the subcuticular stitch is placed, the SQ layer should be approximated with interrupted sutures to minimize tension on the wound. The pullout subcuticular stitch is started at the skin surface approximately 1 to 2 cm away from 1 end of the wound. The needle enters and exits the dermis at the apices of the wound (Fig. 37-36) (Figure Not Available) . Bites through tissue are taken in a horizontal direction, with the needle penetrating the dermis 1 to 2 mm from the skin surface. These intradermal bites should be small, of equal proportion, and at the same level on each side of the wound. [64] [81] Accidental interlocking of the stitch should be avoided. Each successive bite should be placed 1 to 2 mm *behind* the exit point on the opposite side of the wound so that when the wound is closed, the entrance and exit points on either side are not directly apposed (see Fig. 37-36) (Figure Not Available) . Small bites should be taken to avoid puckering of the skin surface. Some physicians prefer to place a fine (6-0) running skin suture in addition to the subcuticular suture for meticulous skin approximation. The skin suture is removed in 3 to 4 days to avoid suture marks.

If the subcuticular stitch is used on lengthy lacerations, it is difficult to remove the suture. The placement of "reliefs" consisting of periodic loops through the skin during the length of the stitch facilitates later removal (Fig. 37-37) (Figure Not Available) . Reliefs should be placed every 4 to 5 cm. The suture is crossed to the opposite side, and the needle is passed from SQ tissue to the skin surface. The suture is carried over the surface for approximately 2 cm before reentering the skin and SQ tissue. The subcuticular stitch is then continued at

approximately the point at which the next bite would have been placed had the relief not been used.

At the completion of the stitch, the needle is placed through the apex to exit the skin 1 to 2 cm away from the end of the wound. One should tighten the stitch by pulling each end taut. If reliefs have been used, one can take up any slack in the stitch by pulling on the

reliefs. The clinician can secure the 2 ends of the stitch by taping them to the skin surface with wound closure tape, by placing a cluster of knots on each tail close to the skin surface, or by tying the 2 ends of the suture to each other over a dressing. Laxity of the subcuticular stitch is often noted with a decrease in tissue swelling 48 hours after wound closure. Some physicians tighten the stitch when they reexamine the wound after 48 hours.

Subcuticular closure using absorbable sutures that do not penetrate the skin is possible. The closure is begun with a dermal or SQ suture placed at one end of the wound and secured with a knot. After placement of the continuous subcuticular stitch from apex to apex, the suture is pulled taut, and a knot is tied using a tail and a loop of suture (Fig. 37-38) (Figure Not Available) . The final knot can be buried by inserting the needle into deeper tissue; the needle exits several millimeters from the wound edge. If one pulls on the needle end, the knot disappears into the wound. [64] The obvious advantage of this technique is that there are no suture marks in the skin. Another method that avoids penetrating the skin is the interrupted subcuticular stitch (Fig. 37-39) . [81] Wounds with strong static skin tension may benefit from a few interrupted dermal stitches placed horizontal to the skin surface instead of a continuous subcuticular stitch.

Nonabsorbable sutures can be left in place for 2 to 3 weeks, thus providing a longer period of support than percutaneous sutures, without the problem of stitch marks. [69] If skin sutures are used in conjunction with the subcuticular stitch, they are removed in 3 to 4 days. A subcuticular closure in itself is stronger than a tape closure. If the subcuticular technique is used exclusively to approximate the skin surface, it is advisable to apply skin tape to correct surface unevenness and to provide a more accurate apposition of the epidermis.

**Mattress stitch.**

The various types of mattress stitches are all interrupted stitches. The *vertical mattress stitch* is an effective method of everting skin edges (Fig. 37-40) (Figure Not Available) . The verticle mattress stich may be used to take a deep bite of skin in lieu of a layered closure in areas where excessive tension does not result. If the superficial loop is placed first, the tails can be pulled upward while the deep loop is placed, ensuring wound eversion in less time than with the traditional technique. [87] Unfortunately, this stitch causes more ischemia and necrosis inside its loop than either simple or continuous stitches. [88] The *horizontal mattress stitch* approximates skin edges closely while providing some degree of eversion (Fig. 37-41) . [69] The horizontal mattress suture may be ideal for areas where eversion is desirable but there is little SQ tissue. The *half-buried horizontal mattress stitch,* also called a *mattress stitch with a dermal component,* combines an interrupted skin stitch with a buried intradermal stitch (Fig. 37-42) (Figure Not Available) . It is effective in joining the edges of a skin flap to the edges of the "recipient site"; the dermal component is placed through the dermis of the flap. [81] The half-buried horizontal mattress stitch is also useful at the scalp-forehead junction when there is tension on the wound edges. This technique halves the number of suture marks in the skin and avoids necrosis of the edge of a skin flap.

The half-buried horizontal mattress stitch is particularly

useful in suturing the easily damaged apex of a V-shaped flap (Fig. 37-43) . In the execution of the "corner stitch," the suture needle penetrates the skin at a point beyond the apex of the wound and exits through the dermis. The corner of the flap is elevated, and the suture is passed through the dermis of the flap. The needle is then placed in the dermis of the base of the wound and returned to the surface of the skin. All dermal bites should be placed at the same level. The suture is tied with sufficient tension to pull the flap snugly into the corner without blanching the flap. [69] [89] If the tip of a large flap with questionable viability may be further jeopardized by postoperative swelling, a cotton stent can be placed underneath the knot of the corner stitch. The cotton absorbs the tension produced by swelling.

**Figure-of-eight stitch.**

The figure-of-eight stitch is useful in wounds with friable tissue, on the eyelids where the skin is too thin for buried sutures, or in areas in which buried sutures are undesirable (Fig. 37-44) (Figure Not Available) . [90] This stitch reduces the amount of tension placed on the tissue by the suture, allowing the stitch to hold in place when a simple stitch would tear through the tissue. One disadvantage of this technique is that more suture material is left in the wound. A vertical variation of the figure-of-eight stitch is sometimes used to approximate close, parallel lacerations (Fig. 37-45) (Figure Not Available) . [91] Another technique involves a vertical mattress stitch. The central "island" of tissue is secured by passing the superficial portion of the stitch through the island at the subcuticular level (Fig. 37-46) (Figure Not Available) . [92] If the viability of the central island is questionable and the surrounding tissue is loose, it can be excised.

**Correction of dog-ears.**

When wound edges are not precisely aligned horizontally, there will be an excess of tissue on 1 or both ends. This small flap of excess skin that bunches up at the end of a sutured wound is commonly

called a *dog-ear.* This effect also occurs when one side of the wound is more elliptical than the opposite side or when an excision of a wound is not sufficiently elliptical--that is, when it is either too straight or too nearly circular. [39] [81]

If a dog-ear is present, it can be eliminated on one side of the wound in the following manner: The flap of excess skin is elevated with a skin hook, and an incision is carried at an oblique angle from the apex of the wound toward the side with the excess skin. The flap is then undermined and laid flat. The resulting triangle of skin is trimmed, and the closure is completed (Fig. 37-47 (Figure Not Available) *A*). [78] [89] An alternative method consists of carrying the incision directly from the apex, in line with the wound. The flap of excess tissue is pulled over the incision while skin hooks are used to retract the extended apex of the wound. Excess tissue is excised, and the remainder of the wound is sutured. [81] If dog-ears are present on *both* sides of 1 end of the wound, the bulge of excess tissue can be excised in an elliptical fashion, and the wound can be closed (Fig. 37-47 (Figure Not Available) *B*). [89]

**V-Y advancement flap.**

If a corner stitch produces excessive tension on the tip of the flap, a V-Y closure can be used to approximate the edges without undue tension. An incision carried away from the apex of the wound converts it from a V to a Y configuration (Fig. 37-48) (Figure Not Available) . The newly formed wound edges are undermined, and the repair is completed. A half-buried mattress stitch is placed at the fork of the Y.

**Stellate lacerations.**

The repair of a stellate laceration is a challenging problem. Usually a result of compression and shear forces, these injuries contain large amounts of partially devitalized tissue. The surrounding soft tissue is often swollen and contused. Much of this contused tissue cannot be debrided without creating a large tissue defect. Sometimes tissue is lost, yet the amount is not apparent until key sutures are placed. In repairing what often resembles a jigsaw puzzle, the physician can remove small flaps of necrotic tissue with an iris scissors; large, viable flaps can be repositioned in their beds and carefully secured with half-buried mattress stitches. If interrupted stitches are used to approximate a thin flap, small bites should be taken in the flap and larger, deeper bites in the base of the wound. A modification of the corner stitch can be used to approximate multiple flaps to a base (Fig. 37-49) . The V-Y advancement flap technique is also useful. Thin flaps of tissue in a stellate laceration with beveled edges are often most easily repositioned and stabilized with a firm dressing. [69]

Closure of stellate lacerations cannot always be accomplished immediately, especially if there is considerable soft tissue swelling. It may be best in some instances to consider delayed closure or revision of the scar at a later date. In complicated lacerations, inexact tissue approximation may be all that is possible initially.

## Repair of Special Structures

### Facial Wounds (General Features)

The ideal result in the repair of a facial laceration is an extremely narrow, flat, and inapparent scar. In addition to basic wound management, a few additional techniques can be used to achieve this result. One of the factors that contributes to wide scars is necrosis of partially devitalized wound edges. However, skin with apparently marginal circulation may survive because of the excellent vascularity of the face. SQ fat, which in other locations may be debrided thoroughly, should be preserved if possible in facial wounds to prevent eventual sinking of the scar and to preserve normal facial contours. Therefore, debridement of most facial wounds should be conservative. [72] Facial and forehead lacerations that follow natural skin creases or lines will heal with a less noticeable scar than those that are oblique or perpendicular to the natural wrinkles of the skin (Fig. 37-50) .

Converse pointed out that "precise approximation of skin edges without undue tension ensures primary healing with minimal scarring." [81] A layered closure is essential in the cosmetic repair of many facial wounds. Approximation of the dermis with an SQ stitch or a combination of SQ and subcuticular stitches should bring the epithelial edges together or within 1 to 2 mm of apposition--close enough that the use of additional sutures seems almost unnecessary. [78] If an SQ stitch is the only stitch used to close the deeper layers, it should pass through the dermal-epidermal junction or within 1 to 2 mm of the skin surface without causing a dimpling effect. The clinician must tie this stitch snugly, pulling the 2 ends of the suture in the same direction (see Fig. 37-20) . Should the first SQ stitch placed at the midpoint of a wound perfectly appose the skin edges, one can "protect" that stitch from disruption during further suturing by immediately placing a percutaneous stitch in the same location. If there is a slight gap in the wound edges after SQ closure, the skin can be partially approximated with a few guide stitches. The first is placed at the midpoint of the wound, and subsequent stitches bisect the intervening spaces. Guide stitches allow the definitive epithelial sutures to be placed with little tension on each individual stitch, and they protect the SQ stitches from disruption. Once the definitive stitches have been placed, the guide stitches, if slack, can be removed. Because a needle damages tissue with each passage through the skin, guide stitches should be used only when necessary.

The epithelial stitch should never be used to relieve the wound of tension; it serves only to match the epidermal surfaces precisely along the length of the wound. If there is significant separation of the wound edges after closure of the SQ layer, a 5-0 or 6-0 subcuticular suture can be used to eliminate the tension produced by this separation and to provide prolonged stability. Once the skin edges are apposed, the epithelial stitch can be used to correct discrepancies in vertical alignment. A 6-0 synthetic nonabsorbable suture is an excellent material for this stitch. A continuous stitch is preferable because it can be placed quickly, but interrupted stitches are acceptable. In a straight laceration, better apposition is achieved if the wound is stretched lengthwise by finger traction or by the use of skin hooks. When the needle is placed on one side of the wound, if that side is higher than the opposite side, a shallow bite is taken. The needle

is used to depress the wound edge to the proper height, after which the needle "follows through" to the other side, pinning the two sides together. If the first side entered is lower, the needle is elevated when entering the second side to match the epithelial edges.

Grabb pointed out that "the closer the needle lies to the skin edge, the greater will be its effect in controlling the ultimate position of that edge." [59] Epithelial stitches should be spaced no more than 2 to 3 mm apart and should encompass no more than 2 to 4 mm of tissue. [71] If widely spaced, the sutures will leave marks. [78] Once skin closure is complete, final adjustments in the tension on any continuous suture line are made before the end of the stitch is tied. If any level discrepancies persist, interrupted sutures or tape can be used to flatten these few irregularities.

Surgical tape is useful as a secondary support, protecting the epithelial stitch from stresses produced by normal skin movements (Fig. 37-51) . Facial wounds have a tendency to swell and place excessive stretch on an epithelial stitch. This can be minimized by applying a pressure dressing and cold

**Figure 37-51** Wound closure tape can be used to provide additional support while sutures are in place and after they are removed. This may be especially useful in cosmetic areas, such as the face.

compresses to the wound following closure. Surgical tape can serve to a limited extent as a pressure dressing.

**Forehead**

Although the forehead is actually a part of the scalp, lacerations in this region are treated as facial wounds. Vertical lacerations across the forehead are oriented 90° to skin tension lines, and the resulting scars are more noticeable than those from horizontal lacerations. Midline vertical forehead lacerations may result in cosmetically acceptable scars with standard closure techniques; those lacerations that are not centered may benefit from S-plasty or Z-plasty techniques during the initial repair or during later revision of the scar.

Superficial lacerations may be closed with skin stitches alone, but deep forehead lacerations must be closed in layers. The periosteum should be approximated before the closure of more superficial layers. If skin is directly exposed to bone, adhesions may develop that in time may limit the movement of skin during facial expressions. The frontalis muscle fascia and adjacent fibrous tissue should be approximated as a distinct layer; if left unsutured, the retracted ends of this muscle will bulge beneath the skin. If the gap in a muscle belly is later filled with scar tissue, movement of the muscle pulls on the entire scar and makes it more apparent. [72]

A U-shaped flap laceration with a superiorly oriented base poses a difficult problem. Immediate vascular congestion and later scar contraction within the flap produce the "trap-door effect," with the flap becoming prominently elevated (Fig. 37-52) . This effect can be minimized by approximation of the bulk of SQ tissue of the flap to a deeper level

on the base side of the wound; the skin surfaces of the 2 sides are apposed at the same level (Fig. 37-53 *A*). A firm compression dressing helps eliminate "dead space" and hematoma formation within the wound. Despite these efforts, secondary revision is sometimes necessary. [69] Often, swelling of the flap resolves over a 6- to 12-month period. Because flap elevation can be quite disconcerting, the physician should forewarn the patient and family about a possible trap-door effect.

When a forehead laceration borders the scalp and the thick scalp tissue must be sutured to thinner forehead skin, a horizontal mattress stitch with an intradermal component can be used (Fig. 37-53 *B*). [81]

**Eyebrow and Eyelid Lacerations**

Jagged lacerations through eyebrows should be managed with little, if any, debridement of untidy but viable edges. The hair shafts of the eyebrow grow at an oblique angle, and vertical excision may produce a linear alopecia in the eyebrow, whereas with simple closure, the scar remains hidden within the hair. If partial excision is unavoidable, the scalpel blade should be angled in a direction parallel to the axis of the hair shaft to minimize damage to hair follicles.

Points on each side of the lacerated eyebrow should be aligned precisely; a single percutaneous stitch on each margin of the eyebrow should precede SQ closure. The edges of the eyebrow serve as landmarks for reapproximation; therefore, the eyebrow must not be shaved, as these landmarks will be lost. Shaved eyebrows grow back slowly and sometimes incompletely, and shaving them often results in more deformity than the injury itself. Care must be taken not to invert hair-bearing skin into the wound. [84]

The thin, flexible skin of the upper eyelid is relatively easy to suture. A soft 6-0 suture (or smaller) is recommended for closure of simple lacerations. Traumatized eyelids are susceptible to massive swelling; compression dressings and cool compresses can be used to minimize this problem.

It is essential that the emergency physician recognize complicated eyelid lacerations that require the expertise of an ophthalmologist. Lacerations that traverse the lid margin require exact realignment to avoid entropion or ectropion (Fig. 37-54 *A*). Injuries penetrating the tarsal plate frequently cause damage to the globe. A deep horizontal laceration through the upper lid that divides the thin levator palpebrae muscle or its tendinous attachment to the tarsal plate produces ptosis. If this muscle cannot be identified and repaired by the emergency physician, a consultant should repair the injury primarily. A laceration through the portion of the lower lid *medial* to the punctum frequently damages the lacrimal duct or the medial canthal ligament and requires specialized techniques for repair (Fig. 37-54 *B*). If adipose tissue is seen within any periorbital laceration, one must assume that the orbital septum has been penetrated and that retrobulbar fat is herniating through the wound (Fig. 37-54 *C*). The repair of lid avulsions, extensive lid lacerations with loss of tissue, and any of the other complex types of lid lacerations mentioned above should be left to ophthalmologists.

**Ear Lacerations**

The primary goals in the management of lacerations of the pinna are expedient coverage of exposed cartilage and minimization of wound hematoma (Fig. 37-54 *D* and *E*). Cartilage is an avascular tissue, and when ear cartilage is denuded of its protective, nutrient-providing skin, progressive erosive chondritis ensues. The initial step in the repair of an ear injury involves trimming away jagged or devitalized cartilage and skin. If the skin cannot be stretched to cover the defect, additional cartilage along the wound margin can be removed. Depending on the location, as much as 5 mm of cartilage can be removed without significant deformity. Cartilage should be approximated with 4-0 or 5-0 absorbable sutures initially placed at folds or ridges in the pinna representing major landmarks. Sutures tear through cartilage; therefore, the anterior and posterior perichondrium should be included in the stitch. No more tension should be applied than is needed to touch the edges together.

In through-and-through ear lacerations, the posterior skin surface should be approximated next, using 5-0 nonabsorbable synthetic sutures. Once closure of the posterior surface is completed, the convoluted anterior surface of the ear can be approximated with 5-0 or 6-0 nonabsorbable synthetic sutures, with landmarks joined point by point. On the free rim, the skin should be everted if later notching is to be avoided. Care should be taken to cover all exposed cartilage. In heavily contaminated wounds of the ear (e.g., bite wounds) that already show evidence of inflammation, the necrotic tissue should be debrided, the cartilage covered by a loose approximation of skin, and the patient placed on antibiotics. [69] [93] After a lacerated ear has been sutured, it should be enclosed in a compression dressing (see Fig. 68-24) .

**Lacerations of the Nose**

In the repair of lacerations of the nose, reapproximation of the wound edges is difficult because the skin is inflexible, and even deeply placed stitches will slice through the epidermis and pull out. When the wound edges cannot be coapted easily, 6-0 absorbable sutures can be placed in the fibrofatty junction in an SQ stitch before skin closure. Because it is difficult to approximate gaping wounds in this location, debridement must be kept to a minimum. Nasal cartilage is frequently involved in wounds of the nose, but it is seldom necessary to suture the cartilage itself.

The free rim of the nostril must be aligned precisely to avoid unsightly notching. Many physicians recommend early removal of stitches to avoid stitch marks, yet the oily nature of skin in this area makes it difficult to keep the wound closed with tape. A subcuticular stitch is recommended if the `wound is gaping before closure, as this will provide support for a prolonged period. [94]

**Lip and Intraoral Lacerations**

Lip lacerations are cosmetically deforming injuries, but if the physician follows a few

guidelines, these lacerations usually heal satisfactorily.

The contamination of all intraoral and lip wounds is considerable; they must be thoroughly irrigated. Regional nerve blocks are preferred to local injection, because the latter method distends tissue, distorts the anatomy of the lip, and obscures the vermilion border. Losses of <25% of the lip permit primary closure with little deformity; losses of >25% require a reconstructive procedure. Extensive lacerations directly through the commissure of the mouth also require surgical consultation in most cases. [93] Deep scars in the vermilion of the upper lip may produce a redundancy of tissue that requires later revision.

Large through-and-through lacerations of the lip should be closed in 3 layers. With a multilayer closure, the muscle layer is approximated with a 4-0 or 5-0 absorbable suture securely anchored in the fibrous tissue located anterior and posterior to the muscle. The vermilion-cutaneous junction of the lip is a critical landmark that, if divided, must be repositioned with precision; a 1-mm "step-off" is apparent and cosmetically unacceptable. The vermilion border should be approximated with a 5-0 or 6-0 nonabsorbable stay suture before any further closure to ensure proper alignment throughout the remainder of the repair (Fig. 37-55 A). The vermilion surface of the lip and the buccal mucosa are then closed with interrupted stitches using an absorbable 4-0 or 5-0 suture. Finally, the skin is closed with 6-0 nonabsorbable sutures. [95]

Small puncture-type lacerations heal well if only the skin is closed and the small intraoral laceration is left open. Such injuries are common from a punch in the face when the victim's tooth lacerates the lip. In general, small lacerations of the oral mucosa heal well without sutures. If a mucosal laceration creates a flap of tissue that falls between the occlusal surfaces of the teeth or if a laceration is extensive enough to trap food particles (e.g., 2 to 3 cm or greater in length), it should be closed. Small flaps may be excised. Closure is easily accomplished with 4-0 Dexon or Vicryl using a simple interrupted suturing technique. These materials are soft and less abrasive than gut sutures, which become hard and traumatize adjacent mucosa. Similarly, nylon sutures whose sharp ends are annoying and painful should be avoided inside the mouth. Muscle and mucosal layers should be closed separately. Sutures in the oral cavity easily become untied by the constant motion of the tongue. Each suture should be tied with at least 4 square knots. These sutures need not be removed; they either loosen and fall out within 1 week or are rapidly absorbed.

All lacerations that penetrate the oral mucosa should be evaluated for the presence of a fragment of tooth. A retained tooth fragment should be searched for in the depths of the wound if a tooth is missing or chipped. The search should be intensified if the patient returns with an infection of a sutured wound (Fig. 37-55 B). Probing the wound with forceps may identify fragments not seen directly in the wound. In the setting of marked facial swelling, a radiograph of the soft tissue may help identify an embedded tooth fragment.

**Tongue Lacerations**

There is some controversy regarding when to suture tongue lacerations. Surprisingly

large (simple or linear) lacerations, especially those in the central portion of the tongue, heal quickly with minimal risk of infection (Fig. 37-56) . Most tongue lacerations that occur from falls or seizures do not require sutures. The majority of tongue lacerations in children heal well without sutures. Snyder suggests that only those lacerations that involve the edge or pass completely through the tongue, flap lacerations, and lacerations that continue to bleed excessively need to be sutured. All lacerations bisecting the tongue require repair. [94] Small flaps on the edge of the tongue may be excised, but large flaps should be sutured. When dilute peroxide mouthrinses and a soft diet are used for a few days, healing is rapid. Persistent bleeding from minor lacerations brings most patients to the hospital, and closure may be necessary to prevent further bleeding.

The repair of a tongue laceration in any patient is somewhat difficult, but in an uncooperative child, the procedure may prove impossible under anything other than general anesthesia. A Denhardt-Dingman side mouth gag aids in keeping the patient's mouth open. A localized area of the tongue may be anesthetized topically by covering the area with 4% lidocaine-soaked gauze for 5 minutes; the maximum safe dose of local anesthesia should be determined and exposure to greater doses avoided. Large lacerations require infiltration anesthesia (1% lidocaine with buffered epinephrine) or a lingual nerve block. If the tip of the tongue has been anesthetized, a towel clip or suture can be used to secure the tongue. Further anesthesia and subsequent wound cleansing and closure are possible while an assistant applies gentle traction to the tongue.

Size 4-0 absorbable sutures should be used to close all 3 layers--inferior mucosa, muscle, and superior mucosa--in a single stitch, or the stitch should include one half of the thickness of the tongue, with sutures placed on the superior and inferior surfaces as well as on the edge of the tongue. [94] Sutures on the tongue frequently become untied. This problem can be avoided if the stitches are buried. Do not use nylon sutures in the tongue, because the sharp edges are quite uncomfortable. [72] Closure of the lingual muscle layer is usually sufficient to control bleeding and return motor function to the lacerated tongue. Mucosal healing is rapid, and closure of the muscle layer with only a deep absorbable suture may be desirable when a surface suture is likely to be tugged at, as occurs with small children.

**Scalp**

The scalp extends from the supraorbital ridges anteriorly to the external occipital protuberances posteriorly and blends with temporalis fascia laterally. There are 5 anatomic layers of the scalp: skin, superficial fascia, galea aponeurotica, subaponeurotic areolar connective tissue, and periosteum (see Fig. 37-17 *A*). Surgically, the scalp may be divided into 3 distinct layers. The outer layer consists of the skin, superficial fascia, and galea (the aponeurosis of the frontalis and occipitalis muscles). These 3 layers are firmly adherent and surgically are considered as 1 layer. The integrity of the outer layers is maintained by inelastic, tough, fibrous septa, which keep wounds from gaping open unless all 3 layers have been traversed. Wounds that gape open signify a laceration extending beneath the galea layer. The galea itself is loosely adherent to the periosteum by means of the slack areolar tissue of the subaponeurotic layer. The periosteum covers the skull. *The periosteum is often mistakenly identified as*

*the galea*, and vain attempts are made to suture the flimsy periosteum in the hope of "closing the galea" (Fig. 37-57) . [97]

Several unique problems are associated with wounds of the scalp. The presence of a rich vascular network in the superficial fascia results in profuse bleeding from scalp wounds. Severed scalp vessels tend to remain patent, because the fibrous SQ fascia hinders the normal retraction of blood vessels that have been cut, allowing persistent or massive hemorrhage in simple lacerations (Fig. 37-58) . The subgaleal layer of loose connective tissue contains "emissary veins" that drain through diploic vessels of the skull into the venous sinuses of the cranial hemispheres. In scalp wounds that penetrate this layer, bacteria may be carried by these vessels to the meninges and the intracranial sinuses. Thus, a scalp wound infection can result in osteomyelitis, meningitis, or brain abscess. [94] Careful approximation of galeal lacerations not only ensures control of bleeding, but also protects against the spread of infection (Fig. 37-59) .

Shear-type injuries can cause extensive separation of the superficial layers from the galeal layer (Fig. 37-60) . Debris and other contaminants can be deposited several centimeters from the visible laceration. Careful exploration and cleaning of scalp wounds are of obvious importance.

Because the scalp is very vulnerable to blunt trauma and because its superficial fascial layer is inelastic and firmly adherent to the skin, stellate lacerations are common in this region. Stellate lacerations not only pose additional technical problems in closure, but also have a greater propensity for infection. Multiple scalp wounds that are hidden by a mat of hair are easily overlooked.

When scalp wounds are debrided, obviously devitalized tissue should be removed, but debridement should be conservative, because closure of large defects is difficult on the scalp. When facing profuse bleeding, especially from extensive lacerations, the physician should instruct an assistant to maintain compression around the wound during the closure rather than try to tie off bleeding vessels. Unless the vessels are large or few, ligation of individual scalp vessels seldom provides effective hemostasis, and considerable blood loss can occur during the attempt. Bleeding from scalp lacerations is best controlled by expeditious suturing. [89] A simple procedure that often provides hemostasis of scalp wounds is

**Figure 37-61** *A,* To achieve hemostasis of a scalp laceration, a wide, tight, sterilized rubber band or Penrose drain may be placed around the forehead and occiput. This compresses the arterial supply to the scalp. *B,* Raney scalp clips and instrument for application to scalp wound edges.

placing a *wide*, tight rubber band around the scalp, from forehead to occiput (Fig. 37-61 *A*). Sterile rubber bands may be kept on the suture cart for this purpose. The clinician also may control bleeding temporarily in some cases by grasping the galea and the dermis with a hemostat and everting the instrument over the skin edge. The disadvantage of this technique is that tissue grasped by the hemostat may be crushed and devitalized, [89] and if the SQ tissue also is everted for a prolonged period, necrosis

can occur.

If an assistant is not available to apply direct pressure, local anesthetics containing epinephrine are sometimes effective in controlling the persistent bleeding from small vessels in scalp wounds. If bleeding from the edge of the scalp wound is vigorous, and definitive repair must be postponed while the patient is resuscitated, Raney scalp clips can be applied quickly to the edge of the scalp wound to control the hemorrhage. The applicator is loaded by inserting the tip of the instrument into the back of the clip and then locking the handles. The clip is slid onto the bleeding wound edge and released from the applicator. When the wound is repaired at a later time, the clip is removed by reversing the procedure. The plastic clips are radiolucent and do not interfere with plain radiography or computed tomography scanning (Fig. 37-61 *B*). [98] [99]

Before wound closure, the underlying skull should be visually examined and palpated in an attempt to detect fractures. More small skull fractures are detected with the physician's eyes and gloved finger than with radiographs. A common error is to mistake a rent in the galea or the periosteum for a fracture during palpation inside the wound. Direct visualization of the area should resolve the issue. In wounds that expose bone but do not penetrate the skull, prolonged exposure may leave a nidus of dead bone that may develop osteomyelitis. Exposed bone that is visibly necrosed should be removed with rongeurs until active bleeding appears. [89] Hair surrounding the scalp wound usually must be clipped far enough from the wound edge so that suturing can proceed without entangling the hair in knots or embedding hair within the wound. If hairs along the wound edges become embedded in the wound, they will stimulate excessive granulation tissue and delay healing. [100] Vaseline or tape may be placed on stubborn hairs that persistently fall into the wound. Although clipping scalp hair is not popular with some patients, failure to expose an area adequately is a common cause of improper preparation and closure of scalp wounds.

Unlike most wounds involving multiple layers of tissue, scalp wounds should be closed with a single layer of sutures *that incorporate skin, SQ fascia, and the galea* (Fig. 37-62). The periosteum need not be sutured. To minimize the chance of infection, SQ deep sutures generally are avoided. In superficial wounds, skin and SQ tissue should be approximated with simple interrupted or vertical mattress stitches using a nonabsorbable 3-0 nylon or polypropylene suture on a large needle. Smaller suture material tends to break while firm knots are being tied and should not be used. The ends of the tied scalp sutures should be left at least 2 cm long to facilitate subsequent suture removal. The use of blue nylon, as opposed to black, may make suture removal easier. If the galea is also torn, it should be included in the skin stitch. [101] Some investigators recommend a separate closure of the galea with an absorbable 3-0 or 4-0 suture, using an inverted stitch that "buries" the knot beneath the galea. [89] Separate closure of galea is not required in the vast majority of scalp lacerations sutured in the emergency department. When performed, separate closure of the galea introduces additional suture material into the wound, but in extremely large wounds provides a more secure approximation of the galea than obtained with large needle single layer closure.

Stellate lacerations or crush lacerations may be excised to produce elliptical incisions if

the area involved is not extensive. With microvascular techniques, large sections of skin avulsed from the scalp can be reimplanted. The emergency physician should use the same techniques in salvaging avulsed scalp as are used for amputated extremities. [101] (See Chapter 50 for further discussion.)

It has been suggested that there is no absolute time interval between injury and closure that automatically precludes primary suturing of scalp lacerations. Because of the extensive collateral blood supply of the scalp, most lacerations in this area heal without problems. Nonetheless, wound care must be thorough if the devastating complication of scalp infection is to be avoided.

Sutured scalp lacerations need not be bandaged, and patients can wash their hair in 24 hours. If bleeding is persistent, an elastic bandage can be used as a compression dressing. Gauze sponges are placed over the laceration to provide direct local pressure beneath the elastic bandage.

**Figure 37-63** Anatomy of the fingernail. The fingernail rests on the nailbed, also termed the *matrix.* The distal nail covers the sterile matrix; the proximal nail arises from and covers the germinal matrix. The tissue adherent to the proximal dorsal nail is the eponychium (also termed the *cuticle*), and the potential space between the nail and the eponychium is the nail fold.

**Nail Lacerations**

Injuries to the nail and nailbed (also called the *nail matrix*) are common problems in emergency medicine, yet controversy exists over proper management (Fig. 37-63) . Sixty percent of patients with subungual hematomas that are greater than one half the size of the nailbed and with associated fractures of the distal phalanx have a nailbed laceration. [102] [103]

In the case of a simple subungual hematoma (even in the presence of a tuft fracture) in which the nail is firmly adherent and the disruption of the surrounding tissue is minimal, the nail *need not be routinely removed to search for nailbed lacerations* (Fig. 37-64) . Despite the presence of a nailbed laceration, a good result can be expected as long as the tissue is held in anatomic approximation by the intact fingernail. Nail trephination is discussed in Chapter 40 . If the nail is partly avulsed (especially at the base) or loose, or if there are deep lacerations that involve the nailbed, the nail should be lifted to assess and repair the nailbed (Fig. 37-65) . When the integrity of the fingernail is disrupted and the nailbed is not approximated anatomically, a rippled nail is believed more likely as the new nail grows over the rough, scarred surface (Fig. 37-66) .

If the nailbed is exposed and has been extensively lacerated or partially avulsed, it may be necessary to refer the patient to a hand surgeon who can raise a flap of tissue extending from the proximal nail fold, explore the wound for foreign bodies, and clean under the nailbed. A simple nailbed laceration should be approximated with 6-0 or 7-0 absorbable sutures (to obviate the need for suture removal), generally using loupe magnification and a finger tourniquet to maintain a bloodless field (Fig. 37-67) . The

exposed nailbed should be protected by reapplying the avulsed nail (best choice) or by applying a nonadherent dressing or Silastic sheet for approximately 3 weeks. After cleaning, the avulsed nail may be sutured in place or secured with wound closure tape.

The replaced nail serves three purposes: (1) it acts as a splint or mold to maintain the normal anatomy of the nailbed, (2) it covers a sensitive area and facilitates dressing changes, and (3) it maintains the fold for new nail growth. Splinting should be maintained for 2 to 3 weeks. If longitudinal scar bands are formed between the proximal nail fold and the matrix, a permanently split or deformed nail may result.

A nail that is partially avulsed distally can be used as a temporary splint or "dressing" that protects and maintains the integrity of the underlying nailbed. When the base of the nail is avulsed from the germinal matrix, its replacement may occasionally result in infection. Some authors advocate trimming the proximal portion of the traumatized nail so that it can be placed more easily in the nail fold. [104] If the *germinal matrix* of the nail is avulsed intact, the nail should be reimplanted using a 5-0 or 6-0 absorbable suture in a mattress stitch (Fig. 37-68) (Figure Not Available) . [72] [105] If the root is not replaced, the space between the proximal nail fold and the nailbed is obliterated within a few days. [106] [107] If an open fracture exists, the matrix must not be allowed to remain trapped in the fracture line. [108] A replaced nail may grow normally, acting as a free graft, but often it is dislodged by a new nail. Nails grow at a rate of 0.1 mm/day, and it requires approximately 6 months for a new nail to reach to the finger tip.

If part of the nailbed has been lost, the patient should be referred to a surgical consultant for a matrix graft. Conservative therapy that allows large portions of an avulsed nailbed to granulate is inadvisable, although this is quite acceptable therapy for a fingertip avulsion that does not involve the nailbed. If the exposed nailbed is left open to granulate, it will heal with scar tissue and could produce a distorted and sensitive digit.

Wounds should be rechecked in 3 to 5 days following repair. At that time the nail fold may be repacked if nonadherent material was used, and the wound is assessed for infection. The use of absorbable suture for nailbed repair makes suture removal unnecessary. Tape or sutures are removed from any replaced nail in 2 weeks, and the old nail is allowed to fall off as the new nail grows. The value of antibiotics is unproven. All patients with nail injuries should be advised of a possible cosmetic defect in the new nail.

When repairing distal digit lacerations involving a nail, the physician should first approximate the onychial fold (Fig. 37-69) (Figure Not Available) . A sturdy needle attached to a 4-0 thread is recommended for suturing lacerated nails. Needles seem to penetrate nails with the least difficulty when they enter at 90°. The point of the needle carves a rigid path through the nail. Unless the entire length of the needle is allowed to follow this path as it passes through the nail, the needle is likely to bend or break. Alternatively, an electrical cautery instrument or a heated paper clip can be used to perforate the nail, thus permitting easy passage of the needle. The method for atraumatically removing a nail is demonstrated in Fig. 37-70 .

**Drains in Sutured Wounds**

Drains do not prevent infection; they primarily keep wounds open to encourage drainage of purulence or blood that may otherwise collect in the wound. When no infection exists and drains are used in soft tissue wounds "prophylactically," they are more harmful than beneficial. Edlich and coworkers state that "drains act as retrograde conduits through which skin contaminants gain entrance into the wound. Furthermore, the presence of a drain impairs the resistance of the tissue to infection." [63] Magee and colleagues found that drains placed in experimental wounds contaminated with subinfective doses of bacteria greatly enhanced the rate of infection, whether the drain was placed entirely within the wound or was brought out through the wound. [110] Drains behave as foreign bodies, provoking rather than preventing infection. If the wound is considered at high risk for infection, instead of suturing the wound with a drain in place (in anticipation of disaster), the physician should leave the wound open and consider delayed primary closure later when the risk of infection is minimal. Furthermore, drains should not serve as substitutes for other methods of achieving hemostasis in traumatic wounds.

## SUMMARY

A variety of techniques are available for reapproximating wound edges. Stapling is fast, but this technique does not allow meticulous control of wound edges, as may be necessary for a cosmetically appealing repair. Tape and tissue adhesive are the quickest and least painful methods of wound closure. Both eliminate the risk of self-injury with suture needles. These techniques can be used only on small superficial wounds or after approximation of the SQ layer.

The traditional and most commonly used method of closure is suturing. Stitches provide the most secure closure initially, but placement of sutures is time consuming and technically more difficult than other methods. All suture materials provoke inflammation and increase the risk of infection. Suture repair is the most appropriate method for wounds with complex configurations, those that extend into SQ tissue, and those in mobile areas.

At the conclusion of any wound repair, dried blood on the skin surface should be wiped away gently with moistened gauze, and the wound should be covered with a dressing. Dressing techniques, wound care instructions, and suture removal skills are discussed in Chapter 36 .

# Chapter 38 - Skin Grafting in the Outpatient

**Jose Eric Diaz Alcala**

Epithelial grafting is best defined as detaching a portion of epithelium from its original blood supply and placing it in a new area where the recipient site blood supply nourishes the grafted tissue. Free epithelial grafts allow one to close a clean wound that cannot be closed primarily because of an insufficient epithelial cover. The wound could be traumatic or secondary to surgical excision or tissue loss caused by a burn injury or chronic nonhealing ulcer.

The epithelium covers the internal and external surfaces of the body. The internal epithelium is mucosa, and the external epithelium is skin. Both can be used as free tissue transplants, but only skin grafting is discussed in this chapter. The outer covering of the body is a natural barrier between the body and the environment. Early coverage of an open wound and reestablishment of this barrier function are essential in the restoration of the internal equilibrium and the prevention of further wound complications. Epithelial transplantation serves many purposes, including enhanced cosmesis, reduced scar contracture, improved function, accelerated wound healing, and reduced fluid loss.

Epithelial transplantation originated approximately 3000 years ago. Currently, free tissue transplant has evolved from a reconstructive option of last resort to one that is routinely and sometimes preferentially used during soft tissue reconstruction. Although uncommonly performed in the emergency department, minor skin grafting can be done easily in the outpatient setting with minimal equipment. Results are excellent with knowledge of the physiology of skin grafting and when careful attention is given to proper site preparation for both recipient and donor sites; appropriate selection of the type of skin graft; precise techniques for harvesting and insetting the graft; proper dressing techniques; and adequate postoperative care.

While many emergency physicians would not consider skin grafting because of time constraints, lack of familiarity with the procedures, or local protocols, in the proper circumstances the procedure is readily adaptable to emergency medical practice. In reality, minor skin grafting is not as difficult or exotic as once promulgated and is well within the expertise of the emergency physician. Obviously one would not consider grafting of facial or other exquisitely cosmetic or functionally complex areas in the emergency department; however, uncomplicated wounds, usually of the extremities, represent candidates for emergency department skin grafting (Fig. 38-1) .

## TYPES OF SKIN GRAFTS

The skin is composed of the epidermis and the dermis resting on the subcutaneous tissues. The epidermis is composed of squamous epithelial cells in progressive stages of differentiation. The epidermis lacks a direct blood supply and receives its nutrients by diffusion from the dermis. A vascular plexus and many of the skin appendages, such as thermoregulatory sweat glands, sebaceous glands, and hair follicles, are located within the dermis (Fig. 38-2) . Free epithelial grafts can be classified according to site of origin

(skin or mucosa). Graft thickness is classified as follows: thin skin, full-thickness, split-thickness, dermal, and composite.

A *thin skin graft* consists only of epidermis. It is not routinely used and therefore will not be discussed here. A *full-thickness skin graft* contains the entire thickness of the epidermis and the dermis, including the adnexal structures such as hair follicles, but not subcutaneous tissue. It is most useful in repairing defects of limited size in cosmetically or functionally important sites and provides better wear and acceptable color and texture match. Other than for occasional use in resurfacing of the palmar aspect of the hand and the fingers, a full-thickness skin graft is rarely indicated in emergency situations.

A *split-thickness skin graft* includes the full thickness of the epidermis and a partial thickness of the dermis. Depending on the thickness, these grafts can be further subdivided into thin (0.005 to 0.012 in.), intermediate (0.013 to 0.018 in.), or thick (0.019 to 0.028 in.). The thinner grafts have the advantage of requiring less revascularization and consequently have a more rapid and complete adherence, thus improving the chance for graft survival. An intermediate split-thickness skin graft is preferred, because it may offer both improved graft survival and durability.

A *dermal graft,* which includes only the dermis, is a collagen-rich layer. It is used either as a buried reinforcing layer for protection of other structures or as an exposed epithelial graft for resurfacing in reconstructive surgery. It is harvested after cautious elevation of the overlying epidermal layer. However, the high incidence of defect during harvesting, the variability of graft resorption, and the availability of more predictable alloplastic implants have diminished the use of dermal grafts.

A *composite graft* is composed of at least 2 different tissue types or several tissue layers transplanted as a unit. Most commonly, this graft is composed of skin and cartilage and is used for facial reconstructive surgery. Dermal and composite grafts are not indicated in the emergency department, and further discussion is beyond the scope of this chapter.

Graft thickness can be judged by the appearance of the graft and donor site. Thicker grafts are more opaque. Immediately after elevation the edges of the thicker graft tend to curl up more toward the raw surface as a result of shortening of the elastic fibers in the skin. The donor site for a thin split-thickness skin graft shows a velvety field of numerous very fine bleeding points (Fig. 38-1 *B*). The bleeding pattern of a thick split-thickness skin graft donor site is much coarser. The punctuate bleeding points are larger in size and fewer in number.

Once skin grafts are harvested, they tend to shrink quickly as a result of the inherent elasticity of the dermal element, a process known as *primary contraction*. The thicker the graft, the greater the potential for early shrinking. A thin split-thickness skin graft barely shows evidence of early shrinking, whereas the full-thickness skin graft shrinks markedly. As skin grafts heal and undergo further maturation, progressive contraction of the graft-recipient complex occurs, a process known as *secondary contraction*. The recipient bed, not the skin graft itself, is usually the site of the most significant secondary contraction. The degree of delayed contraction depends on the thickness of the

transplanted graft. Thin split-thickness skin grafts contract the most, whereas full-thickness skin grafts show minimal evidence of delayed contraction. In a split-thickness skin graft, the contrast between the graft and its surrounding skin can create a "tire patch" appearance that is somewhat more pronounced than that seen in full-thickness skin grafts. This secondary contraction phenomenon usually starts at approximately 10 days after grafting and may continue for up to 6 months.

Skin grafts acquire pigmentation as they mature. The degree of pigmentation is also dependent on the thickness of the skin graft. A thin split-thickness skin graft is more apt to develop a dark pigmentation than is a thicker split-thickness skin graft or a full-thickness skin graft. The hyperpigmentation is thought to be secondary to stimulation of melanocytes by hormones and ultraviolet ray exposure. The problem of pigmentation is most pronounced in skin grafts on sun-exposed areas of the body.

## SKIN GRAFT HEALING

Graft healing proceeds through a series of unique stages that are not well appreciated in sutured wounds. Initially a skin graft is anchored on a temporary basis to the recipient bed by a *fibrin network glue* from the recipient bed. For the first 48 hours, survival of the skin graft is largely dependent on *serum* or *plasmatic imbibition*. The endothelial channels of the skin graft become filled with serum-like transudate fluid from the recipient bed. This is likely due to capillary action and diffusion within the skin graft. The nutritional supply and metabolic exchange are mediated through this fluid medium. This process prevents the graft from drying and serves to keep the vessels open for later communication with the recipient vessels. [1] [2] [3]

During this early phase of serum imbibition, restoration of circulation proceeds concurrently, as seen by a gradual change of the color of the graft from pale white to pink. Concurrently the fibrin glue is replaced by granulation tissue, which provides permanent adherence of the graft to the recipient bed. Vascular anastomoses that arise from the vascular-rich recipient bed allow percolation of blood through the preexisting graft vasculature. In ideal circumstances this collateral circulation bridges a gap of 0.5 cm from any wound margin. The bridged area will require more time to regain full vascularity.

Normal circulation is restored in the skin graft in 4 to 7 days. Epidermal proliferation and hyperplasia are seen in 4 to 8 post-transplant days and persist for several weeks. Restoration of the lymphatic circulation parallels reestablishment of the blood supply. Graft reinnervation begins as early as 2 to 4 weeks after transplantation, but full sensation may not occur for several months to years later. However, in partial thickness grafts, specialized dermal adnexa structures, such as those responsible for hair growth or sweating, will not be evident upon healing. Rapid gain in adherent strength in most skin grafts occurs within the first 8 hours after grafting and continues to gain slowly with each subsequent 24-hour period.

The viability of a thin split-thickness skin graft can be maintained longer by imbibition alone than can a thick split-thickness or a full-thickness graft. This is attributed to the shorter distance for diffusion in thinner grafts and the fact that there is less cellular mass

to be nourished. Revascularization of a thin split-thickness skin graft is also more rapid than revascularization of a thick split-thickness graft or a full-thickness graft for the same reason.

## DONOR SITE HEALING

The surface of the split-thickness graft donor site is a raw dermal surface with multiple openings into the remaining portions of the transected skin appendages, such as sweat ducts and glands, sebaceous glands, and hair shafts and follicles. These appendages are lined with squamous epithelium and are the source of epithelial cells for resurfacing of the exposed dermal surface. The epithelial cells proliferate, migrate out to the dermal surface, and spread radially until they become confluent and cover the entire raw surface. The dermal layer itself may become thicker with scar tissue but does not regenerate. The greater the thickness of the split-thickness skin graft, the fewer the number of skin appendages left in the donor surface. For this reason, the donor site of a thick split-thickness graft takes longer to heal than the donor site of a thinner split-thickness graft. Generally, the donor area is treated as an open wound and is allowed to reepithelialize from its margins and form its dermal rest. Depending on the thickness of the split-thickness graft, the donor site is usually healed within 7 to 56 days (thin, 7 to 10 days; intermediate, 10 to 21 days; thick, 21 to 56 days).

Once the donor site is reepithelialized, its appearance is largely dependent on the graft thickness. A thin split-thickness skin graft donor site containing a thicker residual dermis will have an appearance closer to that of its surroundings and will be less conspicuous than a thicker split-thickness graft donor site. For the most part, the final appearance of both the recipient and the donor site reflects the amount of dermis that has been transferred and the amount of dermis that is left behind. However, *the donor site of full-thickness skin graft should not be allowed to heal by secondary intention.* The removal of the dermis prevents epidermal regeneration, resulting in significant scar contracture. The donor site of

full-thickness skin graft must be either closed primarily or covered by a split-thickness skin graft.

## UNFAVORABLE FACTORS

Many clinicians are overly concerned with skin graft aesthetics (e.g., size and shape) and are less concerned with the more important final outcome. Even partial success is better than the alternative of nongrafting for the majority of candidate wounds. Several factors adversely influence the outcome of skin grafting by either interfering with the revascularization process or disturbing the neovascular network that has already been formed; these include hematoma and seroma, graft movement, necrosis, and infection. [4] Viability of a salient thickness graft can be best enhanced by preventing unfavorable conditions, especially minimizing the buildup of fluid between the graft and recipient site and movement of the grafted tissue. In the emergency department, attention to these factors is paramount.

**Hematoma and seroma**

Hematoma formation between the graft and recipient site is the most common cause of skin graft failure. A hematoma under the skin graft literally causes separation of the skin graft from its nutrient bed. Consequently, revascularization of the graft is delayed or altogether prevented by the space-occupying effect of this intervening layer of blood or blood clot. The skin graft may survive for a short period on serum imbibition alone. If revascularization is delayed beyond this period of serum imbibition, however, the graft is doomed to fail. To prevent hematoma, one should obtain complete hemostasis of the graft bed prior to application of a skin graft. If complete hemostasis is not possible, the wound should be dressed, and skin grafting should be delayed until there is no further hemorrhage. One loses little clinical advantage by waiting a few days to perform the graft until conditions of the recipient site are more favorable. A seroma also prevents graft adherence and revascularization through a mechanism similar to that of a hematoma.

**Movement**

Graft survival depends on reconstitution of the capillary vascular network between the recipient bed and the skin graft. Even minimal motion of the skin graft relative to the recipient bed could disrupt and interfere with the formation of these fine, early vascular connections. Movement also promotes formation of a seroma or hematoma. For these reasons, immobilization of the graft to its bed is essential in graft healing. Immobilization is enhanced by suturing; stent or pressure dressings; and bandaging and splinting techniques, discussed later.

**Necrosis**

Any residual nonviable tissue left in the recipient bed will undergo necrosis and will lead to failure of the overlying graft. In particular, the vascularity of fatty tissue in a traumatic wound is often uncertain. Bits of fat may die and necrose, and therefore, it is important to debride all tissues of questionable vascularity before grafting. If the vascularity of the recipient bed is uncertain, it is best to delay skin grafting. Likewise, it is prudent to carefully debride or defat the undersurface of the graft prior to placement. Minor necrosis of portions of the graft, such as the edges, are not disastrous, and do not necessarily predict failure of the entire graft. Often even only a partial take is better than the alternative of relegating total healing to secondary intention without grafting.

**Infection**

Despite its devastating effect on skin grafting, infection is the least common cause of graft failure. In addition to the obvious space-occupying effect of infection, a purulent collection actively separates the graft from its bed and destroys the newly formed vessels. The abundant proteolytic enzymes from inflammation and from the microorganisms are responsible for the lysis of the fibrin adhesion and the destruction of vascular connections. The most notable virulent organism that affects skin grafting is

group A beta-hemolytic streptococcus *(Streptococcus pyogenes),* which rapidly destroys the skin graft and literally melts it away. Topical or systemic antibiotics effective against common microorganisms (i.e., staphylococcal, streptococcal, or *Pseudomonas* organisms) may be helpful in selective situations if administered early on, particularly for patients with diabetes or impaired immunosuppression or after a prolonged intraoperative time. However, prophylactic antibiotics need not be administered routinely in immunocompetent individuals and do little to guarantee ultimate graft survival in questionable cases.

## INDICATIONS AND CONTRAINDICATIONS FOR SKIN GRAFTING

Whether to graft a wound or to leave it open to heal by secondary intention depends on the nature and history of formation of the wound. Traumatic open wounds may be classified as either clean or contaminated. The majority of traumatic wounds can be considered clean, except for those resulting from bites, those made in a grossly contaminated environment, and those that are 24 hours old. Of particular concern is wound contamination by microorganisms. Wounds that contain inorganic material, such as gravel, glass, metal, industrial lubricants, and the like, are not necessarily extensively contaminated. As long as there is no suspicion of major contamination by microorganisms, these wounds can be made clean by debridement and removal of foreign substances. Untidy wounds resulting from tearing, crushing, or mangling or explosive injuries with devitalized tissue debris can also be debrided and converted to clean, tidy wounds. In general, all clean wounds should be closed when possible, and contaminated wounds should be left open (see Chapter 36) .

A skin graft should be contemplated only when primary wound closure or flap reconstruction is impractical or contraindicated. Grafts are more likely to fail than flaps. In general, grafting is the best possible dressing material for an open wound when an increased risk for additional cosmetic deformity is not avoided with primary closure or flap repair. Another common indication for grafting is a wound that is healing too slowly by granulation. In many cases grafting can be a life-saving procedure, such as with burn care.

When there is full-thickness skin loss of a small area and the wound cannot be closed with local tissue alone, closure with a distant tissue is considered. In these circumstances a full-thickness skin graft may be indicated. To prevent failure in revascularization, a full-thickness skin graft should not exceed 2 cm at its largest cross-sectional width, since its circulation relies on invasion of vessels from the periphery. Relatively superficial and large wounds are most often closed with split-thickness skin grafts. For those wounds in which graft color, texture match, and graft contraction

are not of concern, a split-thickness skin graft is an ideal wound cover. In fact, a split-thickness skin graft is often used because of this propensity to undergo secondary contraction. For instance, a split-thickness skin graft on a fingertip wound would contract, pulling the surrounding healthy pulp pad skin over the tissue defect, thereby minimizing the size of the wound. On the other hand, certain anatomic areas, such as the face and the flexion surfaces of the hand and fingers, require coverage that

produces minimal secondary contraction. Facial wounds also demand color and texture match, which are best met by full-thickness skin grafts. If deep structures, such as neurovascular bundle, tendon, bone, and joint, are exposed, some other means of distant tissue cover in addition to skin grafting may be considered.

Skin grafting of selected acute wounds in an outpatient setting is advantageous. Grafting affords early closure of the wound and obviates further wound complications, such as desiccation of exposed structures, repeated trauma to tissue, and infection. Grafting may considerably decrease the degree and the length of the convalescence period. For example, when grafted, a fingertip wound >1 cm2 would heal much sooner than a wound of equal size that is allowed to close by contraction and epithelialization. Grafted wounds are also more comfortable for the patient than open wounds and may allow an earlier return to work.

## RECIPIENT BED

One can best ensure that the graft will "take" by carefully preparing the recipient bed and keeping it clean and relatively dry at all times. All the nonviable tissue and granulation tissue must be removed surgically from the wound, creating a well-vascularized surface without barriers to graft adherence.

Meticulous hemostasis of the recipient bed is also a key to a successful graft. A common mistake is to attempt grafting immediately after wound cleaning/debridement when the site is still actively oozing. Often merely waiting 15 to 20 minutes for normal clotting to occur will create a dry surface. Gentle pressure applied with a warm, saline-soaked gauze is often all that is required. In an extremity, a tourniquet may be used to provide hemostasis, but the graft should be sutured into place and a compression dressing applied before the tourniquet is removed. Judicious use of topical vasoconstrictors and cautery may help if active bleeding persists.

Skin grafts can be located on any exposed vascular surface. This includes all musculoskeletal tissue and all internal organs. Skin grafts do not survive on nonvascular surfaces, such as bare bone without periosteum, bare cartilage without perichondrium, bare tendon without peritenon, and bare nerve without perineurium cover. However, a skin graft can serve as a bridge over a nonvascular area by vascularization through the graft edge, a process known as *bridging phenomenon.* Theoretically, a maximum of 10 mm of nonvascular area can be covered by bridging, provided that there is an adequate vascular rim of recipient bed at the perimeter of the skin graft.

## SELECTION OF THE DONOR SITE

In theory, a skin graft should be able to be taken from anywhere on the body. Indeed, numerous donor sites are necessary when large areas must be covered, as in a major burn injury. As a general rule, it is crucial to inspect all available donor sites, and it is best to use tissue as close as possible to the site of the defect, looking for the most appropriate texture-color match. In addition, proper selection of a well-vascularized donor site is important, because such skin becomes vascularized more rapidly once

transplanted. However, the donor tissue should not be obtained from areas that will be irritated when the patient sits or lies supine, and all feasible attempts to minimize scar formation upon healing should be pursued. In young women, it is preferred to take the graft from within the bikini line to conceal the donor site scar. Another concern in choosing the donor site is that someone may misinterpret the donor scar as a self-inflicted wound (i.e., wrist slashing).

For smaller wounds, the functional and cosmetic quality of the skin graft at the recipient site and the resulting donor site deformity dictate the selection of the donor site (see Fig. 38-2) . A full-thickness skin graft is usually taken from a glabrous area of the body. There are many favored areas from which to take full-thickness skin grafts (Fig. 38-3) . Among them, the hypothenar skin, antecubital flexion creases, the wrist flexion crease, the medial arm, and inguinal flexion creases are most readily accessible and appropriate for outpatient situations. For completeness, other donor sites for full-thickness skin grafts include the preauricular groove, postauricular groove, mentolabial groove, supraclavicular skin, and upper eyelid skin. These donor sites are mainly used for facial reconstruction surgery and are rarely indicated in the emergency department.

When a thin split-thickness skin graft is desired (as is the case for most emergency department skin grafting), the anteromedial aspect of the forearm is suitable (see Fig. 38-1 C). One objection to this site is obvious scarring in a frequently exposed area. However, in experienced hands a very thin split-thickness skin graft from this area leaves minimal to no appreciable scarring. The anterior, medial, and lateral aspects of the upper thighs, the inner aspect of the upper arms, the back, the buttocks, and the lower abdomen are also available for skin grafting. Relatively thick and large skin grafts can be taken safely from these areas. In addition, the instep of the plantar foot could be contemplated as an applicable donor site for split-thickness skin graft for selected cases of soft tissue defects of the palmar aspect of the hand that require either primary or secondary surgical reconstruction.

## HARVESTING EQUIPMENT (DERMATOMES)

A wide variety of instruments can be used to harvest the graft. These can be classified into freehand, drum-type, and powered dermatomes. For outpatient use in an emergency facility, freehand dermatomes are quite adequate to harvest a small skin graft. Only those that are useful for outpatient skin grafting are described here.

### Freehand Dermatomes

Freehand dermatomes include scalpels, razors, and knives. Even though acceptable small grafts can be obtained using these devices, they are often uneven in thickness and size and have irregular edges, despite the adjustable roller mechanism fitted in some of them. Undoubtedly, the final product depends on the physician's touch, experience, and sense of self-confidence.

A *scalpel blade* is the simplest dermatome. A No. 10 or 20 blade is quite effective for

taking a small split-thickness skin graft (Fig. 38-4 *A*). A sterile, regular single side of a *double-edged razor blade* can be used to take a small skin graft. The razor blade is held with a straight clamp and is used in a freehand manner (Fig. 38-4 *B* and *C*). Various thicknesses of split-thickness skin grafts can be cut with this dermatome. The thickness of the skin graft can be judged by the clarity with which the writing on the blade can be read through the skin graft. One can see through the usual thin and intermediate-thickness skin grafts quite readily.

## Silver Dermatome

This dermatome consists of a handle and a platform at the opposite end that holds a regular, double-edged razor blade. The razor blade is fixed in place with a cover plate, which is secured with a wing nut. There is a roller just above and parallel to the blade edge. The thickness of the graft can be adjusted roughly by setting the distance between the roller and the blade, which is accomplished by turning the knobs at the ends of the blade (Fig. 38-5) .

## Goulian-Weck Knife

The Goulian-Weck knife consists of a handle with a metal slot at one end that holds a safety razor blade 5.5 cm long. A blade guard is placed over this assembly (Fig. 38-6) . The blade guard determines the thickness of the skin graft. Three different blade guards with thicknesses of 0.008, 0.010, and 0.012 in. are available. Although these guards are made to cut skin grafts of fixed thicknesses, after repeated use they become sprung and are not very reliable. These blade guards should be used as rough guides to the thickness of the skin graft. The actual thickness should be controlled visually and by touch.

## Davol Disposable Dermatome

This dermatome is a sterile, disposable blade unit that cuts a split-thickness skin graft of intermediate thickness and 3.5 cm in width (Davol Inc., Providence, RI). This blade unit is driven by a battery-operated motor in an electric toothbrush handle unit (Fig. 38-7) . The handle is placed in a sterile plastic bag. The blade unit is then pushed onto the handle, puncturing the plastic bag, and is attached to the handle. The device is operated by pressure placed on the button switch while the blade unit is kept lightly pressed against the skin with an equally light forward force to advance the dermatome. The battery in the handle is rechargeable through a recharging unit.

# HARVESTING THE SKIN GRAFT

After meticulous preoperative evaluation has been rendered, the defect should be measured and the surrounding tissue shaved if needed. Measurements should not be done by estimation or "eye-balling"; rather, the recipient and donor sites should be carefully plotted out using templates and marking pens. Ideally a material that is flexible, transparent, not stretchable, and able to be sterilized and that can conform to the defect is the best for making a pattern or template (i.e., sterile glove, paper, aluminum foil,

gauze or Telfa dressing).

Once the donor site is outlined, local anesthesia is administered, thereby avoiding the inexact sizing caused by tissue stretch resulting from the infiltration. The donor site is scrubbed with any of a number of common antiseptic solutions. The area should be rinsed with saline and draped with sterile towels. Some physicians advocate wiping the area with acetone or ether to remove oil from the skin surface prior to donor site anesthetization. Local anesthetic (0.5% or 1% lidocaine [Xylocaine] and 1:100,000 or 1:200,000 epinephrine solution) is used for anesthesia and hemostasis. Epinephrine in the anesthetic will not compromise the procedure. An area larger than the size of the desired graft is locally infiltrated. A plane of anesthetic infiltration is placed in the deep dermis, allowing the surgical separation of the dermis from the underlying fat. The anesthetic solution is injected continuously while the needle is being passed back and forth in multiple parallel passes. A 25- or 27-ga hypodermic needle 3.8 cm (1.5 in.) long is used. This results in uniform infiltration of the entire area, forming an evenly elevated plateau and facilitating the harvesting of the skin (Fig. 38-8) .

**Full-Thickness Skin Graft**

One should plan carefully to orient the long axis of the true template parallel to the adjacent skin creases. This allows primary closure of the donor defect and produces favorable orientation of the resulting scar. Using a scalpel, a skin incision is made along the lenticular pattern (Fig. 38-9) . The graft should be 3% to 5% greater in size than the true template to compensate for natural graft shrinking and contraction after its removal from the donor site. The full

**Figure 38-8** Infiltration of anesthetic in the donor site.

thickness of the skin is removed by running the blade of the scalpel along the junction between the dermis and the subcutaneous fat. *Fat is then removed from the graft by stretching it over a finger with the epithelial side down and snipping the bits of fat from the dermal surface with a pair of small, curved sharp scissors*. Defatting is completed when all the yellow globular material is gone and the white, glistening surface of the dermis remains. The graft pattern is cut, and the skin graft is then ready for placement. In the meantime, it can be placed between layers of saline-moistened gauze, where it will remain viable for approximately 1 to 2 hours until the recipient site is prepared for transplantation. The graft may be used up to 21 days later if properly stored (i.e., refrigerated or kept on ice at 4 °C and with antibiotic solution [e.g., Hank's tissue culture solution], if warranted).

Often the patient presents to the emergency department with a portion of skin or an amputated fingertip that has been removed in a slicing injury. The amputated tip or skin, if relatively superficial, can be treated as a full-thickness skin graft. The tissue should be irrigated with saline to remove debris, defatted, and placed in saline-soaked gauze while the recipient bed is being prepared. The thick epidermis of the fingertip is often centrally cut 5 or 6 times with a scalpel to avoid separation of the graft and recipient bed as the fingertip dries. The graft is then attached by one of the techniques discussed in the

following sections.

## Split-Thickness Skin Graft

It is easiest and preferable to perform split-thickness skin grafting using one of the specialized cutting apparatuses previously described. [6] This can be done with a freehand device or with a powered dermatome, with or without a

**Figure 38-9** To harvest a full-thickness skin graft, the donor site is outlined with a marking pen. Note that a template of the area to be grafted has been placed over the donor site to ensure full coverage *(A)*. An elliptical site is removed so that the donor site can be closed primarily with sutures, leaving a linear scar. A minimal amount of subcutaneous skin is removed using a scalpel and forceps *(B)*. The graft is rolled back *(C)*. The underside of the graft is fully defatted with scissors *(D),* and the graft is placed in saline-soaked gauze, where it will remain viable for 1 to 2 hours.

predetermined depth to be harvested, depending on the instrument used. The skin graft donor site is first lubricated so that the dermatome can glide smoothly. This facilitates taking an even skin graft. Sterile substances such as mineral oil, petrolatum, saline, or any of the usual topical ointments can be used. The lubricant is applied thinly over the donor skin surface. The donor skin is stretched manually and placed under tension. The skin is held proximally and distally to the graft donor site by firmly pressing the skin with either a sterile wooden tongue blade or a piece of gauze. Traction is applied by pulling away from the donor site in both directions (Fig. 38-10 *A*). This maneuver usually requires 2 people. The operator's free hand should hold the traction toward the direction of the dermatome movement. An assistant applies countertraction, and the operator cuts the skin graft toward the free hand.

The dermatome is set for the desired thickness; it should be held lightly with the fingers and the thumb. During the procedure, the operator's upper extremity is relaxed, and the wrist is maintained in a relatively fixed position. The cutting motion is mainly at the elbow and the shoulder and consists of frequent to-and-fro strokes with minimal forward pressure. Too much forward pressure may result in irregular thickness of the graft and possible interruption of graft continuity. The dermatome should contact the skin at an angle when the cut is begun. Once the cut is initiated, the dermatome is flattened out to effect tangential excision of the skin (Fig. 38-10 *B*). The downward pressure on the dermatome determines the thickness of the skin graft. For thin and intermediate-thickness skin grafts, the weight of the dermatome itself, without much additional external pressure, is sufficient to cut the desired thickness. Tissue forceps or hemostats may be used to advance the graft into the dermatome and away from the blade. When the appropriate length of harvest tissue is reached, the dermatome is then tilted away from the skin, cutting the skin and completing the harvesting phase. At this time, the harvested graft can be washed in normal saline to remove any excess povidone-iodine or lubricant previously applied. Concurrently, the donor site should be temporarily covered with a pressure dressing.

Once harvested, the skin naturally curls and shrinks immediately. Uncurling the harvested graft by placing it on moist gauze until time for transplantation is helpful. A sheet of sterile semipermeable film (i.e. Op-Site, Tegaderm) may be applied to the

donor site prior to the harvesting phase. When removed in conjunction with the skin graft, it will prevent to some extent curling of the harvested graft because of its adhesive qualities. Of importance, its thickness (0.002 in) should be accounted for (i.e., added to the desired tissue depth) when setting the dermatome depth to ensure adequate tissue harvesting. In addition, when transferred to the recipient site, the semipermeable film can serve as a primary dressing for 1 to 2 weeks postoperatively. In split-thickness skin grafts, primary contraction of the harvested tissue is not as clinically significant as that in full-thickness

**Figure 38-10** *A,* The cutting of a split-thickness skin graft with a double-edged razor blade held in a straight clamp. The skin is held taut by traction and countertraction. *B,* A tangential excision producing a skin graft of uniform thickness.

skin grafts. Commonly, in split-thickness grafting there is no need for harvesting more tissue than is required.

# APPLICATION OF THE SKIN GRAFT

## Full-Thickness Skin Graft

Following meticulous hemostasis of the recipient bed, the previously cut skin graft is laid on the recipient bed at the desired position. At all times one should *avoid raising the graft from its bed once it has been applied.* If needed, the graft may be stretched or rolled to remove wrinkles, or trimmed to fit. As the graft is being sutured into place, a cotton applicator stick can be twisted underneath the graft to remove any remaining clots. The sutures used to approximate the skin graft to the margins of the wound are denoted as anchoring sutures, basting sutures, and circumferential sutures. Several *anchoring sutures* (4-0 polypropylene or nylon) are placed on the four quadrants of the graft for proper fitting. Alternatively, stainless steel staples provide rapid and precise edge eversion of both the graft and the recipient borders. Also, additional interrupted sutures can be placed between the primary anchoring sutures as needed. These sutures are left long (4 to 6 cm) for a tie-over dressing, although a tube gauze dressing is also effective for digits. *Basting sutures* (5-0 or 6-0 chromic gut) are necessary if the central portion of the graft requires more bed contact for additional graft stability and to prevent further hematoma formation. In some situations a properly applied basting suture may obviate the need for a sophisticated and time-consuming graft dressing. The remaining edges are sutured with a simple *running circumferential suture* (5-0 to 6-0 nylon or polypropylene) for further epidermal wound approximation. Sutures are easier to place if the needle is driven through the graft first at a slightly higher level in the dermis and then through the skin edge of the recipient area at a slightly deeper level in the dermis in an almost epicuticular fashion. This prevents tenting of the edges of the graft, thus enhancing contact for revascularization.

## Split-Thickness Skin Graft

The split-thickness skin graft is placed on the recipient bed with the dermal side down, similarly to a full-thickness skin graft. The dermal side of the split-thickness skin graft is

characterized by the wet, glistening sheen, as opposed to the relatively dry, dull appearance of the epithelial surface. If the recipient bed is larger than a single sheet of graft, several sheets of graft may be required. Any overlapping of skin grafts will not influence the graft take. On the other hand, it is important to make sure that the free edges of the graft are fully uncurled (i.e., the graft should *not* be doubled over on itself). Obviously, any curled portion will not get revascularized, and sectional failure of the graft will result.

The split-thickness skin graft should be laid in such a way that it follows all the "hills and valleys" of the wound and is in contact with the entire raw surface of the recipient bed. If the skin graft tends to tent over a deep concavity, it is useful to tack down the tented portion to the base of the concavity using 1 or 2 through-and-through stitches (5-0 or 6-0 nylon or polypropylene). This is supplemented by a conforming dressing. The overhanging edges of the skin graft beyond the wound margin are trimmed. Suturing of the skin graft at the edges is not always necessary but may be desirable to offset the curling of the skin edges. Often adhesive

closure tapes are used rather than sutures at the skin graft edge, with satisfactory results.

When there is a need for the skin graft to conform better to the recipient site surface owing to the site's irregularities, or when a larger surface area must be grafted from a smaller donor site, the necessity of meshing the graft obtained should be contemplated. This is accomplished by passing the skin through a mechanical device that produces multiple uniform slits in the graft. However, slight meshing of the graft with simple scalpel slits also can be done. When tension is applied perpendicular to these incisions, they open and increase the surface area that can be covered by the graft. Another relative indication for meshing the graft is to allow any blood or serous fluid to drain through the incisions without compromising graft vitality. These openings eventually epithelialize, but the aesthetic appearance is usually not as good as that achieved with an unmeshed graft. For the most part, the use of this method in the emergency department is rarely indicated, because it may implicate a complicated and larger wound that requires an in-patient approach.

## DRESSINGS

### Full-Thickness Skin Graft

A full-thickness or partial thickness skin graft is classically dressed with a tie-over bolster dressing. This dressing facilitates immobilization and affords moderate, even graft site pressure to prevent collection of blood or serum under the skin graft during the critical period of revascularization. Once the graft has been secured, the skin graft could be covered with a single layer of nonadhesive dressing. The nonadhesive dressing will minimize the adherence of the graft to the bulky pressure dressing that follows, which, at the time of dressing removal, tends to pull the graft away. It is followed by Xeroform, petrolatum, or antibiotic-petrolatum-impregnated fine gauze, which is cut larger than the grafted area. A bolster that fits the size of the graft is formed using a moist gauze followed by a dry wad of cotton, lamb's wool, gauze, or a polyurethane foam pad. The

overhanging edges of the nonadherent gauze dressing are swept up to cover the rough edges of the bolster. The long tails of the sutures are tied, and the bolster is secured in place providing molded constant pressure over the graft (Fig. 38-11) . An additional soft dressing can be applied to protect the bolster dressing as necessary. After this step, the graft is not disturbed until dressing removal 5 to 10 days later, depending on recipient site conditions. If motion of the graft bed is an anticipated problem, immobilization of the parts involved with a loose plaster cast, splint, or sling may be necessary.

**Split-Thickness Skin Graft**

There are numerous individual variations among physicians in dressing split-thickness skin grafts, but all approaches can be classified as closed or open. All closed techniques are all quite functional, as long as they meet several basic requirements. The skin graft dressing should be nonadherent, absorptive, immobilizing, and protective. A split-thickness skin graft on a concave surface can be effectively immobilized with a tie-over bolster technique, which has been described previously. For uncomplicated small split-thickness skin grafts, there are much simpler and easier methods of applying dressings. Ordinarily, open techniques of skin grafting dressing (e.g., a wire cage or a cardboard box placed over the graft) are not used routinely. They are not suitable for commonly encountered wounds in emergency situations and are not used in any patient whose willingness or ability to cooperate is in doubt.

A small and dry split-thickness skin graft on a flat surface can be secured with several strips of adherent porous adhesive closure strips without sutures (Fig. 38-12) . The strips can also be positioned across the wound margin in a radial fashion, like spokes on a wheel. The graft is then covered with nonadherent petrolatum gauze sufficient to cover the entire extent of the wound closure strips. If the strips are not covered entirely by the greasy dressing, they may get lifted off as the dressing is removed, which in turn may disrupt the skin graft. Next, a couple of layers of saline-moistened gauze are applied. This layer of dressing aids in absorption of the early drainage through capillary action of the moist gauze fibers. The entire area is then covered with an oversized, thin sponge with an adhesive backing, such as a Reston pad (3-M Company, St. Paul, Minn). The overhanging portion of the sponge is pressed and allowed to adhere to the surrounding skin, which has been wiped dry.

If an adhesive sponge dressing is not available, the last step can be modified as follows: A surgical adhesive such as tincture of benzoin or Aeroplast is applied to the skin surrounding the moist gauze dressing. An oversized dry gauze is applied over the entire area, and the edges are pressed to stick to the skin, which has been painted with surgical adhesive. The edges of the dressing can be reinforced with tapes if necessary. This last layer of dressing protects the graft from external shearing forces. The entire dressing and the entire graft-recipient unit may move, but the graft is not allowed to move relative to the recipient bed. This layer should not be occlusive, as such a layer (e.g., an adhesive plastic dressing) would prevent evaporation and would allow collection of drainage in the dressing and consequent maceration of the graft.

Contrary to common impression, a split-thickness skin graft on a fingertip wound is quite simple to dress. Fixing the skin graft with sutures is not always necessary; this extra

step is time consuming and does not add to the outcome of grafting. The skin graft is simply kept in place with several strips of petrolatum gauze that are placed across the skin graft and the adjacent skin in a crisscross fashion. The strips should be narrower than the thickness of the finger, so that the gauze strips can be molded to the contour of the fingertip without folding or pleating. A thin layer of moist dressing gauze cut to size is placed next. Two strips of adhesive sponge foam pad are laid across each other over the fingertip. Dry gauze strips can be used in place of the foam pad. The entire assembly of dressing is then covered with tube gauze, if available. No more than 2 layers of tube gauze should be used so that the dressing is not constricting.

The final, and often most critical, procedural step of skin graft dressing is immobilization of the graft site. External splinting is important for grafts that are on parts of the body that normally are in motion (e.g., the extremities [see Figure 38-1 *E*]). The best way to splint an extremity with a skin graft is with a plaster cast. Although a cast may appear to be too much for a fingertip graft, in the long run, patients are more comfortable and tolerate it well. Small individual finger

**Figure 38-11** A method of applying a tie-over bolster dressing to provide pressure to the graft site to minimize movement and fluid accumulation. While tying the bolster, the gauze is depressed with broad forceps or an assistant's finger.

splints that are taped on are not as reliable. These splints allow much motion and, hence, discomfort and graft disruption. With reinforcing strips of plaster in key areas, a relatively light cast that does the job can be fabricated.

The skin graft on the forearm can be splinted with a long arm cast that includes the wrist and the elbow. The wrist should be kept in 20° to 30° of extension and the elbow in 90° of flexion. A skin graft on a digit or the hand can be effectively immobilized with a short arm cast or bivalve plaster splint. Even if only a single digit is injured, it is advisable to immobilize the fingers in groups, such as the index and middle fingers or the ring and little fingers. The thumb is immobilized with a thumb spica cast. The hand and the fingers are kept in the functional position. All casts should be generously padded with cast padding. The plaster roll should be applied loosely and without constriction, since excessive pressure could cause vascular or neurologic damage and even loss of the extremity.

## CARE OF THE SKIN GRAFT

Postoperatively, skin grafts should be examined at frequent intervals. It is reasonable to check the grafted area within 24 to 48 hours for possible infection, seroma, or hematoma. If no complications are apparent or suspected, the graft should be reexamined within a week for the first dressing change and suture removal, if indicated. Early dressing change just for curiosity may damage the graft. Therefore, re-dressing the grafted area within the first 48 postoperative hours is a matter of judgment. The ideal graft is pinkish-red in appearance at early stages of healing. Often the graft may appear darker blue or purple, depending on the extent of revascularization, and will spontaneously revitalize. Certainly, a black graft is considered indicative of necrosis,

and aggressive therapy is justified.

Seromas and hematomas are to be avoided, and if they occur, they should be drained by a small stab incision made in the overlying skin graft with a No. 11 scalpel blade or a pair of scissors. The incision should be made directly over the center of the fluid collection. One then expresses the fluid by rolling 2 cotton swabs from the periphery to the center of the collection (Fig. 38-13) . Each seroma or hematoma should be drained individually; if more than 1 are drained through a single stab incision, the intervening portion of adherent skin graft may be lifted off the bed and disturbed. Following this, the skin graft is redressed and examined every 1 to 2 days and is drained if necessary until the graft is fully taken. If there is gross infection, the involved portion of the skin graft is debrided and lavaged, and appropriate dressing change is initiated.

Dressings on small split-thickness skin grafts (e.g., fingertip grafts) and tie-over bolster dressings on full-thickness skin grafts are left undisturbed for 5 to 7 days. Nonetheless, the patient should be seen 2 to 3 days following the operation, and the area of the graft dressing should be examined for signs of infection. Signs and symptoms that should alert the caregiver to the need for prompt intervention to try to save the graft include severe increasing local pain, soft tissue redness and swelling, local warmth, purulent malodorous drainage, and unexplained low-grade fever. If any combination of the above signs or symptoms is present, the graft should be exposed and examined in its entirety. Early debridement, culturing, and treatment with an antibiotic are recommended to reduce the risk of graft loss and to avoid enlargement of the defect. If the infection is local, controlling the local flora with topical antimicrobials (e.g., silver sulfadiazine, mafenide acetate, silver nitrate, or norfloxacin) may

**Figure 38-13** Techniques for draining a hematoma or seroma. Fluid collections under the graft are great deterrents to proper take and should be drained.

be sufficient in selected cases. On the other hand, if the infection is considered cellulitic in nature, a combination of topical proteolytic-antimicrobial ointment plus a systemic antibiotic is usually warranted. Prophylactic antibiotics are *not* routinely used with outpatient skin grafts. The pain from a skin graft is usually minor and seldom requires opioid analgesics.

## CARE OF THE SPLIT-THICKNESS DONOR SITE

The split-thickness donor site requires proper attention. The donor defect can cause more postoperative discomfort than the grafted area itself, so proper care must be given to hasten the healing process and prevent the donor site from becoming infected. Current donor site dressing approaches can be classified as open, semi-open, occlusive, and semi-occlusive.

The open technique, in which the wound is left uncovered, is associated with significant prolonged healing time and discomfort when compared with a dressed site.

The semi-open technique using fine mesh gauze impregnated with various substances

(e.g., Xeroform [Chesebrough-Ponds, Inc., Greenwich, Conn], bismuth, scarlet red) is frequently used for a large donor site. It is considered relatively inexpensive, easy to manage, and associated with a low infection rate. A nonadherent gauze pad (e.g., Telfa [The Kendall Company, Boston]) can be used between the fine mesh gauze and the dry-absorbent outer gauze. By doing so, the fine mesh wound gauze will not stick to the outer gauze when it dries. This minimizes discomfort when the dressing is removed at wound check. Alternatively, Biobrane (Winthrop Pharmaceuticals, a division of Sterling Drug Inc., New York), a transparent collagen-synthetic composite membrane, may be used as a semi-open donor site dressing. In general, Biobrane has been found to be more comfortable, but unfortunately, it is associated with a higher rate of infection and has a higher cost when compared with fine mesh gauze dressings. [7] For the most part, in semi-open techniques the outer absorbent gauze is removed after 24 to 48 hours, leaving the impregnated gauze now adherent to the wound undisturbed. The wound is then lightly dressed or left open to dry. The fine mesh gauze along with a thin layer of scab is gradually separated from the healing donor site in 10 to 21 days when reepithelialization is completed. Once it is completely exposed, the donor site can be lubricated with either lanolin or cocoa butter.

Early occlusive dressings consisted of fine mesh gauze covered with an impermeable dressing. These dressings had a greater risk of bacterial proliferation and fluid collection. More recently, DuoDerm (ConvaTec) dressings have been used. DuoDerm, an opaque oxygen-impermeable hydrocolloid membrane, does not adhere to the wound, is pain free upon dressing changes, and permits rapid infection-free reepithelialization. The semi-occlusive technique using synthetic transparent adhesive moisture vapor-permeable membranes (e.g., Op-Site [T. J. Smith & Nephew Ltd., Victoria, Greater London], Tegaderm [3-M Company, St. Paul]) covered with loose gauze is an acceptable alternative method that is easy to care for and provides rapid healing. Care is taken to dry the surrounding skin well so that there is good contact between the adhesive plastic sheet and the skin.

Overall, if an occlusive or semi-occlusive technique is preferred, the dressing should remain in place until reepithelialization has occurred or for approximately 10 days, unless there are signs of infection. In the case of infection, the plastic dressing is removed, and frequent moist saline dressing changes are started. Once gross signs of infection have cleared, petrolatum gauze dressings may be applied and the wound cared for as described previously.

Another technique for donor site care is the use of previously harvested residual tissue. If the harvested tissue has been meshed, then residual tissue may be reapplied to the donor site. Doing so shortens the time required for healing.

# Chapter 39 - Soft Tissue Foreign Body Removal

**Gail S. Rudnitsky, Richard C. Barnett**

The presence (or suspicion) of soft tissue foreign bodies (FBs) is a common problem seen in the emergency department. Successful identification and efficient removal of an FB is gratifying to both patient and physician. However, once identified, not all FBs can or should be removed in the emergency department. Occasionally FBs are missed during the initial emergency department evaluation, resulting in discomfort or complications. Missed FBs are one of the leading causes of malpractice claims made against emergency physicians. This chapter will provide guidelines for the evaluation and removal of a variety of FBs.

## GUIDELINES FOR APPROACHING FOREIGN BODIES

Initially the physician should take a history of the method of injury to quickly ascertain the specific characteristics of the foreign material and to formulate the best plan for judicious removal. The history, physical examination, and localization techniques available significantly influence decisions about the time and place of FB removal. Some material, such as wood, should be removed immediately, because retained wood will invariably lead to inflammation and infection. Other material, such as glass or plastic, may be removed on an elective basis, whereas innocuous metallic FBs may often be permanently left embedded in soft tissue. If localization is certain and if removal can be effected under local anesthesia within a manageable period of time (1 hour is usually the upper limit of operative time using local anesthesia), an attempt at removal is generally indicated on the initial visit (given physician and support staff availability). *The patient should be informed before the procedure that the FB may not be located in the time allotted and that subsequent referral or additional procedures may be necessary*.

If, in contrast, the material is deeply imbedded, relatively inert and small (such as a BB), and not located near any vital structures, the time, energy, and effort involved in the removal may be excessive compared with the possible adverse effects of the foreign material remaining in the soft tissue. An ill-conceived extended search for an elusive but otherwise innocuous FB often results in frustration for the physician and discomfort and dissatisfaction for the patient.

The possibility of the FB migrating to involve vital structures is quite remote but should be reviewed in the decision of when and how to remove the FB. Cases of reported missile embolization in the vascular system are influenced by the missile caliber, impact velocity, physical wound characteristics, point of vessel entrance, position and movement of the body, and the velocity of blood flow. [1] Retained bullets usually remain in the soft tissues but may make their way into the vascular system. This usually occurs at the time of injury. Schurr and colleagues [2] reported a paradoxical bullet embolization from the left external iliac vein to the left iliac artery via a patent foramen ovale. When the patient was first examined by physicians, a bullet was

noted on the chest radiograph, and an isolated chest wound was suspected. However,

the bullet had apparently entered the chest, traversed the abdomen to the iliac vein, and then embolized back to the chest and the arterial system.

All clinical decisions require an evaluation for the possibility of infection. Some FBs produce infection in a few days, whereas with other objects, infection or an intense inflammatory response may be delayed for weeks or months, often flaring up for no apparent reason. Some retained FBs, such as wood, will always eventually produce inflammation, while others, such as bullets, rarely do so. If the FB carries dirt particles, pieces of clothing, or other sources of bacterial contamination with it, expeditious removal of the material may be necessary, even though the FB itself is relatively small and unlikely to cause a reaction. If some time has elapsed since the initial injury, careful review of the history of the type of foreign material and the method of introduction is warranted. One should not attempt a hasty or extensive exploration for foreign material that may not exist or is best left alone. The initial history should also include any unusual medical problem that would preclude the use of adequate local anesthesia, such as allergy to local anesthetics, any bleeding diathesis, or any medical problems (including diabetes mellitus, vascular disease, uremia, or a compromised immune status) that might lead to unusual or more difficult wound management. Finally, one needs a cooperative and willing patient. Attempting to remove an FB in an intoxicated, mentally retarded, or overtly uncooperative patient is obviously self-defeating.

It is not rare to encounter a soft tissue FB even though its presence has not been suggested by the history. Anderson and associates reported that physicians who initially treated a series of hand injuries did not suspect the presence of an FB in 75 of 200 consecutive cases. [3] The patient who experiences a sharp, sudden pain in the foot while walking barefoot across the carpet may have a sewing needle or toothpick embedded in the foot, rather than the "sprained foot" that provoked the initial complaint (Fig. 39-1) . *An abscess or cellulitis that recurs or wounds that do not heal as expected should always be investigated for an initially unsuspected retained FB.* [4] [5] Finally, metallic or other FBs visible on the radiograph of a multiple trauma patient should be proved to be extrinsic to the patient--that is, present on the radiograph table or clothing rather than being embedded in the patient. Foreign objects, such as keys or coins, may be surreptitiously embedded in a trauma patient and easily mistaken for artifact (Fig. 39-2) .

If an FB was left in place, the patient should be told why it was not removed. If the patient is referred for delayed removal, this should also be carefully explained and documented. Regardless of whether the FB is removed, all wounds should be cleaned appropriately and tetanus prophylaxis updated (see Chapter 36) .

Rarely, retained lead FBs, such as bullets or shotgun pellets, may leach out lead into the general circulation and produce systemic lead poisoning (Fig. 39-3) (Figure Not Available) . Such a process may take years to develop and can cause vague or nondescript symptoms (e.g., fatigue, arthralgias, headache, or abdominal pain) many years after the offending missile has been forgotten. Elevated blood lead levels are most likely to occur if the lead object is bathed by bodily fluids, such as joint fluid, pleural or peritoneal fluid, or cerebrospinal fluid, and bullets retained in muscle or other soft tissues are not likely to produce any sequelae related to their lead content. Farrell and

coworkers [6] reported unsuspected elevated lead levels in patients with retained lead fragments who presented to the emergency department with a variety of complaints. Lead levels of up to 50 mug/dL were reported. Levels >45 mug/dL are generally considered an indication for chelation therapy. The relation between the retained lead and the presenting symptoms was unclear, but this report verifies the observations of others that retained lead FBs in selected areas can significantly elevate blood lead levels and may produce symptomatic plumbism.

Finally, if foreign material has been found and removed, or if a wound has been explored and no FB found, the patient should be clearly informed that there is *no absolute guarantee that all foreign material has been identified or extracted*. The prudent clinician always leaves open the option that an occult FB may still remain in any wound and informs the patient of signs and symptoms of problems related to retained material. Patients should be assured that additional steps will be undertaken should the presence of foreign material be subsequently suspected.

## IMAGING TECHNIQUES

A variety of imaging techniques are available to the emergency physician to help detect and localize FBs. Many emergency physicians mistakenly believe that if the base of the wound can be clearly visualized and explored and the wound has not entered adipose tissue, an FB can always be ruled out. While this is commonly true, Avner and Baker were able to detect glass by routine radiographs in 11 of 160 wounds (6.9%) that were inspected and believed by the physician to be free of glass. [7] Whenever there is an index of suspicion for a retained FB as a result of the history, mechanism of injury, patient complaint, or examination, attempts should be made to visualize it. Modalities available include plain radiographs, xeroradiographs, fluoroscopy, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound (US) (Fig. 39-4) (Figure Not Available) . Fluoroscopy is helpful for localizing FBs that are visualized on routine plain films, but even fluoroscopy under magnification will not identify plastic or wooden FBs. [8]

### Plain Radiographs

Plain radiographs are readily available and easily interpreted in the emergency department, and the cost is significantly less than for CT, US, or MRI. [9] The ability of plain films to detect FBs in soft tissues depends on the object's composition (relative density), configuration, size, and orientation. One should never rule out an FB by plain films unless *multiple projections are examined*, since many clearly radiopaque objects are obscured by superimposed bone on one view, yet are quite obvious when viewed from another angle. Metallic objects, such a pins, bullets, and BBs, are readily visualized. Aluminum, which has traditionally been deemed radiolucent, can occasionally be visualized on plain films if the object is projected away from the underlying bone. Ellis demonstrated that pure aluminum fragments as small as 0.5 mm × 0.5 mm × 1 mm could be identified in a chicken wing model simulating a hand or foot, but cautioned that other aluminum FBs, such as pull tabs from cans, may not be visualized in other parts of the body such as the esophagus or stomach. [10]

It is a common misconception that glass must contain lead to be visualized on a plain radiograph. Studies have shown that unless obscured by bone, almost all types of glass in soft tissue (bottles, windshield glass, light bulbs, microscope cover slips, laboratory capillary tubes) can be detected by plain radiographs (Fig. 39-5) (Figure Not Available) . [9] [11] Very small glass fragments (<1 mm) may be more difficult to detect by this technique, [12] but the absence of an FB on multiple projections is strong, although not absolute, evidence that glass is not contained in a wound. Other nonmetallic objects readily visualized include teeth, bone, pencil graphite, asphalt, gravel, and some plastics. [9] [13]

Detection of FBs on plain films can be enhanced by requesting that the technician use an underpenetrated soft tissue technique. [14] Plain films may provide indirect evidence of the presence of an FB if one sees trapped or surrounding air, a radiolucent filling defect, or secondary bony changes such as periosteal elevation, osteolytic and osteoblastic changes, or pseudotumors of bone. [14] Vegetative material, such as thorns, wood, splinters, and cactus spines, are not readily visualized by plain radiographs. These materials absorb body fluids as they set in situ and become isodense with the surrounding tissues. Because of their varying chemical composition and density, plastics may or may not be visible on plain films. However, plastics, which are more brittle and most likely to shatter, are for the most part radiolucent and invisible on plain films. [15]

## Xeroradiography

Xeroradiography is a technique used to enhance soft tissue images. Ionizing radiation passes through the patient and interacts with an electrostatically charged selenium plate. The image is then transferred to a permanent record using a Xerox processor. Although some authors claim this technique is superior to plain radiographs in detecting nonradiopaque FBs, Russell and associates [9] found that xeroradiography was no better than routine radiographs in detecting glass and gravel, and the technique failed to detect plastic and wood FBs. While occasionally useful, xeroradiography is not usually available to the emergency physician.

## Computed Tomography

CT is readily available to most emergency physicians. Since CT depends on x-ray absorption, it generally visualizes the same substances that are detected on plain films. [13] However, because CT can detect subtle differences in soft tissue densities, it may detect FBs not readily visible on plain films. [9] Wood may or may not be detected depending on its degree of hydration. CT produces a better three-dimensional image of tissue than plain films and may also visualize objects embedded in or behind bone.

## Magnetic Resonance Imaging

Although MRI is expensive and not readily available to emergency physicians, it may be superior to CT in detecting small, *nonmetallic*, radiolucent FBs, such as wood,

particularly in the orbit. [16] FBs, which have little or no free water, appear as a signal void on MRI. [9] Plastic is more easily visualized with MRI than with CT. MRI cannot be used for metallic objects and gravel, which contain various ferrometallic particles that produce signal artifacts on MRI. [9] Metallic objects, in addition to producing a high degree of artifact on MRI, have a theoretical risk of shifting within the magnetic field and causing structural damage to adjacent structures. This is of little importance in superficial extremity wounds, but it is particularly important when evaluating FBs in the eye, brain, or deep structures of the neck, face, or extremities.

**Ultrasound**

As US becomes more readily available in emergency departments, it is becoming the imaging modality of choice for objects not readily apparent on plain films. Like fluoroscopy, it can be used to guide the tip of a hemostat to a nonvisualized object [14] while not exposing the operator or patient to ionizing radiation. US is both highly sensitive and highly specific in localizing FBs of all types, [17] but the success of the technique is quite operator dependent. US is especially useful in detecting nonradiopaque FBs such as wood or thorns. A wooden object is usually seen as a bright hyperechoic focus when the scan plane parallels the long axis of the FB or is at right angles to its long axis. [17] US may have more difficulty in visualizing small FBs in the hand or foot, where there are many echogenic structures. [18] While most useful for larger FBs in extremities, US may be difficult to use in some sites such as the web space of the hand. The presence of gas in the surrounding tissue may be responsible for the failure of US to detect FBs; therefore, US should preferably be done before wound exploration. [18] Occasionally, calcific tissue or small sesamoid bones may give a false-positive US examination. Overall, the sensitivity and specificity of high-resolution US in detecting radiolucent FBs is about 90%.

**General Imaging Approach**

A reasonable initial approach for localizing nonvisualized FBs in the emergency department is to obtain multiple-projection plain radiographs (ideally with a soft tissue technique). This will visualize the majority of FBs. Metal and glass should be most visible with this technique. US may be considered for objects known to be radiolucent, such as wood or thorns. Both US and fluoroscopy may be used to guide FB extraction. CT or MRI probably should not be routinely ordered from the emergency department unless one suspects a particularly dangerous FB, such as an intraorbital FB ( *use only CT with a suspected intraorbital or intracranial FB*), or if a previously negatively explored wound exhibits recurrent infection, poor healing, or persistent pain.

# FOREIGN BODY REACTION

Many soft tissue FBs have to be removed because of either infection or FB reaction. A purulent bacterial infection *may* develop in the presence of any FB, but *not in all cases.* Karpman and coworkers found a 15% infection rate ( *Staphylococcus aureus* and Enterobacteriaceae) in a series of 25 patients treated for cactus thorn injuries of the extremities. [19] Certain thorns (black thorn, rose thorns), redwood and Northwest cedar splinters, toothpicks, hair, and stingray or sea urchin spines are noted for their ability to

initiate chronic FB reactions. Sea urchin spines and other marine FBs are covered with slime, calcareous material, and other debris that commonly initiates an FB granuloma. The inflammatory reaction seen with cactus thorns may be an allergic reaction to fungus found on the cactus plant. Many FB reactions are

thought to be due to the inflammatory response to organic material and may represent infection from bacteria introduced at wounding. Clinically evident reactions may be delayed for weeks or even years following injury (Fig. 39-6) . The chronic infection or inflammatory reaction may not be accompanied by the production of pus, but it may be quite painful and may result in loss of function. FBs may also be associated with the formation of a chronic pseudotumor, development of a sinus tract, or evidence of osteomyelitis-like lesions of bone and soft tissue. [4] Organic material has also been noted to induce chronic tenosynovitis, chronic monarticular synovitis, and chronic bursitis.

Rapidly traveling projectiles with considerable inherent heat (e.g., bullets) are less likely to cause infection but are more apt to cause damage during passage through the tissue. As noted above, the composition and location of the FB, as well as patient medical status and vocational/avocational activities, greatly affect decision making related to FB removal. One must judiciously evaluate and manage each FB injury individually.

## FOREIGN BODY SCENARIOS

Certain mechanisms of injury, such as punching or kicking out a window or stepping on an unknown object while walking in a field or stream, are highly suggestive of a retained foreign body (Fig. 39-7) . While not all lacerations caused by glass require a radiograph, imaging should be liberally used under such circumstances.

Generally, lacerations from metal objects do not contain foreign material. However, if the patient states that considerable force was applied during injury and the instrument is not available for inspection, radiographic imaging may be warranted. Occasionally a piece of a knife blade's tip may be broken off as the knife encounters bone. Animal or human bites often warrant radiographs to assess for associated fractures. Such films should be viewed carefully for imbedded teeth in the wound. Since the patient's perception of an FB correlates with the presence of an FB, *it is axiomatic that the clinician ask the patient if he or she thinks that a wound may harbor foreign material* and proceed more cautiously if the answer is affirmative.

Many, but not all, retained FBs will produce pain when the patient moves the injured area or when the wound edges are palpated or depressed. It is prudent to carefully palpate the periphery of all wounds to elicit such tenderness. Superficial  FBs may be palpated through the skin, but surprisingly large FBs may be found in seemingly minor wounds, without any external evidence. While puncture wounds are more likely to contain an FB than wide, gaping lacerations, the external characteristics of the wound do not yield firm evidence as to the presence or absence of an FB.

# GUIDELINES FOR FOREIGN BODY REMOVAL

Following the initial history, examination, and *preoperative and preanesthetic documentation of the neurovascular status of the patient*, a decision must be made as to the time and place of removal. If the FB is to be removed in the emergency department, it is wise to set a time limit and stick to it. Thirty minutes is probably reasonable in a busy emergency department. More difficult procedures should be referred. Many FBs appear superficial on radiographs, suggesting that removal will be quite easy. However, surprisingly large or presumed superficial FBs often prove quite elusive.

**Localization**

Superficial FBs, such as splinters, bullets, or embedded glass, may be palpated if they are near the skin surface. Deeper FBs must be localized by other techniques. A metal probe may identify the FB by feel or sound. Glass is difficult to identify by sight in soft tissue but creates a characteristic grating sound when touched with metal. Because of the increasing incidence of the human immunodeficiency virus (HIV), *probing a wound with a gloved finger to locate or identify an FB is strongly discouraged* (Fig. 39-8) , since sharp objects can easily penetrate the examining finger.

Radiographs are the best method for estimating the general location, depth, and structure of radiopaque FBs. If one strategically attaches a marker (needle or paper clip) to the skin surface at the wound entrance before taking a radiograph, the FB will be seen in relation to the entrance wound. This also helps to identify the path that leads to the FB and the relative distance from the surface to the FB. [20] Needles at 2 angles may also be passed to aid localization (Fig. 39-9) (Figure Not Available) . A special technique using measurements on anteroposterior and lateral radiographs and a blind dissection method have been advocated to remove needles from the foot. [21] When the material to be detected is suspected of being difficult to visualize on a conventional radiograph, then xeroradiography, high-resolution US, CT, or MRI should be considered.

While rarely available, fluoroscopic image-intensifying equipment may be used to follow the wound's entrance, localize the material, grasp the FB, and remove it without making a larger incision. A potential disadvantage of this procedure is the increased amount of radiation that may be required. Ariyan has described a technique in which 2 needles are placed in the soft tissue from opposite directions, pointing toward the FB. [22] The extremity is rotated while the physician watches the image under the image intensifier to obtain a three-dimensional effect. An incision is placed perpendicular to the plane of the needles, and the object is removed. US can also be used to remove an FB under direct visualization. This is particularly useful for radiolucent FBs.

Some authors have suggested injecting the entrance wound with methylene blue to outline the tract of the FB. [23] Note that excess methylene blue that spills onto the skin surface may be removed with ether. The blue line of injected dye is followed into the deeper tissues. This technique is of limited value, because the tract of the FB often

closes tightly and does not allow passage of the methylene blue.

## Equipment

A standard suture tray with a scalpel is usually adequate equipment for removal of most simple FBs. Tissue retractors, special pickups, and loupes may be added as needed. Good direct light is essential for success, and some physicians prefer to use a head lamp. Sitting on a stool makes the procedure easier on the physician's legs and back.

Local soft tissue injection with buffered bupivacaine or lidocaine (with epinephrine for other than digital blocks) is the recommended anesthesia for the removal of most soft tissue FBs. IV regional anesthesia or selected nerve blocks may be useful. *The judicious use of sedation (parenteral, rectal, or oral) is strongly advised if the clinician senses undue apprehension or anxiety in the patient.* This may be especially helpful in children or patients otherwise unable to cooperate with

the operator. If the patient is totally uncooperative, exploration should be postponed for a more opportune time.

The use of an arterial tourniquet is essential to provide a bloodless field for the removal of a soft tissue FB in an extremity. A blood pressure cuff or portable self-contained pneumatic cuff inflated above arterial pressure may be used on the upper arm, forearm, leg, or thigh. To limit bothersome backbleeding, the extremity is elevated and wrapped with an elastic bandage to exsanguinate the extremity before the tourniquet is inflated. In the digits, a Penrose drain or specialized tourniquet may be used as a tourniquet at the base of the finger or toes. A sterile glove may also be used as a finger tourniquet. The fingertip of the glove on the involved finger is cut, and the glove is rolled down to the base of the finger. Most patients can tolerate an ischemic tourniquet for 15 to 30 minutes, and it is safe to stop circulation to an extremity for this time period.

## Operative Technique

The specific technique for removal of an FB is tailored to each clinical situation. In general, FBs should be removed only under direct vision. *Blind grasping into a wound with a hemostat in an effort to remove an FB should be avoided.* This technique is especially dangerous in the hand, foot, neck, or face, where vital structures may be easily damaged.

In most cases one should *enlarge the entrance wound with an adequate skin incision.* Attempting to remove an FB through a puncture wound or an inadequate skin incision is a common error that is both frustrating and self-defeating. Following a proper skin incision, the wound is explored by carefully spreading the soft tissue with a hemostat (Fig. 39-10) (Figure Not Available) . The FB can often be felt with an instrument before it can be seen. In an extremity that has been made ischemic by a tourniquet, the tract of the FB may be followed, although the tract frequently cannot be identified in muscle or fat.

If the FB is difficult to visualize (such as with fiberglass or plastic FBs) and if it is located in the superficial soft tissue, excision of a small block of tissue, rather than removal of the FB alone, may be necessary. Block excision is also required if the FB has contaminated the surrounding soft tissue. It must be noted that excision of a block of tissue is done only under direct vision and after nerves, tendons, and vessels have been identified and excluded from the excision.

If an FB such as a thorn or needle enters the skin perpendicularly, a linear incision may pass to 1 side of the FB, and it will be difficult to determine where the FB lies in relation to the incision (Fig. 39-11 (Figure Not Available) *A* and *B*). The search must then be extended into the walls of the incision rather than through the skin. [24] In such cases it is advisable to excise a small ellipse of skin and undermine the skin for 0.5 to 1.0 cm in all directions (Fig. 39-11 (Figure Not Available) *C*). The tissue is then compressed from the sides in hopes that the FB will extrude and can be grasped with an instrument.

Following FB removal, the wound is irrigated under pressure with saline. If a small incision has been made in a noncosmetic area (such as the bottom of the foot), the incision is left open and bandaged. The area may be soaked in hot water for a few days, and a return visit is necessary only if signs of infection develop. If a large incision has been created, the skin may be primarily sutured. In cases in which gross contamination has occurred, the wound should not be closed on the initial visit. The wound may be packed open, and the skin may subsequently be sutured, if free of signs of inflammation, in 3 to 5 days (delayed closure). Tetanus prophylaxis should be given, but the use of postoperative antibiotics is not standard. They may be indicated for immunocompromised patients, if there was excessive time between injury and removal, if the wound was obviously contaminated, or when the ability to adequately clean a wound is suspect; however, under these circumstances it is more prudent to opt for an open wound and a delayed closure. If antibiotics are prescribed prophylactically, 3 days of a penicillinase-resistant penicillin or a first-generation cephalosporin should suffice. Under certain circumstances (e.g., stepping on a nail or a marine FB), alternative antibiotics may be indicated. The majority of wounds that contained glass or metal FBs may be irrigated and closed primarily. Importantly, the presence of infection on a subsequent visit strongly raises the concern for an occult retained FB.

**Traumatic Tattooing**

Ground-in foreign material or tattooing of the skin is a troublesome problem, because foreign matter will permanently disfigure the skin. Many cases may be managed with adequate local anesthesia and meticulous debridement with a sponge, a scrub brush, or a toothbrush. If it is impossible to remove all the foreign material with these methods, careful consideration should be given to a secondary excision of the tattooed area and primary closure with subsequent plastic surgery to repair the defect. It is often impossible to safely and easily remove traumatic tattooing in the emergency department; referral for more extensive surgical treatment following local wound care is quite acceptable. Dermabrasion may be an acceptable delayed treatment when the tattooing is superficial. [25]

**Foreign Bodies in Fatty Tissue**

FBs located in fatty tissues may be removed by making an elliptical incision surrounding the entrance wound; grasping the skin of the ellipse loosely with an Allis forceps; undercutting the incision until the FB is contacted; and removing the FB, skin, and entrance tract in one block (Fig. 39-12) (Figure Not Available) . In most instances, a small portion of subcutaneous (SQ) fat should be removed along with the FB to minimize infection. FBs in fat are very mobile, and probing may displace them even more. FBs that are embedded in fat and are perpendicular to the skin may also be removed, as shown in Figure 39-11 (Figure Not Available) .

**Puncture Wounds to the Sole of the Foot**

FBs are often introduced with puncture wounds to the sole of the foot. A common scenario is stepping on a nail while wearing tennis shoes and socks. If the patient reports that the nail was removed intact, the possibility remains that small fragments or fibers from the shoe or sock were introduced into the wound. When present in the wound, this material will invariably serve as a nucleus for infection. Therefore, these wounds should always be evaluated for the presence of foreign material, and some may require exploration (see Fig. 54-18) (Figure Not Available) . Proper evaluation requires that the patient be placed prone on a stretcher and adequate lighting used. A magnifying device may be helpful. Routine radiographs are probably not helpful, as most retained material is radiolucent. If a deep FB is suspected, CT, MRI, or US may be indicated.

Initially one visualizes the punctured area searching for obvious threads or pieces of rubber by merely elevating the small flap of calloused epidermis that commonly covers the entrance wound. Superficial and readily seen FBs, including small pieces of rust or debris, are often present. If foreign material is found, it should be removed by excising a small piece of tissue. A large laceration under the skin flap also warrants local wound exploration. Although local anesthesia is often sufficient, regional nerve blocks for the sole should be considered if extensive exploration or debridement are anticipated (see Chapter 32) . The surface of the site is irrigated, left open, and appropriately bandaged. Generally this is all that is required under these circumstances.

If infection is already present, the incidence of a retained FB is high. If infection is present, often with accompanying lymphadenitis, the puncture site may be cored out with a 2- to 4-mm-diameter incision carried up to 2 cm deep. The cored-out area is superficially irrigated and left open. It is best to avoid advancing an irrigating catheter into the deep recesses of the tract, as this serves no useful purpose and may disseminate infection.

Routinely removing a plug of tissue or coring a noninfected wound with no visible foreign material is quite controversial. [26] [27] This empiric procedure has been advocated by some, but it increases patient discomfort and disability and has never been shown to reduce the incidence of serious sequelae. It is best reserved for patients with early inflammation or other findings on wound inspection that suggest a retained FB. It is

likely overtreatment in the majority of cases.

A first-generation cephalosporin or a penicillinase-resistant penicillin is a reasonable antibiotic choice for obviously infected puncture wounds. Noninfected puncture wounds have not been shown to benefit from antibiotics; routine use of antibiotics in noninfected wounds is discouraged except in high-risk patients. Empiric antibiotics may select out resistant organisms. Although rare, the most dreaded complication of a deep puncture wound of the foot is *Pseudomonas* osteomyelitis (the organism lives in the rubber soles of tennis shoes), but there is no evidence that routine use of prophylactic antibiotics will prevent this complication. The key to a successful outcome of any puncture of the foot is to realize that pain that persists for more than a few days after stepping on a nail may represent the beginning of a limb-threatening infection. In the early course of a deep *Pseudomonas* infection, fever may be absent; the complete blood cell (CBC) count and sedimentation rate, normal; and a plain film, negative. A bone scan is the best way to evaluate a foot that still remains painful or swollen 2 weeks after stepping on a nail.

**Subungual Foreign Bodies**

Special attention is required for subungual FBs that are deeply embedded in the nailbed. [28] In some instances this may require removing a small portion of the nail with double-pointed heavy scissors and grasping the foreign material with the splinter forceps (Fig. 39-13) (Figure Not Available) . Occasionally, complete removal of the nail may be required. Obviously, a digital block is needed for techniques involving manipulation of the nail or nailbed. An interesting technique has been suggested in which a sterile hypodermic needle, bent at its tip, is slid under the nail and hooks the FB, allowing its withdrawal. Alternatively, a 19-ga hypodermic needle can be slid under the nail to surround a small splinter. The needle tip is then brought against the underside of the nail to secure the splinter. The needle and splinter are then removed as a unit. [29] Wooden splinters are commonly embedded under the fingernail. *Such FBs must be completely removed, because subsequent infection is certain*. The proximity of the distal phalanx to the subungual area is a constant concern for the development of osteomyelitis.

**Fishhooks**

There are several methods of removing a fishhook. The preferred method depends on the conditions under which the removal is to take place. [30] [31] [32] The traditional manner for removal requires advancement of the fishhook and cutting the fishhook proximal to the barb. Generally, local anesthesia (1% lidocaine) is infiltrated into the tissue overlying the barb, the barb is forced through the anesthetized skin and clipped off, and the rest of the hook is removed along the direction of entry (Fig. 39-14) (Figure Not Available) . In the field or stream, removal of a fishhook may be accomplished without local anesthetic using a quick tug technique. The same technique may be used in the emergency department; some prefer to use local 1% lidocaine to facilitate removal. This "stream" technique (Fig. 39-15) (Figure Not Available) uses a looped string or fishing line passed around the belly of the hook at the point at which it enters the skin. Approximately 1 foot of string should be wrapped around the dominant hand to give strong traction. The shank of the hook should be held parallel to and in approximation with the skin by the

index finger of the opposite hand. The thumb and middle finger of the opposite hand stabilize and depress the barb, which helps the index finger to disengage the barb from the SQ tissue. When the barb has been disengaged, a *sharp* pull (i.e., a quick tug with a snapping motion) with the dominant hand removes the hook through the wound of entry. The hook often flies out of the patient, and care should be taken to keep bystanders out of the expected path. A commercial fishhook extractor device that is based on this method but grasps the hook during removal is available (Minto Research and Development Inc., Redding, Calif.).

Alternatively, an 18-ga needle may be used to cover the barb (Fig. 39-16) (Figure Not Available) . After adequate local anesthetic has been administered, the needle should be passed through the entrance wound of the hook parallel to the shank of the hook to sheath the barb and allow the hook to be backed out while the barb is covered. An alternative to this procedure is to insert a No. 11 blade parallel to the shank of the hook down to the barb. Using the point of the blade, free the SQ tissue that is engaged on the barb, sheath the barb with the point of the No. 11 blade, and back the hook out, with the blade protecting the barb.

The retrograde techniques may cause less tissue trauma, if the barb does not already protrude from the skin. Tetanus prophylaxis should be given. Antibiotics are not necessary.

**Wooden Splinters**

Because of the potential for inflammation, *pieces of wood must be completely removed from soft tissue*. Simply grasping the end of a superficial protruding splinter may be adequate, but care should be taken not to leave small pieces of the FB in the wound. Some splinters cannot be visualized at the point of entry but can be easily and readily palpated beneath the skin. When a wooden FB is SQ, it is advisable to cut down on the long axis of the FB to remove it via a skin incision, rather than pulling it out through the entrance wound (Fig. 39-17) . An incision may seem extensive, and it does create a laceration where only a puncture wound existed, but opening the tract allows for thorough cleaning and mandatory removal of small pieces of the splinter that may otherwise remain. The linear skin incision may then be sutured.

Particular mention should be made of certain wood splinters that are reactive and pliable, such as California redwood and Northwest cedar. Any wood that is easily fragmented requires meticulous care to ensure removal of all the material. Wood is generally not visible on a standard radiograph or xeroradiograph unless it is covered with lead paint. US is the technique of choice to evaluate for a wood FB, but CT or MRI may also be helpful.

Occasionally, the most expeditious method of removing small wooden splinters is complete excision of the entrance tract and the FB en bloc, followed by a linear closure.

**Pencil Lead**

Good judgment must be used in removing graphite from pencils when lodged in the skin. Because graphite invariably leaves a pigmented tattooing in the soft tissue, it is preferable to excise the material en bloc when pencil lead is found in a cosmetic area. The graphite specks cannot be irrigated or scrubbed off, and tattooing results if they are not removed.

**Metallic Fragments**

High-velocity fragments (e.g., bullets, BBs, chips of wood-splitting mauls, or other metallic particles caused by metal striking metal) are easy to visualize radiographically and relatively simple to remove unless they are embedded in areas that are anatomically difficult to approach. Before removal of the FB, the area in which the fragment is embedded should be assessed to determine which structures are involved along the wound entrance, which structures might be encountered in attempting to cut down on the FB, and which of those structures can be sacrificed to allow for adequate removal of the foreign material. It is preferable to defer the removal of deeply embedded metallic FBs unless symptoms of infection develop.

The treatment of high-velocity FBs (as seen with modern military or sporting ammunition) and their associated wounds is beyond the scope of this discussion. Retained nonexplosive metallic fragments are inert and rarely cause infection. They usually become encysted after a period of

time. Lead toxicity from bullet fragments is rare and generally only of concern when the fragment is in contact with synovium (see previous discussion). The value of routine prophylactic antibiotics for metallic FBs left in the soft tissue has not been proved.

A sterile magnet may be used to facilitate removal of small metallic fragments. [33] The magnet is introduced into the entry site using a small scalpel and hemostat to extend and open the wound, respectively, as needed. When the magnet contacts the metal, a click is heard. The FB is then removed, attached to the magnet. If there is resistance to extraction of the object, directed exploration can be done with the FB attached to the magnet.

Taser darts used for immobilization of violent individuals are like fishhooks and must be removed under local anesthesia after the attached wires have been cut. Backing the dart out as with a fishhook is not possible owing to the dart's unique construction. Cutting down on the dart under local anesthesia is the preferred method of removal. [34] [35]

**Marine Foreign Bodies**

While most marine FBs, such as shell fragments, may be treated like other FBs, a number of marine animals carry toxins and may leave FBs that require special consideration.

**Catfish.**

Several species of catfish in North America contain toxic venom, and their sting can imbed an FB. Envenomation occurs when the fish becomes agitated and the dorsal and pectoral spines become locked in the extended position and penetrate the hand or foot. The venom is then secreted from an epidermal gland at the base of the spine. [36] This is initially quite painful but is usually transient, and there is no specific antitoxin. Treatment consists of local care and analgesics. The affected part should be immersed in hot water (approximately 43.3 °C [110 °F]) for at least 30 minutes if pain is severe. This is believed to provide symptomatic relief by decreasing vascular and muscle spasm. [37] Local injection of the wound with alkalized bupivacaine provides local analgesic and may also neutralize the toxin. [36] The wound should be inspected and any remaining spine removed. A radiograph may be taken to confirm the absence of FBs, but catfish spines and cartilage may be radiolucent. The wound should be thoroughly cleaned and irrigated. Tetanus prophylaxis should be updated. Some authors [36] recommend empiric antibiotic therapy to cover gram-negative bacilli (e.g., *Aeromonas hydrophila*), but infection is quite rare, and routine antibiotic prophylaxis is not standard.

**Coelenterates.**

Coelenterates, including the Portuguese man-of-war, the true jellyfish, fire coral, the box jellyfish, and sea anemones, inject a toxin that is responsible for many marine envenomations. Reactions to the toxin may be local or systemic, and pain may be severe. Systemic reactions usually consist of fever, chills, and muscle spasm, but severe reactions may result in neurologic sequelae ranging from malaise and headache to coma and paralysis. Cardiopulmonary manifestations include dysrhythmias, hypotension, syncope, bronchospasm, laryngeal edema, and cardiorespiratory failure. [38] [39]

Coelenterates do not inject FBs per se, but deposit their venom-containing organelles, called *nematocysts,* on the skin of the unfortunate victim (Fig. 39-18) . Nematocysts are present by the thousands on the tentacles of coelenterates, and even minimal contact with the animal causes the tentacles to break off and adhere to the skin. Nematocysts are released from the tentacles, cling to the skin, and discharge venom. An injection apparatus in the nematocyst penetrates the dermis and diffuses the venom into the soft tissue. Decontamination and removal of the nematocysts decrease pain and systemic reactions.

Vinegar (5% acetic acid) is the initial decontaminating agent of choice and will inactivate nematocystic discharge of most species of jellyfish, Portuguese man-of-war, and sea anemones. [38] This should be applied continuously for 30 minutes, or until the pain is gone. [39] Fresh water should not be applied to the wound, as this may worsen the envenomation by stimulating nematocyst discharge. Isopropyl alcohol has also been used as a decontaminating agent but has been shown to cause nematocyst discharge in vitro. [38] Other suggested but unproven remedies include meat tenderizer, ammonia,

baking soda, urine, olive oil, sugar, and papaya latex.

After the wound has been decontaminated, remaining tentacle fragments should be removed. Large fragments may be removed with forceps. Individual nematocysts are quite small (<1 mm in length) and are not easily visible to the eye, but if there is local pain, it should be assumed that the organelles remain on the skin. Some nematocysts are so small that they must be seen with a microscope on skin biopsy. Nematocysts should not be removed by rubbing the

skin with sand, as this increases venom discharge. To remove remaining nematocysts, the skin should be scraped with a hard edge, such as a knife blade or credit card held perpendicular to the skin. Remaining fragments may also be removed by applying shaving cream and shaving the area gently. [39]

After decontamination, topical anesthetics or steroids may be used. Prophylactic antibiotics are not necessary. Routine wound care should be followed. Allergic and systemic reactions should be treated appropriately. Antivenin is available only for box jellyfish envenomation (1 to 3 ampules).

**Coral.**

Fire corals are another type of coelenterate that produces toxicity by stinging. Other corals are sharp and irritating if touched. "Coral cuts" occur in divers and snorkelers exploring coral reefs. These organisms can produce deep cuts, with local reactions such as pruritus, erythema, and urticaria occurring at the site of the injury. Delayed healing may occur with secondary development of cellulitis or ulceration, perhaps as a result of contamination of the wound with bacteria or microparticles of coral. [38] Treatment consists of saline irrigation. Hydrogen peroxide may be used to remove small coral particles from the wound. [38] The wound should not be closed; wet-to-dry dressings may be used.

**Sponges.**

Sponges produce both an irritant and a contact dermatitis. The irritant dermatitis occurs as a result of sponge spicules embedded in the victim's skin. These spicules may be removed with adhesive tape (applied to the skin and then peeled back) and the area should then be bathed with vinegar. [38] The contact dermatitis which is believed to be caused by a toxin produces erythema, pruritus, and vesicles similar to poison oak. [38] Treatment is initial immersion in vinegar followed by local steroid creams.

**Sea urchins and starfish.**

Sea urchins and starfish are free-living echinoderms covered with spines that may contain toxins. These spines are sharp and brittle and may become embedded in victims if they inadvertently step on or handle these creatures. A severe local reaction may result from the venom contained in the spines. Local pain usually responds quite well to immersion in hot water (43.3 to 46.1 °C [110 to 115 °F]) for 30 to 90 minutes.

Retained spines may become infected or cause delayed (up to 1 to 2 months) FB granulomas. This reaction is poorly understood but may produce an intense and persistent inflammatory reaction. Spines that penetrate joints may induce a synovitis. Echinoderm spines may discharge a purple dye that may be mistaken for a retained spine. [39] Spines are usually visible on radiographs and should be removed if possible, although they are brittle and can break off in the skin. If located in a joint or near a nerve, surgical extraction may be necessary using an operative microscope. [38] Otherwise, if removal is difficult, the spine may be left in place until it resorbs or a local reaction takes place. The wound may then be opened and drained and allowed to close by secondary intention.

**Stingrays.**

Stingray envenomation usually occurs when a bather accidentally steps on an animal that is resting on the bottom in shallow water, covered by sand (Fig. 39-19) . This causes the stingray to lash out its whip-like caudal appendage, or tail, which contains 1 to 4 venom-containing stinging spines. The spines are sharp and jagged and can produce a significant laceration. Portions of the spine may become buried in the victim's skin. Each spine is covered with a sheath containing venom glands, and in addition to immediate toxin-induced pain, pieces of the spine or sheath may be left in the wound. These fragments do not dissolve and must be removed, but they are often difficult to locate. Persistent pain and inflammation (weeks to months after the attack) mandate consideration of a retained FB, but a persistent and difficult-to-treat irritative process can occur in the absence of a retained spine or sheath. Immediate local and systemic reactions occur as a result of injection of a complex toxin. Systemic reactions may be severe and can include muscle cramps, vomiting, seizures, hypotension, arrhythmias, and (rarely) death.

Treatment consists of irrigation with saline or fresh water followed by hot water immersion at 43.3 to 46.1 °C (110 to 115 °F). Local anesthetics without vasoconstrictors provide effective analgesia. All wounds should be explored and debrided, all remnants of the spine and integumentary sheath removed. [38] The wound should not be closed.

**Antibiotic therapy.**

Prophylactic antibiotic therapy for marine injuries is common. Unlike other soft tissue infections, marine injuries become infected with unusual gram-negative organisms, particularly *Vibrio* species. Although there are little data evaluating the effect of specific antibiotics, it is recommended that quinolones, trimethoprim-sulfamethoxazole, or aminoglycosides be used in lieu of penicillin, ampicillin, erythromycin, or first-generation cephalosporins. [39] It is always difficult to differentiate chronic inflammation caused by toxins and foreign material from true infection, and often surgical exploration is required in persistent cases. Tetanus prophylaxis should be routine.

**Cactus Spines**

Cactus spines vary considerably in size. The difficulty of removal is generally inversely

proportional to the FB size. [40] Larger embedded cactus spines are managed like wood splinter and sea urchin spine FBs. More advanced imaging techniques (xeroradiography, ultrasonography, CT, or MRI) may be required for localization of deeply embedded spines.

Deeply embedded cactus spines generally produce granulomatous reactions, and infections are rare. [19] Hence, efforts to remove deeply embedded spines should be made after carefully weighing the benefit and potential harm related to a deep exploration, especially in a sensitive location. [40] Superficially embedded medium- to large-sized cactus spines are best removed by direct axial traction of each spine using forceps. Smaller spines (glochids) may be difficult and tedious to remove individually. Adherent facial mask gel application and removal of spines en masse with the mask are recommended (Fig. 39-20) (Figure Not Available) . Depilatory wax melted in a microwave oven and applied warm, [41] commercial facial gels, [40] [42] and household glue (Elmer's Glue-All [Borden Inc., Columbus, OH]) have all been recommended for this purpose. [43] The practitioner should be aware that over-the-counter "home use" facial mask gels are not adherent enough to be effective without multiple applications (up to 8 or more).

### Postoperative Foreign Bodies

FBs in the form of nonabsorbed suture material are frequently encountered in the postoperative period. Drainage, localized inflammatory reaction along the suture line, and localized pain and tenderness are characteristic of a retained FB (suture abscess). In this instance, probing the wound with a sterilize needle bent in the shape of a crochet hook is frequently rewarding. Hooking the suture material through the sinus tract and removing it allows the wound to heal over the tract.

### Ring Removal

Frequently, a ring must be removed to prevent laceration of tissue or vascular compromise. If removal is not possible using thorough lubrication (a water-soluble lubricant [e.g., K-Y jelly]) and a circular motion with traction on the ring, it may be necessary to either cut the ring off or remove it by the string-wrap method. It is preferable to remove all rings before the edema is extensive enough to cause pain or vascular compromise.

#### String-wrap method.

An occasional patient can remain calm during this procedure, but if swelling is significant or the digit has been traumatized, anesthesia is necessary (Fig. 39-21) . Anesthesia is obtained by a digital or metacarpal block applied to produce minimal tissue distention. Prior to ring removal, a wide Penrose drain is wrapped circumferentially in a distal-to-proximal direction to reduce soft tissue swelling. For maximum effect, the wrap should remain in place for a few minutes. Some nonanesthetized patients panic during the procedure because of increasing pain due to

compression and unwinding. [44]

A 20- to 25-inch piece of string, umbilical tape, or thick silk suture is first passed between the ring and the finger. Shorter lengths are discouraged, as one may need to repeat the wrapping procedure midway. If there is marked soft tissue swelling, the tip of a hemostat may be passed under the ring to grasp the string and pull it through the ring. The distal string is wrapped clockwise around the swollen finger (proximal to distal) to include the proximal interphalangeal (PIP) joint and the entire swollen finger. The wrapping is begun next to the ring. The wrap should be snug enough to compress the swollen tissue. The successive loops of the wrap are placed next to each other to keep any swollen tissue from bulging between the strands. When the wrapping has been completed, the proximal end of the string is carefully unwound in the same clockwise direction, forcing the ring over that portion of the finger that has been compressed by the wrap. The PIP joint is the area that is most difficult to maneuver and that causes the most pain to the patient.

Occasionally, one must rewrap the finger if it was not carefully wrapped initially. It is not uncommon to produce abrasions or other trauma to the skin during this procedure. If the finger with the ring is lacerated or there are underlying fractures, it is prudent to cut off the ring instead of attempting this technique.

Two alternatives to this procedure have been described. The first one uses an entire skein of 2.0 surgical silk ties instead of a single piece of string. The procedure is the same: The ties are passed underneath the ring with a hemostat. The short ends of the ties are clamped with a hemostat on the hand side of the ring. The long end of the skein is wrapped around the finger and then unwound from the short end, as described above. This method may be less traumatic to the finger than a single piece of string. [45]

The second technique uses a 3- to 4-mm rubber band that is passed beneath the ring after the finger has been lubricated with soap or petroleum jelly. The physician then places a finger through both loops of the rubber band (1 above and 1 below the ring) and pulls the rubber band distally while moving the rubber band circumferentially around the ring and the finger until the ring is removed.

**Ring cutter.**

A ring cutter should be used if the ring is not of high value or there is excessive swelling. Manual and power devices are available. The ring cutter has a small hook that fits under the ring and serves as a guide for a saw-toothed wheel that cuts the metal. The cut ends of the ring are spread using large hemostats (e.g., Kelly clamps), and the ring is removed. Cut rings may be repaired by a jeweler.

**Tick Removal**

Early removal of ticks is advisable, since the hard tick of the Ixodid family is likely to transmit disease. Rocky Mountain spotted fever, Lyme disease, tularemia, and ascending paralysis have been identified as tick-borne diseases. Tick removal of Ixodid

ticks is difficult, because the mouth parts are cemented to the skin of the host (Fig. 39-22 *A*). The longer the tick is attached, the more difficult removal may become. Traditional and folk methods of forcing the tick to disengage (e.g., the use of petroleum jelly, fingernail polish, a hot match, or alcohol) are probably ineffectual, and removal by mechanical means is recommended. [47]

Protection of the operator by use of a hemostat or gloves is advisable. The tick is grasped as close to the patient's skin surface as possible and gently pulled free with steady axial traction (Fig. 39-22 *B*). The tick body should not be squeezed, crushed, or punctured. If mouth parts are left behind after removal of the body, excision under local anesthesia is needed to prevent local infection.

Many patients have great anxiety over subsequent tick-borne diseases following tick removal. There is no standard of care for the use of prophylactic antibiotics to prevent Lyme disease or Rocky Mountain spotted fever. Theoretically, a tick infected with Lyme disease must remain attached for 24 hours to transmit the disease, and even then, only 10% to 20% of bites from infected ticks will result in transmission.  Although all patients should be advised about the signs and symptoms of these diseases, routine prophylactic antibiotic use is controversial. Prophylactic antibiotics (ampicillin or tetracycline) following tick removal may be more reasonable in endemic areas.

### Zipper Injuries

The skin of the penis may become painfully entangled in a zipper mechanism. Unzipping the zipper frequently lacerates the skin and increases the amount of tissue caught in the mechanism. Although the physician may anesthetize the skin and excise the entrapped tissue, a less invasive method may be useful.

The interlocking teeth of the zipper fall apart if the median bar (diamond or bridge) of the zipper is cut in half (Fig. 39-23) (Figure Not Available) . The skin is subsequently freed. A bone cutter or wire clippers and a moderate amount of force may be required to break the bar. Patients with penile lacerations warrant urologic follow-up to assess for urethral injury.

### Hair-Thread Tourniquet

Hair or thread fibers adherent to infant clothing occasionally become tightly wrapped about the child's digits or genitals (Fig. 39-24) . [48] If these are left in place, automatic amputation may eventually occur. The offending fibers may be difficult to visualize, and the child is often brought for evaluation only after signs of distal ischemia appear. Occasionally the fiber can be grasped with toothless forceps or a small hemostat and unwrapped. More commonly the fibers cannot be identified and are deeply imbedded in swollen tissue.

A No. 11 blade can be used to cut the constricting bands under a regional nerve block. It may be difficult to identify individual hairs that are deeply imbedded in a swollen digit and even more difficult to assess the success of one's intervention. Often multiple hairs

are involved. Because the bands may be quite deep, the incision should avoid known neurovascular tracts. Barton and colleagues [48] recommend a dorsal, rather than lateral, incision on the digits. If the soft tissue of the distal digit has been rotated following a circumferential dermal laceration from the tourniquet, the distal tissue can be realigned with the proximal tissue and 2 dorsolateral sutures placed to maintain the digit in alignment.

Generally, conservative wound care is sufficient once the band has been removed. Application of an antibiotic ointment may enhance healing and allow easier removal of serous drainage from the circumferential laceration. Clinical reassessment in 24 hours will indicate whether any constricting bands remain.

# Chapter 40 - Incision and Drainage

**Howard Blumstein**

Cutaneous abscesses are among the soft tissue infections most frequently encountered in the emergency department (ED). Approximately 1 to 2% of patients presenting to the ED receive care for cutaneous abscesses. [1] [2] In contrast with most bacterial diseases, which are usually described in terms of their etiologic agent, cutaneous abscesses are best described in terms of their location. There has been little systematic investigation into the bacteriology of simple cutaneous abscesses, and there have been few new recommendations for improved management over the years. The probable reason for this lack of scientific rigor is the predictable and striking clinical recovery once a mature abscess is incised and drained. The exact reasons for this amelioration of local and constitutional symptoms are unknown; however, it is clear that the exact bacteriology of cutaneous abscesses, while academically interesting, is essentially inconsequential to the final outcome in most cases. [3]

Although most incision-and-drainage procedures are performed for decompression of purulent collections, drainage of sterile hematomas or seromas may be required in the ED. In general, the same principles used for formal drainage of pus in the soft tissues apply to drainage of a sterile fluid collection, and hence one can directly apply the principles of this chapter to the drainage of sterile fluids. In addition, when a sterile fluid collection is drained, the operator has the option of primarily closing the incision site following wound irrigation (see Chapter 37 for wound closure techniques). Drainage of a soft tissue hematoma is generally best postponed several days following an initial injury to permit hemostasis and to minimize the risk of hematoma reaccumulation following drainage. The procedure is generally reserved for those soft tissue hematomas that are large and painful (secondary to tissue distention) and are expected to either resolve slowly or result in soft tissue deformity if not drained. Drainage of a subungual hematoma represents a special case of hematoma drainage and is discussed in detail later in this chapter.

## ABSCESS ETIOLOGY AND PATHOGENESIS

Localized pyogenic infections may develop in any region of the body and usually are initiated by a breakdown in the normal epidermal defense mechanisms, with subsequent tissue invasion by normal resident flora. Thus, an abscess is likely to be caused by the flora that are indigenous to that area. An exception is direct inoculation of extraneous organisms, such as infections that follow mammalian bites.

Staphylococcal strains, which are normally found on the skin, produce rapid necrosis, early suppuration, and localized infections with large amounts of creamy yellow pus. This is the presentation of a typical abscess. Group A beta-hemolytic streptococcal infections, on the other hand, tend to spread through tissues, causing a more generalized infection characterized by erythema and edema, a serous exudate, and little or no necrosis. This is the presentation of a typical cellulitis. Anaerobic bacteria proliferate in the oral and perineal regions; produce necrosis with profuse brownish,

foul-smelling pus [3] ; and may cause both abscess and cellulitis.

Normal skin is extremely resistant to bacterial invasion, and few organisms are capable of penetrating the intact epidermis. In the normal host with intact skin, the topical application of even very high concentrations of pathogenic bacteria does not result in infection. The requirements for infection include a high concentration of pathogenic organisms, such as occurs in the hair follicles and their adnexa; occlusion, which prevents desquamation and normal drainage, creating a moist environment; adequate nutrients; and trauma to the corneal layer, which allows organisms to penetrate. [4] Trauma may be the result of abrasions, hematoma, injection of chemical irritants, incision, or occlusive dressings that cause maceration of the skin. Foreign bodies can also potentiate these infections and decrease the number of bacteria necessary for infection. An example of this is the ubiquitous suture abscess, which frequently develops in otherwise clean wounds closed with suture material.

When favorable factors are present, normal flora of cutaneous areas can then colonize and infect the skin. The bodily area involved depends primarily on host factors. In persons performing manual labor, the arms and the hands are infected most frequently. In women, the axilla and submammary regions are frequently infected because of minor trauma from shaving and garments and because of the abundance of bacteria in these areas. IV drug users may develop infections anywhere on the body, although the upper extremities are most commonly affected. [5] [6] Deep soft tissue abscesses have also been described following attempts at access to the deep venous structures in addicts who have exhausted all peripheral venous access sites. [7] In addition, areas with compromised blood supply will be more prone to infection, because normal host cell-mediated immunity is not as available. [4] Septic emboli from endocarditis may cause abscess formation by bacteremic migration of infected material into subcutaneous (SQ) tissue.

Infections in the soft tissue often begin as a cellulitis. Some organisms cause necrosis, liquefaction, and accumulation of leukocytes and debris, followed by loculation and walling off of pus, all of which result in the formation of 1 or more abscesses. There may be involvement of the lymph tissues, producing lymphangitis and subsequent bacteremia. As the process progresses, the area of liquefaction increases until it "points" and eventually ruptures into the area of least resistance. This may be toward the skin or the mucous membrane, into surrounding tissue, or into a body cavity. If the abscess is particularly deep-seated, spontaneous drainage may occur, with persistence of a fistulous tract and the formation of a chronic draining sinus. This development, or the recurrence of an abscess that has been previously drained, should always suggest the possibility of osteomyelitis, a retained foreign body, or the presence of unusual organisms such as *Mycobacterium* or *Actinomyces.*[3]

**Bacteriology of Cutaneous Abscesses**

Meislin and coworkers [1] cultured abscesses in 135 patients, and their report typifies the bacteriology and natural history of cutaneous abscesses. Their patients received simple incision and drainage, and all subjects were followed as outpatients. Both aerobic and anaerobic cultures were taken. Most (96%) cultures were positive for bacteria (Table

40-1) (Table Not Available) .

In this series predominantly mixed aerobic bacteria were isolated in abscesses of the trunk, axilla, extremities, and the hand. In pure cultures, *Staphylococcus aureus* was found in 72% of cases. One third of the cultures from the perianal region contained only anaerobes. Mixed cultures of both aerobic and anaerobic bacteria were obtained from all sites of the body, but there was a 67% incidence of such mixed cultures from the perirectal area. Commonly isolated anaerobes included various *Bacteroides* spp, peptococci, peptostreptococci, *Clostridium* spp, *Lactobacillus* spp, and *Fusobacterium* spp.

Bacteria from abscesses in areas remote from the rectum were generally aerobic strains and were primarily indigenous microflora of the skin. *S. aureus* was the most prevalent aerobic organism; it was isolated in 24% of all abscesses.

Gram-negative aerobes were isolated infrequently from cutaneous abscesses. *Escherichia coli, Neisseria gonorrhoeae,* and *Pseudomonas* spp were rarely found. The most commonly isolated gram-negative organism was *Proteus mirabilis.* This organism was found almost exclusively in the axilla, and its presence may be related to the use of underarm deodorants. [8]

Brook and Finegold [9] studied the bacteriology of cutaneous abscesses in children. Their results closely correlate with those of Meislin and associates. [1] Brook and Finegold found aerobes (staphylococci and group A beta-hemolytic streptococci) to be the most common isolates from abscesses of the head, neck, extremities, and trunk, with anaerobes predominating in abscesses of the buttocks and perirectal sites. Mixed aerobic and anaerobic flora were found in the perirectal area, head, fingers, and nailbed area. This study found an unexpectedly high incidence of anaerobes in nonperineal abscesses. Anaerobes were found primarily either in areas adjacent to mucosal membranes, where these organisms tend to thrive (e.g., the mouth), or in areas that are easily contaminated (e.g., by sucking fingers, which causes nailbed and finger infections or bite injuries).

Parenteral drug users develop somewhat atypical abscesses. Webb and Thadepalli found anaerobes to be a major pathogen, regardless of anatomic location. [10] A more recent study of IV drug users found that skin abscesses at the site of injection contained predominantly staphylococcal and streptococcal species. Four of the 20 staphylococcal isolates were oxacillin resistant. Anaerobes and gram-negative bacilli accounted for 24% of the isolates. [11] Because IV drug use is associated with immunodeficiency syndromes, unusual isolates such as *Candida albicans*[12] and acid-fast bacilli have been obtained.

The polymicrobial nature of abscesses does not lend itself to a strict scientific interpretation of culture results, but if an unexpected or atypical organism is found in an abscess culture, the clinician should consider an underlying process not readily apparent from the history or physical examination. Most typical is finding tuberculosis or fungal isolates in immunocompromised patients (e.g., those with diabetes or acquired immunodeficiency syndrome [AIDS]). Finding *E. coli* suggests an enteric fistula or even

self-inoculation of feces in psychiatric patients or in patients with Munchausen's syndrome. Recurrent abscesses without an obvious underlying cause could indicate clandestine drug use ("skin popping").

**Special Considerations**

Parenteral drug users, insulin-dependent diabetics, hemodialysis patients, cancer patients, transplant recipients, and individuals with acute leukemias have an increased frequency of abscess formation compared with the general population. Local symptoms may not be the primary complaint, and the patient may present only with an exacerbation of the underlying disease process or an unexplained fever. These abscesses tend to have exotic or uncommon bacteriologic or fungal causes and typically respond poorly to therapy. The diabetic patient with diabetes-induced ketoacidosis should be evaluated extensively for an infectious process; a rectal examination should be included with the physical examination to rule out a perirectal abscess. This also holds true for other patients with abnormal cell-mediated immunity. The increased frequency of abscess formation in these patients and in the parenteral drug user is multifactorial. There may be intrinsic immune deficiencies in all these patients; they have an increased incidence of *Staphylococcus* carriage, and they have frequent needle punctures which allow access by pathogenic bacteria.

It is important to note that a substantial percentage of abscesses in parenteral drug users are sterile and are the result of the injection of necrotizing chemical irritants. Drug users frequently use veins of the neck and the femoral areas, producing abscesses and other infectious complications at these sites. Any abscess near a vein of the antecubital fossa or dorsum of the hand should alert the physician to possible IV drug use; however, substance users may also inject directly into the skin ("skin popping"), causing cutaneous abscesses away from veins (Fig. 40-1) .

The presence of a foreign body may serve as a nidus for abscess formation. A history of a possible foreign body at the site of an abscess should be sought. Because IV drug users frequently break needles off in skin toughened by multiple injections, the clinician should maintain a high index of suspicion for retained needle fragments. If an abscess is recurrent or if the patient is a known or suspected IV drug user, radiographs or other techniques should be considered to search for foreign bodies.

## MANIFESTATIONS OF ABSCESS FORMATION

The diagnosis of cutaneous abscess formation is usually straightforward. The presence of a fluctuant mass in an area of induration, erythema, and tenderness is clinical evidence that an abscess exists. An abscess may appear initially as a definite tender soft tissue mass, but in some cases the presence of a distinct abscess may not be readily evident. If the abscess is quite deep, as is true of many perirectal, pilonidal, or breast abscesses, the clinician may be misled by the presence of only a firm, tender, indurated area without a definite mass. To avoid misdiagnosis of an early abscess, one may aspirate the suspicious infected area with a needle and syringe to confirm the presence of pus. [18] This approach also may help identify a mycotic aneurysm or an inflamed lymph node simulating an abscess. A specific entity that is commonly mistaken

for a discrete abscess is the sublingual cellulitis of Ludwig's angina (see Chapter 69) . Cellulitis and abscess formation may lead to bacteremia and sepsis, especially in the immunocompromised patient, and the presenting complaints may draw attention from the primary focus of infection

## LABORATORY FINDINGS

*Laboratory tests offer no specific guidelines for therapy of a cutaneous abscess and are not generally indicated.* An exception would be a blood or urine glucose determination to assess diabetes in patients with appropriate clinical scenarios. An abscess may produce leukocytosis, depending on the severity and duration of the abscess process; however, the majority of patients with an uncomplicated cutaneous abscess will have a normal complete blood cell (CBC) count and will not experience fever, chills, or malaise. The presence or absence of leukocytosis has virtually no diagnostic or therapeutic implications.

*Gram stain is not indicated in the care of uncomplicated simple abscesses.* Patients who appear "toxic" or immunocompromised and those patients who require prophylactic antibiotics (see Prophylactic Antibiotics) may benefit from Gram stain and cultures. Gram stain results have been shown to correlate well with subsequent culture results, and in compromised hosts the test can be used to direct antibiotic choice. [18] [19] Anaerobic infections should be suspected when multiple organisms are noted on Gram stain, when a foul odor is associated with the pus, when free air is noted on radiographs of the soft tissue, or when no growth is reported on cultures." [10]

In uncomplicated abscesses, *routine culture is unnecessary* because of the expected prompt response to surgical therapy and the polymicrobial nature of abscess formation. However, in complicated cases or in immunosuppressed patients, an abscess should be cultured. The information obtained may later be useful if there is poor response to the initial surgical drainage, secondary spread of the infection, or the occurrence of bacteremia. [3] If one takes a culture, it is best to aspirate the pus with a needle and syringe *before* incision and drainage. Material should be cultured for aerobic and anaerobic bacteria. The finding of a "sterile" culture in an abscess that has been cultured with a standard cotton swab *after* incision is frequently the result of improper anaerobic culture techniques. As a side note, there is a general misconception that foul-smelling pus is a result of *E. coli.* This foul odor is actually caused by the presence of anaerobes; the pus of *E. coli* is odorless.

## INDICATIONS AND CONTRAINDICATIONS

Surgical incision and drainage is the *definitive treatment* of a soft tissue abscess. [18] Antibiotics alone are *ineffective* in the face of a localized collection of pus. The drainage of a suppurative focus results in a marked improvement in symptoms and rapid resolution of the infection in uncomplicated cases. Premature incision before localization of pus will not be curative and theoretically may be deleterious, because extension of the infectious process and bacteremia from manipulation can result. In some cases the application of heat to an area of inflammation may ease pain, speed resolution of the cellulitis, and facilitate the localization and accumulation of pus. It must be stressed that

nonsurgical methods are not a substitute for surgical drainage and should not be continued for >24 to 36 hours before the patient is reevaluated. Diagnostic needle aspiration is recommended if one is unsure of pus localization.

# ANCILLARY ANTIBIOTIC THERAPY

The use of antibiotics remains controversial for both prophylaxis and treatment of cutaneous abscesses. As an overview, there are no data that definitively demonstrate the need for antibiotic therapy in conjunction with incision and drainage of uncomplicated cutaneous abscesses in healthy, immunocompetent patients without valvular heart disease. The specific value of concomitant antibiotics in the immunocompromised patient, while intuitively attractive, is unclear. Patients with risk factors for endocarditis comprise a third group of patients. Because of the concern of inducing a bacteremia by manipulation of infected tissue, parenteral antibiotics are commonly given *prior to the incision-and-drainage procedure* in patients at risk from such bacteremia. Transient bacteremia has been documented (incidence range, 7 to 50%) following manipulation of noninfected tissue (brushing teeth, sigmoidoscopy, Foley catheter, rectal examination) and following simple incision and drainage of abscesses. In a report by Fine and colleagues, 6 of 10 patients with cutaneous abscesses were noted to have positive blood cultures immediately following incision and drainage, whereas all cultures were negative before the procedure. [20] Blick and associates evaluated the use of prophylactic antibiotics in abscesses managed in the operating room under general anesthesia. Three of 19 patients developed bacteremia after the procedure. A similar group treated with parenteral antibiotics before the procedure had only 1 patient with a positive blood culture. That culture yielded an organism resistant to the prophylactic antibiotic used. [21]

## Prophylactic Antibiotics

### Prophylaxis for Endocarditis

The precise risk for endocarditis following incision and drainage of cutaneous abscess is unknown, and it is impossible to predict which patients will develop this infection or which particular procedure will be responsible. However, since bacteremia clearly occurs with manipulation of infected tissue, it is generally agreed that those patients at risk forcardiac complications related to transient bacteremia should be treated with appropriate antibiotics within the hour preceding the procedure. The transient bacteremia secondary to abscess drainage is probably of no concern in otherwise healthy, immunocompetent individuals without valvular heart disease.

No adequate controlled trials of antibiotic regimens appear in the literature, and data predicting the incidence of endocarditis in patients with preexisting cardiac disorders are lacking, thereby making the decision regarding antibiotic prophylaxis quite arbitrary. However, the Committee on Rheumatic Fever and Infective Endocarditis of the American Heart Association (AHA) has recommended that prophylactic antibiotics be given prior to incision and drainage of infected tissue in patients who have *cardiac lesions that place them at high risk for developing endocarditis.*[22] Table 40-2 (Table Not Available) lists conditions that may warrant antibiotic coverage. Durack also

recommends prophylactic antibiotics for a variety of procedures known to have a significant incidence of bacteremia, including incision and drainage of cutaneous abscesses. [23] Interestingly, the antibiotic regimen suggested by the AHA (Table 40-3) (Table Not Available) does not include antibiotics effective against many organisms commonly found in some cutaneous abscesses, specifically *S. aureus,* but is mainly directed against *Streptococcus viridans* and enterococcus. These latter organisms have a predilection for valvular infection. The AHA recommends the same prophylaxis for incision of soft tissue infection that is recommended for genitourinary procedures, but with additional consideration of therapy "directed against the most likely pathogen." [24]

Two clinical situations deserve special note. Because of the frequent incidence of endocarditis and previous valvular damage in the patient who uses IV drugs, prophylactic antibiotics may be indicated prior to the incision and drainage of abscesses in these patients. Clearly, any patient with a documented history of endocarditis must receive prophylactic antibiotics prior to the incision-and-drainage procedure. Because cutaneous abscesses may result from active endocarditis and prophylactic antibiotics may obscure subsequent attempts at identifying an etiologic organism, 2 or 3 blood cultures (aerobic and anaerobic) should be obtained from those at risk for endocarditis prior to antibiotic therapy. Patients with the diagnosis of mitral valve prolapse have traditionally been included for treatment with prophylactic antibiotics. The indication for this is unclear. The risk of an allergic reaction may outweigh the benefits of treatment in this group, [25] and clinical judgment is required. Kaye [26] suggests prophylaxis only for patients who have a holosystolic murmur secondary to mitral valve prolapse.

*From Dajani AS, et al: Prevention of bacterial endocarditis. Circulation 83:1174, 1991.*

(Not Available)

---

* In the case of abscess drainage, include antibiotics directed against most likely pathogen if not included in this regimen.

**Prophylaxis for Bacteremia in Other Conditions**

Immunocompromised patients have not been adequately studied, but this is a subgroup that intuitively may benefit from prophylactic antibiotics. In contrast to patients with endocarditis risks, immunocompromised patients are at risk for developing septicemia secondary to a brief bacteremia. Since IV drug users have a high incidence of human immunodeficiency virus (HIV)-related disease, the treating physician must anticipate various degrees of immunodeficiency in these patients. Clinical judgment must determine the use of antibiotics in these situations.

No specific guidelines have been offered for the antibiotic regimen used prior to incision and drainage of infected cutaneous tissue in patients at risk for conditions *other than endocarditis*. Choice of antibiotics is guided by the organism anticipated to cause the bacteremia. Although the location of the abscess will give some clue to the organism involved, most abscesses contain multiple strains of bacteria. Not all bacteria are potent pathogens, so their mere presence does not predict their role in subsequent morbidity. Because *Staphylococcus* continues to be a significant organism in this setting, a broad-spectrum anti-staphylococcal drug is indicated. [5] Prophylaxis should consist of a single IV dose given a half hour prior to incision and drainage. A first-generation cephalosporin or penicillinase-resistant penicillin is a good initial choice. Vancomycin may also be considered. Others may prefer cefazolin (Ancef, Kefzol), 1 g, IV, given a half hour before surgery. This regimen covers staphylococcal and streptococcal species, many gram-negative organisms, and many anaerobes.

Although not widely used in the United States, parenteral antibiotics have been used to "sterilize" the abscess cavity following curettage in Great Britain. The concentration of clindamycin in the abscess cavity has been shown to be equivalent to the concentration of antibiotics found in the blood. [21] Some British articles report success with "primary closure under antibiotic coverage," although other British reports continue to recommend the traditional procedure.  One limitation to the abscess curettage technique is the need for general anesthesia, because the performance of curettage is extremely painful.

**Therapeutic Antibiotics**

In contrast to prophylaxis prior to surgery, the routine use of oral antibiotics following incision and drainage of simple cutaneous abscesses in otherwise healthy patients with no immunocompromise appears to have virtually no value, and their empiric use cannot be scientifically supported. Llera and Levy [2] performed a randomized double-blind study to compare outcomes of patients treated with a first-generation cephalosporin following drainage of cutaneous abscesses in the ED. They found no significant difference in clinical outcome between the 2 groups and concluded that antibiotics are unnecessary in individuals with normal host defenses. This confirmed previous less well controlled studies. It should be noted that high-risk patients were often excluded from these studies. The immunocompromised patient has not been adequately studied in this situation and is therefore often given antibiotics empirically, but this practice, while common, has not been supported by rigorous prospective studies.

Patients with cutaneous abscesses often have concomitant disease processes that may warrant the use of parenteral or oral antibiotics. Cellulitis or lymphangitis often accompany abscesses, and therapeutic antibiotics may have value under these circumstances, but again, this concept is not well addressed in the literature. Meislin noted that pathogen identification in cases of cellulitis without abscess can be difficult, and empiric antibiotics may be helpful. [35] IV drug users who present with an abscess and fever require parenteral antibiotic therapy after blood cultures have been drawn until subacute bacterial endocarditis can be ruled out. [36] Obviously, patients who are clinically septic require immediate IV antibiotics as well as aggressive surgical drainage

of pus.

As a general guideline, therapeutic antibiotics should be given to all immunocompromised patients (e.g., patients with AIDS or diabetes, patients receiving chemotherapy or steroids, transplant recipients, and alcoholic patients) and to the immunocompetent patient with "significant" cellulitis, lymphangitis, or systemic symptoms, such as chills or fever. Although it has not been studied, it makes sense to also give *antibiotics prophylactically, before surgery, to all patients who will obviously be given therapeutic antibiotics.* As with prophylactic antibiotics, a first-generation cephalosporin or semisynthetic penicillin is a reasonable therapeutic choice unless the specific abscess site dictates alternative therapy. The ideal duration of therapeutic antibiotics is unknown. As a general guideline, immunocompromised patients should receive antibiotics for 5 to 7 days and immunocompetent patients, for 3 to 5 days after the procedure, depending on the severity of the condition and clinical response.

Facial abscesses should be handled carefully and checked frequently. Any abscess above the upper lip and below the brow may drain into the cavernous sinus, and thus manipulation may predispose to septic thrombophlebitis of this system. Treatment with antistaphylococcal antibiotics and warm soaks following incision and drainage has been recommended pending resolution of the process. Areas *not* in this zone of the face can be treated in a manner similar to that used for other cutaneous abscesses.

## INCISION-AND-DRAINAGE PROCEDURE

### Procedure Site

Definitive incision and drainage of soft tissue abscesses is performed in either the ED or the operating room (OR). The choice of the locale for the procedure depends on a number of important factors. Location of the abscess may dictate management in the OR. Large abscesses or abscesses located deep in the soft tissues require a procedure involving a great degree of patient cooperation, which may only be possible under general or regional anesthesia. Proximity to major neurovascular structures, such as in the axillae or antecubital fossa, may necessitate specific management. Infections of the hand (with the exception of distal finger infections) have traditionally been managed in the OR because of the many important structures involved and the propensity for limb-threatening complications.

Lack of adequate anesthesia is the most common limiting factor in ED incision and drainage. If the clinician believes the abscess cannot be fully incised and drained because of inadequate anesthesia, the patient should be taken

to the OR for management under general anesthesia. In addition to limiting proper drainage, it is inhumane and unethical to subject a patient to extreme pain when alternatives are available.

When abscesses are drained in the ED, some centers prefer to use a special area of

the ED to avoid contamination of general treatment rooms.

**Equipment and Anesthesia**

A standard suture tray provides adequate instruments if a scalpel and packing material are added. Although sterility is impossible during the procedure, one should avoid contamination of surrounding tissue. Some physicians prefer to use an obligatory skin scrub with an antiseptic solution, but the value of this step is dubious.

It is often quite difficult to obtain local anesthesia by direct infiltration because of the poor function of local anesthetic agents in the low pH of infected tissue. Furthermore, the distention of sensitive structures by a local injection is quite painful and hence poorly tolerated by most patients. Skin anesthesia is usually possible, but total anesthesia of the abscess cavity itself generally cannot be achieved. If a regional block can be performed (see Chapters 32 and 33) , this type of anesthesia is preferred. Alternatively, a field block may be used. It should be noted that infected tissue is very vascular, and local anesthetics are quickly absorbed. Strict adherence to maximum safe doses of the local anesthetic is required.

The skin over the dome of an abscess is often quite thin, making skin anesthesia difficult. If a 25-ga needle is carefully used, one can often inject the dome of the abscess subcutaneously. The anesthetic solution spreads over the dome through the SQ layers into the surrounding skin and provides excellent skin anesthesia. If the needle is in the proper plane (best accomplished by holding the syringe parallel, rather than perpendicular, to the skin), the surrounding skin blanches symmetrically during infiltration without having to reposition the needle (Fig. 40-2 *A*). In the extremely anxious or uncomfortable patient, the judicious use of preoperative sedation (see Chapter 35) with IV opioids and sedatives or nitrous oxide makes the procedure easier for both patient and physician. If adequate anesthesia cannot be obtained and pain limits the procedure, the patient should be treated under general anesthesia.

Some clinicians recommend the use of topical ethyl chloride or Fluori-Methane spray for the initial skin incision, but the pain relief offered by this agent is variable and fleeting. Ethyl chloride is also highly flammable. These vapocoolant sprays may be useful to provide momentary anesthesia for local anesthetic injection or for the initial skin incision if the injection or incision is made immediately after blanching of the skin. In general, however, this agent is a poor choice for a stand-alone anesthetic agent for all but the smallest of superficial abscesses (e.g., purulent folliculitis).

**Incision**

One should make all incisions conform with skin creases or natural folds to minimize visible scar formation (Fig. 40-3) (Figure Not Available) . Extreme care should be taken in such areas as the groin, the posterior knee, the antecubital fossa, and the neck, so that vascular and neural structures are not damaged.

A No. 11 or 15 scalpel blade is used to nick the skin over the fluctuant area, and then a

simple linear incision is carried the *total length of the abscess cavity* (see Fig. 40-2 *B*). This will afford more complete drainage and will facilitate subsequent breakup of loculations. A cruciate incision or an elliptical skin *excision* is to be avoided in the routine treatment of cutaneous abscess. The tips of the flaps of a cruciate incision may necrose, resulting in an unsightly scar. A timid "stab" incision may produce pus but is generally not adequate for proper drainage. It should be emphasized that *the scalpel is used only to make the skin incision and is not used deep in the abscess cavity*.

Exceptions to this rule regarding aggressive incision are abscesses in cosmetic areas, in areas under significant skin tension (e.g., extensor surfaces), or in areas with extensive scar tissue (e.g., sites of multiple prior drainage procedures). In these special circumstances, a stab incision or simple aspiration alone may be initially attempted, with the goal of limiting tissue injury and resultant scar formation. Use of this less aggressive approach requires that the patient be counseled that multiple decompressions (e.g., via needle aspiration) or delayed aggressive incision and drainage may be required. The abscess will need reassessment in 24 to 48 hours to determine the need for additional intervention.

**Wound Dissection**

Following a standard incision, the operator should probe the depth of an abscess to assess the extent of the abscess and ensure proper drainage by breaking open loculations (see Fig. 40-2 *C*). An ideal instrument for this procedure is a hemostat wrapped in gauze (or a cotton swab for small abscesses) that is placed into the abscess and swirled around to all sides of the cavity (see Fig. 40-2 *D*). Traditionally the operator's gloved finger has been suggested as an ideal way to assess the depth of the abscess cavity and to break up loculations, but *this is a potentially dangerous practice that should be avoided* unless it is certain that the abscess contains no sharp foreign body. Of particular concern is the abscess caused by skin popping or IV drug use. Such patients have a high incidence of HIV infection, and occasionally these abscesses harbor broken-off needle fragments (Fig. 40-4) . One is often surprised at the depth or extent of an abscess during probing. Sharp curettage of the abscess cavity is usually not required and may produce bacteremia. [21] Although tissue probing is usually the most painful aspect of the technique and total local anesthesia is difficult to obtain, this portion of the procedure should not be abbreviated. If the procedure is limited because of pain, the use of appropriate analgesia/anesthesia is mandated.

**Wound Irrigation**

Following the breaking up of loculations, some physicians advocate copious irrigation of the abscess cavity with normal saline to ensure adequate removal of debris from the wound cavity. Although it may seem intuitively to be a helpful step, irrigation of the abscess cavity has not been experimentally demonstrated to significantly augment healing or affect outcome. Hyperemic tissue may bleed profusely, but bleeding usually stops in a few minutes if packing is used. Abscesses of the extremities can be drained during the use of a tourniquet to provide a bloodless field.

**Packing and Dressing**

After irrigation, a loose packing of gauze or other material is placed gently into the abscess cavity to prevent the wound margins from closing and to afford continued drainage of any exudative material that may otherwise be trapped. The packing material should make contact with the cavity wall so that upon removal, gentle debridement of necrotic tissue will spontaneously occur. A common error is to attempt to pack an abscess too tightly with excessive packing material. In essence, the pack merely keeps the incision open, and its main purpose is not to absorb all drainage--a dressing accomplishes this goal. Care must be exercised to ensure that the packing does not exert significant pressure against the exposed tissue and lead to further tissue necrosis. Some prefer to use plain gauze, some use gauze soaked in povidone-iodine, and some use gauze impregnated with iodine (iodoform). For large abscess cavities, gauze pads (without cotton backing) are ideal packing. *If gauze pads are used, the number of pads placed in the wound should be counted and charted--ideally, the corner of each pad should exit from the wound.* The clinician must ensure that all gauze pads will be removed when the packing is changed or discontinued. More commonly, thin (0.6 to 1.2 cm) packing strip gauze, either plain or iodoform, is used. The iodoform gauze may sting the patient for a few minutes after it is inserted. The value of antibiotic-impregnated gauze is uncertain.

An absorbent gauze dressing should be placed over the packed abscess, or, if an extremity is involved, a lightly wrapped circumferential dressing should be used. Generous amounts of dry gauze are used over the packing to soak up any drainage or blood. The affected part should be splinted if possible, and elevation should be routine. The dressing/splint should not be disturbed until the first follow-up visit. Drainage relieves most of the pain of an abscess, but postoperative analgesics may be required.

Following treatment, packing is often changed periodically. Most patients require a repeat visit to the physician for packing change, but if the original packing is to be removed and not replaced (paronychia, hair follicle abscess), selected patients may remove the packing and perform their own wound care totally at home.

## FOLLOW-UP CARE

Reevaluation of a drained abscess should occur in 1 to 3 days, depending on a number of parameters.  Most lesions are reevaluated 48 hours following the procedure, with the first packing change occurring at this time. Some wounds warrant closer monitoring. Diabetic patients or other patients with impaired healing capacity, mental impairment, or physical disabilities may require a home care nurse or admission for more frequent wound care/packing changes. Wounds that are at high risk for complications, such as those about the face or hands or those with significant cellulitis, require close follow-up, ideally by the same examiner. The patient should be encouraged to play an active role in wound care. During the first follow-up visit, the compliant and able patient should be taught to perform packing and/or dressing changes. If this is anatomically impossible, a

friend or family member can be instructed in the technique.

The technique of packing change is usually one of personal preference. It should be emphasized that patients often fear a repeat visit and expect significant pain with subsequent wound care, especially if the initial incision drainage was difficult. Therefore, the specifics of packing change should be addressed prior to release home after the initial drainage procedure. Some clinicians suggest an oral opioid be taken 30 to 40 minutes before the next visit or use local anesthesia or parenteral analgesia if significant pain is anticipated. Removal of packing material is often painful, but if the packing is moistened with saline prior to removal, it may be less traumatic. Once the packing is removed, the wound is inspected for residual necrotic tissue. The cavity may be irrigated with saline prior to replacing the pack if there is significant exudate, but this is often not required because the packing absorbs most debris.

The frequency of packing or dressing changes is also clinically guided. Some wounds require multiple packing changes, while other wounds require only the initial packing. In all facial abscesses, the packing should be removed after only 24 hours, at which time warm soaks should be started. Wounds large enough to require packing should be repacked at least every 48 hours (occasionally daily for the first few visits) until healing continues in a deep to superficial direction. Large wounds that are allowed to close superficially will create an unsterile dead space that will potentiate the formation of recurrent abscesses. After the first few days (and in the motivated and compliant individual), an alternative to packing is to have the patient clean the base of the abscess 3 times a day with cotton swabs soaked in peroxide (Fig. 40-5) . This promotes drainage, produces gentle debridement, and keeps the incision open. Following cleaning, the abscess can be irrigated with tap water and a dry dressing applied.

In general, once healthy granulation tissue has developed throughout the wound and a well-established drainage tract is present, the packing may be discontinued. The patient should then be instructed to begin warm soaks of the wound. [18] Gentle hydrostatic debridement may be performed by the patient in the shower at home. With this procedure the patient holds the skin incision open and directs the shower or faucet spray into the abscess cavity. Wet-to-dry normal saline dressing changes should then follow until healing is completed. When all signs of infection (e.g., erythema, drainage, pain, and induration) have resolved and healthy granulation tissue is present, the patient may be discharged from medical care.

Complicated wounds that require prolonged care are best followed by a single physician and should not be routinely referred back to the ED. These patients should receive early referral to their primary care physician or specialist. Wounds in cosmetically important areas may require revision once healing is complete. Patients should be informed of this possibility early on in their care.

In selected cases in which extensive or prolonged drainage occurs or in patients who are unable to return for proper follow-up care, a catheter system of drainage may be preferred. [37] [38] Following incision, a balloon-tipped or flared-tip catheter is placed into the abscess cavity, and pus is allowed to drain continuously through the catheter lumen. This technique has been most successful in pilonidal and Bartholin gland abscesses,

but the technique is applicable to any abscess *not* on the face.

## SPECIFIC ABSCESS THERAPY

### Staphylococcal Diseases

The *Staphylococcus* bacterium is a ubiquitous pathogen that frequently colonizes the nose, skin, perineum, and gut. The umbilicus of neonates is also commonly colonized. It grows on the skin and thrives particularly well in hair follicles, causing boils (furuncles), wound infections, and occasionally carbuncles. The pathogenesis of staphylococcal disease is a complex host-bacteria interaction. *S. aureus* invades the skin by way of the hair follicles or an open wound and produces local tissue destruction followed by hyperemia of vessels. Subsequently, an exudative reaction occurs, during which polymorphonuclear cells invade. The process then extends along the path of least resistance. The abscess may "point" or form sinus tracts. The process can disseminate by invasion of vessels and thus can infect other organs. Most cases of staphylococcal osteomyelitis, meningitis, and endocarditis occur by this mechanism. [39] [40]

*Folliculitis* represents a small abscess occurring at the root of a hair. Local measures, including warm compresses and antibacterial soaps and ointments, are the usual treatment, but systemic antibiotics may be required if multiple sites are involved or the patient is a chronic staphylococcal carrier. *Furuncles*, or boils, are acute circumscribed abscesses of the skin and SQ tissue that most commonly occur on the face, the neck, the buttocks, the thigh, the perineum, breast, or axilla. *Carbuncles* are aggregates of interconnected furuncles that frequently occur on the back of the neck (Fig. 40-6) . In this area the skin is thick, and extension therefore occurs laterally rather than toward the skin surface. Carbuncles may attain large size and can cause systemic symptoms and complications. They are found in increased frequency in diabetics, and all patients with a carbuncle should be evaluated for this underlying disease. Treatment should consist of surgical drainage and administration of systemic antibiotics. Large carbuncles may be impossible to drain adequately in the ED. Carbuncles usually consist of many loculated pockets of pus, and simple incision and drainage are often not curative. Occasionally, wide excision and skin grafting are required.

Most cases of recurrent staphylococcal skin infections are caused by autoinfection from existing skin lesions or nasal reservoirs. Prevention is directed at eliminating the organism. This is accomplished by application of bacitracin to the nares and by good hygiene, including frequent cleansing with antibacterial soap. If these measures are unsuccessful, then systemic oral antistaphylococcal treatment is instituted for 2 to 3 weeks. Detection and treatment of infection in family members may be necessary.

*S. aureus* produces the ubiquitous suture abscess. A *suture abscess* is often misdiagnosed as a wound infection, but in fact, it is a local nidus of inflammation and/or infection caused and potentiated by suture material. Such an abscess usually appears after sutures have been present for at least 3 to 5 days, with single or multiple discrete areas of redness and tenderness noted at the site of suture penetration of the skin. Simply removing the suture (a drop of pus may be expressed) and providing warm compresses and topical antibiotic ointment is usually all that is required. Wide opening

of the wound and systemic antibiotics are seldom required. When the suture is buried, a small incision should be followed by probing of the wound with a small hook or bent needle (see Chapter 39) to snare the suture for its removal.

## Hidradenitis Suppurativa

Hidradenitis suppurativa (Greek hidros = sweat, aden = gland) is a chronic, relapsing, inflammatory disease process affecting the apocrine gland that primarily involves the axilla, the inguinal region, or both. [41] The condition results from occlusion of the apocrine ducts by keratinous debris, which leads to ductal dilation, inflammation, and rupture into the SQ area. Secondary bacterial infection ensues, leading to abscess formation and scarring. This chronic recurring process leads to draining fistulous tracts, which involve large areas and are not amenable to simple incision-and-drainage procedures. [42]

Genetic factors may play some role in hidradenitis suppurativa. Family history is often significant in these patients. Fitzsimmons has proposed a single dominant gene transmission. [43] Blacks appear to have an increased incidence compared with whites. Although certain groups appear to be predisposed to this condition, the precipitating factor for this process is unclear. Because apocrine glands become active during puberty, it is rare to find hidradenitis suppurativa in the pediatric population. [41] Women are affected more frequently than men, for uncertain reasons. Shaving and depilation have frequently been suggested as causes of this discrepancy; however, this theory was not supported in a study that compared the frequency of these behaviors in patients with hidradenitis suppurativa and a group of controls. [44] Obesity is associated with an increased incidence of the disease. [45] Excessive dermal folds provide dark, wet, and warm areas, which are ideal for the proliferation of the bacteria that are needed for this infectious process. Antiperspirants and deodorants may decrease wetness and bacterial overgrowth, but they have been known to produce inflammatory responses, which could exacerbate the disease process.

The bacteriology of acute abscess formation in hidradenitis suppurativa reflects organisms seen in other soft tissue abscesses. *Staphylococcus* is the most commonly isolated organism, with *E. coli* and beta-hemolytic *Streptococcus* being other important pathogens. In the perineal region, enteric flora are often found. Many of these abscesses have multiple isolates, and anaerobic bacteria are frequently found.

Hidradenitis suppurativa begins as a single inflammatory event involving an apocrine gland, which progresses to frank suppuration and at this stage is no different from a simple furuncle. The clinical entity is distinguishable only in its chronic scarring phase. By then the lesion exhibits multiple foci coupled with areas of induration and inflammation that are in various stages of healing. Progression of the process reveals coalesced areas of firm, raised violaceous dermis. The lesion is usually markedly tender. This disease classically

involves the axilla and perineal or inguinal region, although multiple sites are often involved.

Initial outpatient management usually involves intervention in an acute suppurative lesion. Any fluctuant area requires drainage as described in the section on general abscess management. In cases of extensive cellulitis, a broad-spectrum, antistaphylococcal antibiotic should be used. Unfortunately, hidradenitis suppurativa is often not readily cured with localized incision and drainage. The chronic nature of the disease produces multiple areas of inflammation and SQ fistulous tracts that induce routine recurrences. The patient must be informed of this rather unfavorable prognosis and should be referred to a dermatologist or surgeon for long-term care.

Milder forms of the disease are initially treated with conservative measures. Many different approaches have been tried, with numerous case reports and case series noted in the literature. Unfortunately, few controlled studies have been performed. Patients are often counseled to lose weight, refrain from shaving, stop using deodorants, and improve personal hygiene. The benefits of these efforts are unknown. Oral antistaphylococcal antibiotics are most commonly used, with varying results. [46] There have been reports of success with topical clindamycin, [47] isotretinoin,  and laser therapy, [50] but these treatments have not been studied in a controlled setting and require further investigation. Dermal infection results from breakdown of the normal host defense mechanism, which occurs with irritation, traumatic injury, or inflammation, coupled with the availability of concentrated opportunistic bacteria. Therefore, the physician must institute therapies that will decrease bacterial availability without causing further injury to the affected dermis.

Advanced stages of the disease are routinely managed with wide or local excision and primary or delayed closure.  Despite this radical approach, recurrences do occur. [54] Patients must be counseled about the likelihood of recurrence before the procedure.

**Breast Abscess**

*Postpartum mastitis* occurs in 1 to 3% of nursing mothers within the first 2 to 6 weeks after delivery. The infection is usually precipitated by milk stasis following weaning or missed feedings. The cause is usually bacterial invasion through a cracked or abraded nipple by *S. aureus* or streptococci originating from the nursing child. Manifestations are redness, heat, pain, fever, and chills. Treatment consists of antistaphylococcal antibiotics, continued breast emptying with a breast pump, and application of heat. It is important to encourage continued breast emptying to promote drainage. Nursing can be continued with the noninfected breast, although passage of the antibiotics through the breast milk may result in some infant diarrhea. Cellulitis may progress to frank abscess formation. These patients may be quite ill and may appear toxic. Abscess formation complicating postpartum mastitis usually necessitates OR management, because the area is extremely tender, and adequate local anesthesia is difficult to obtain. Strict adherence to nipple hygiene to avoid cracks or inflammation is helpful in prophylaxis.

Surprisingly, most breast abscesses occur in women who are not in the puerperium, and have been termed *nonpuerperal breast abscesses*. [55] Scholefield and coworkers reviewed 72 breast abscesses over a 10-year period and noted that only 8.5% of

patients were in the puerperium. [56] These lesions have been classified anatomically.

*Peripherally located abscesses* are most commonly caused by *Staphylococcus* and respond well to traditional conservative incision and drainage. [56] Superficial abscesses in the SQ tissue may be drained under local anesthesia by means of an incision that radiates from the nipple (Fig. 40-7 (Figure Not Available) *A*).

*Periareolar abscesses* exhibit a more troublesome profile. The microflora often include multiple organisms, and anaerobic bacteria are important isolated pathogens. These infections may be the result of occluded and inflamed mammary ducts. Chronic disease may lead to ductal ectasia that provides a nidus for infection. The deeper and more extensive

**Figure 40-7** (Figure Not Available) *A,* A superficial breast abscess may be drained with a linear incision that radiates from the nipple. *B* and *C,* Diagrams of intramammary abscess *(B)* and retromammary abscess *(C).* Both require drainage under general anesthesia. The abscess itself may not be fully appreciated if it is deep seated, and the mistaken diagnosis of cellulitis may be made. (Redrawn from Wolcott MW: Ferguson's Surgery of the Ambulatory Patient. 5th ed. Philadelphia, JB Lippincott, 1974. Reprinted with permission.)

intramammary abscess appears as a generally swollen, tender breast (Fig. 40-7 (Figure Not Available) *B*). Fluctuance is not always obvious, since the abscess is located in the mammary tissue itself. Maier and colleagues reported that more than half of their series of 96 patients had nipple inversion due to chronic scarring. [59] These intramammary infections are complex and require incision and drainage under general anesthesia. Dixon has reported successful treatment with repeated aspiration in both lactating [60] and nonlactating patients. [61] This approach is probably best left to surgeons able to see such patients on a regular scheduled basis to track the progress of abscess resolution.

A *retromammary abscess* lies in the undersurface of the breast between the breast and the chest wall (Fig. 40-7 (Figure Not Available) *C*). Fluctuance may be difficult to appreciate because of the depth of the infection. Drainage under general anesthesia is required.

Recurrent abscesses are a common, troublesome complication, occurring in up to 38% of primary periareolar abscesses treated with standard incision, drainage, and antibiotics. [62] These cases require total excision of the involved area and necessitate the care of a general surgeon and further intraoperative management. It may be difficult to diagnose a breast abscess in the early stages, when cellulitis predominates. In equivocal cases antibiotics may be curative, but when pus is present, incision and drainage must be performed.

**Bartholin Gland Abscess**

The Bartholin glands (vestibular glands) are secretory organs located at the 5 and 7 o'clock positions on each side of the vestibule of the vagina. Asymptomatic cysts frequently occur from duct blockage and retention of secretions. Chronic low-grade inflammation from gonococcal infections has been implicated as an etiologic factor in

cyst formation, but occasionally frank abscess formation results. Such patients present with swollen and tender labia and a fluctuant, grape-sized mass that may be palpated between the thumb and the index finger. *Neisseria gonorrhoeae* organisms are infrequently cultured from the abscess cavity, and various anaerobes, especially *Bacteroides* species and other colonic bacteria, are usually found. It is reasonable to take cervical and anal cultures for gonorrhea from women with Bartholin gland abscesses because of the association of these infections with venereal disease, but one need not routinely treat patients for gonorrhea.

Word [63] has described an effective treatment of Bartholin gland abscess with a single-barreled, sealed-stopper, balloon-tipped catheter that may obviate the need for marsupialization (Fig. 40-8 (Figure Not Available) *A* and *B*). In his original description, Word reports only 2 recurrences in 72 lesions, both of which were successfully treated with a second catheter; no patient required marsupialization. The procedure involves fistulization of the duct cavity by a catheter, which acts as a foreign body. While not a standard incision-and-drainage procedure, the technique permits continued drainage of the Bartholin gland.

Following a small incision into the mucosa, the scalpel or a hemostat is used to puncture the abscess cavity proper (Fig. 40-9) . It is helpful to stabilize the abscess with the thumb and forefinger to ensure entrance into the abscess. Care is required to make a stab incision only large enough to accommodate the catheter and small enough to prohibit the inflated balloon from being extruded. Once the abscess has been entered (signaled by the free flow of pus), the deflated balloon is placed in the abscess cavity. Using a 25-ga needle to minimize the hole in the stopper, the balloon is then filled with 2 to 4 mL of water (not air). Persistent pain indicates that too much fluid has been used. The device is left in place for 6 to 8 weeks to allow for fistula formation, so follow-up is required. If the catheter falls out prematurely, it should be quickly replaced to fulfill the 6 to 8 weeks needed for fistulization. This is an interesting technique that even allows for sexual intercourse with the catheter in place.

The initial treatment of a Bartholin gland abscess may also include simple incision and drainage. The abscess is packed for 24 to 48 hours, and sitz baths are started after the first revisit. Broad-spectrum antibiotics are helpful if there is significant cellulitis or actual abscess formation has not yet occurred, but these agents are not required following routine incision and drainage.

It is preferable to make the drainage incision on the mucosal surface rather than on the skin surface. The incision is made over the medial surface of the introitus on a line parallel to the posterior margin of the hymenal ring. The abscess cavity is slightly deeper than most cutaneous abscesses, and one must be certain to enter the actual abscess cavity to achieve complete drainage. This is most easily accomplished if one inserts a hemostat through the mucosal incision and spreads the tips of the instrument in the deeper soft tissue. If the abscess recurs, more definitive therapy in the form of marsupialization or complete excision of the gland may be required, but these procedures are not performed initially. Because recurrence is common with simple incision and drainage, some authorities suggest definitive surgery routinely following the

first infection, whereas others prefer to wait until a recurrence is documented.

**Pilonidal Abscess**

Pilonidal sinuses are common malformations that occur in the sacrococcygeal area. The etiology of the sinus formation is unclear, but the malformation may occur during embryogenesis. Pilonidal cyst formation is thought to be secondary

to blockage of a pilonidal sinus. The result of pilonidal sinus obstruction is repeated soft tissue infection, followed by drainage and partial resolution with eventual reaccumulation. The blockage is most commonly the result of hairs in the region, and the lesion may in part be a foreign body (hair) granuloma. Although pilonidal sinuses are present from birth, they usually are not manifested clinically until adolescence or the early adult years, and pilonidal abscess formation most commonly affects young (often white) adults. The sinuses and cysts are lined with stratified squamous epithelium and may contain wads of hair and debris when excised. When cultured, pilonidal abscesses generally yield mixed fecal flora with a preponderance of anaerobes. [64]

The patient with a pilonidal abscess will seek care for back pain and local tenderness. On physical examination the area is indurated, but frank abscess formation may not be appreciated. One will usually see barely perceptible dimples or tiny openings at the rostral end of the gluteal crease (Fig. 40-10) (Figure Not Available) . A hair or a slight discharge may be noticed at the opening. One may find a more caudal cyst or abscess, possibly with a palpable sinus tract connecting the two. The sinus and cyst may be chronically draining, or they may become infected as the size increases and blockage occurs. [65]

Treatment of the acutely infected cyst is the same as previously discussed for any fluctuant abscess; all hair and pus should be removed, and the lesion should be packed. Antibiotic therapy is not usually required. The abscess cavity may become quite large, necessitating a rather lengthy incision to ensure complete drainage. It may take many weeks for the initial incision to heal. The area may be repacked at 2- to 4-day intervals as an outpatient procedure, although some prefer to discontinue packing after the first week.  Because simple incision and drainage are often not curative, secondary removal of both the cyst and the sinus should be planned after the inflammatory process has resolved. The elective surgical procedure should be complete and should involve all of the possible arborizations of the sinus.

Recurrence is occasionally prevented by simple incision and drainage, especially if the incision is wide, and adequate drainage is obtained. More commonly, recurrence can be expected unless excision of the sinus tract is performed. Small abscesses may be incised and drained as an outpatient procedure performed under local anesthesia, but the disease process is often extensive, and general anesthesia may be required to complete drainage. One is often surprised by the extent of the cyst cavity and the volume of pus that is encountered when the area is probed during initial incision; because of the degree of these abscesses, only localized infection lends itself to outpatient therapy. A method of catheter drainage for pilonidal abscesses has been described [37] [38] in which a flared-end Pezzer catheter is used for extended periods in

the abscess cavity. The catheter allows the patient more freedom from local care and provides continual drainage (Fig. 40-11) (Figure Not Available) .

## Perirectal Abscesses

Perirectal infections can range from minor irritations to fatal illnesses. Successful management depends on early recognition of the disease process and adequate surgical therapy. Because of the morbidity and mortality associated with inadequate treatment of these conditions, patients with all but the most localized abscesses should be promptly admitted to the hospital for evaluation and treatment under general or spinal anesthesia.

It is important to understand the anatomy of the anal canal and the rectum in order to appreciate the pathophysiology of these abscesses and their treatment (Fig. 40-12) (Figure Not Available) . The mucosa of the anal canal is loosely attached to the muscle wall. At the dentate line, where columnar epithelium gives way to squamous epithelium, there are vertical folds of tissue, called the rectal *columns of Morgagni,* which are connected at their lower ends by small semilunar folds called *anal valves.* Under these valves are invaginations termed *anal crypts.* Within these crypts are collections of ducts from anal glands. These glands are believed to be responsible for the genesis of most, if not all, perirectal abscesses. These glands often pass through the internal sphincter but do not penetrate the external sphincter.

The muscular anatomy divides the perirectal area into compartments that may house an abscess, depending on the direction of spread of the foci of the infection (Fig. 40-13) (Figure Not Available) . [65] [66] The circular fibers of the intestinal coat thicken at the rectum-anus junction to become the internal anal sphincter. The muscle fibers of the levator ani fuse with those of the outer longitudinal fibers of the intestinal coat as it passes through the pelvic floor. These conjoined fibers then are connected by fibrous tissue to the external sphincter system, which consists of three circular muscle groups.

### Pathophysiology

As described previously, the anal glands are mucus-secreting structures that terminate in the area between the internal and external sphincters. It is believed that most perirectal infections begin in the *intersphincteric* space secondary to blockage and subsequent infection of the anal glands. Normal host defense mechanisms then break down, followed by invasion and overgrowth by bowel flora. [67]

If the infection spreads across the external sphincter laterally, an *ischiorectal abscess* is formed. If the infection dissects rostrally, it may continue between the internal and external sphincters, causing a *high intramuscular abscess.* The infection may also dissect through the external sphincter over the levator ani to form a *pelvirectal abscess.* [66]

When infection of an anal crypt extends by way of the perianal lymphatics and continues between the mucous membrane and the anal muscles, a *perianal abscess* forms at the anal orifice. The perianal abscess is the most common variety of perirectal infection.

The abscess lies immediately beneath the skin in the perianal region at the lowermost part of the anal canal. It is separated from the ischiorectal space by a fascial septum that extends from the external sphincter and is continuous with the SQ tissue of the buttocks. The infection may be small and localized or very large, with a wall of necrotic tissue and a surrounding zone of cellulitis. [39] Perianal abscesses may be associated with a fistula in ano. The *fistula in ano* is an inflammatory tract with an external opening in the skin of the perianal area and an internal opening in the mucosa of the anal canal. The fistula in ano is usually formed after partial resolution of a perianal abscess, and its presence is suggested by recurrence of these abscesses with intermittent drainage. The external opening of the fissure is usually a red elevated piece of granulation tissue that may have purulent or serosanguineous drainage on compression. Many times the tract may be palpated as a cord. Patients with anal fistulas should be referred for definitive surgical excision.

*Ischiorectal abscesses* are fairly common. They are bounded superiorly by the levator ani, inferiorly by the fascia over the perianal space, medially by the anal sphincter muscles, and laterally by the obturator internus muscle. These abscesses may commonly be bilateral, and if so, the 2 cavities communicate by way of a deep postanal space to form a "horseshoe" abscess.

*Intersphincteric abscesses* are less common. They are bounded by the internal and external sphincters and may

extend rostrally into the rectum, thereby separating the circular and longitudinal muscle layers.

The *pelvirectal,* or *supralevator, abscess* lies above the levator ani muscle in proximity to the rectal wall and remains extraperitoneal. The etiology of this abscess is controversial. Kovalcik and colleagues [67] suggest that supralevator abscesses are primarily an extension of an intra-abdominal process, such as diverticulitis or pelvic inflammatory disease. Read and Abcarian [68] evaluated 404 patients with perirectal abscesses in a prospective study and found that of the 36 supralevator abscesses, none was caused by an intra-abdominal or pelvic pathologic condition. They determined that supralevator abscesses were most commonly associated with ischiorectal abscesses and suggested that these conditions may be an extension of ischiorectal abscesses through the floor of the levator ani. Nonetheless, they found rare isolated pelvirectal abscesses without intra-abdominal, pelvic, ischiorectal, or perianal infection.

Causes of perirectal abscesses other than the so-called cryptoglandular process have been documented but are fairly rare. It is believed that hemorrhoids, anorectal surgery, episiotomies, or local trauma may cause abscess formation by altering local anatomy and thus destroying natural tissue barriers to infections.

**Epidemiology**

Anorectal abscesses occur most commonly in healthy adults and are more frequent in males (>2:1 ratio).  These abscesses commonly appear during the fourth decade of life. Possible predisposing medical conditions are diabetes mellitus, inflammatory bowel

disease, and other immunocompromised states. Many patients (30%) have a history of previous perirectal abscess, and 75% of anorectal abscesses occur in the same location as the prior abscesses. [67] Of perirectal abscesses, usually >45% are perianal, 20% are ischiorectal, 12% are intersphincteric, and 7% are pelvirectal. [68]

**Physical and Laboratory Findings**

The diagnosis of a perianal abscess is generally not difficult. The throbbing pain in the perianal region is acute and is aggravated by sitting, coughing, sneezing, and straining. There is swelling, induration, and tenderness, and a small area of cellulitis is present in proximity to the anus. Rectal examination of the patient with a perianal abscess reveals that most of the tenderness and induration is below the level of the anal ring.

Patients with *ischiorectal abscesses* present with fever, chills, and malaise, but at first there is less pain than with the perianal abscess. Initially on physical examination, one will see an asymmetry of the perianal tissue, and later erythema and induration become apparent. Digital examination reveals a large, tense, tender swelling along the anal canal that extends above the anorectal ring. If both ischiorectal spaces are involved, the findings are bilateral.

Patients with *intersphincteric abscesses* usually present with dull, aching pain in the rectum rather than in the perianal region. No external aberrations of the perianal tissues are noted, but tenderness may be present. On digital examination one frequently palpates a soft, tender, sausage-shaped mass above the anorectal ring; if the mass has already ruptured, the patient may give a history of passage of purulent material during defecation.

Diagnosis of *pelvirectal abscesses* may be very difficult. Usually fever, chills, and malaise are present, but because the abscess is so deep seated, few or no signs or symptoms are present in the perianal region. Rectal or vaginal examination may reveal a tender swelling that is adherent to the rectal mucosa above the anorectal ring.

Laboratory findings usually do not aid in the diagnosis. Kovalcik and coworkers [67] found that <50% of their patients had a white blood cell count >$10.0 \times 10^9$ /L. Cultures of perirectal abscesses usually show mixed infections involving anaerobic bacteria, most commonly *Bacteroides fragilis* and gram-negative enteric bacilli.

**Treatment**

Successful management of perirectal abscesses depends on adequate surgical drainage. Complications from these infections may necessitate multiple surgical procedures, prolong hospital stay, and result in sepsis and death. Bevans and associates [69] retrospectively studied the charts of 184 patients who were surgically treated over a 10-year period. These patients were evaluated primarily to identify the factors that contributed to morbidity and mortality. Initial drainage was performed under local anesthesia in 38% of the patients and under spinal or general anesthesia in 62%. The authors identified 3 key factors in excessive morbidity and mortality: (1) a delay in

diagnosis and treatment, (2) inadequate initial examination or treatment, and (3) associated systemic disease. It was their belief that the only way to examine effectively and drain adequately all but the most superficial perirectal abscesses was under spinal or general anesthesia. This assessment was supported by evidence of an increased incidence of recurrence and of sepsis and death in patients treated with local anesthesia. Drainage under local anesthesia generally does not allow drainage of all hidden loculations. In addition, local anesthesia is not adequate for treatment of associated pathologic conditions.

Small, well-defined perianal abscesses are the only perirectal infections that lend themselves to outpatient therapy. The result of incision and drainage is almost immediate relief of pain and rapid resolution of infection. Indications for inpatient drainage are failure to obtain adequate anesthesia, systemic toxicity, extension of the abscess beyond a localized area, or recurrence of a perianal abscess. Recurrence may be caused by the presence of a *fistula in ano.*

A perianal abscess is drained through a single linear incision over the most fluctuant portion of the abscess in a manner previously described for other cutaneous abscesses. It is extremely painful to probe a perianal abscess and to break up loculations, and liberal analgesia is advised. The patient may begin sitz baths at home 24 hours following surgery. Packing is replaced at 48-hour intervals until the infection has cleared and granulation tissue has appeared. This usually occurs within 4 to 6 days. Antibiotics are generally not required. All other perirectal abscesses require hospitalization for definitive therapy.

Use of Pezzer catheters in anorectal abscesses has been described as an alternative to traditional incision and packing. Kyle and Isbister reported a series of 91 patients treated in this manner. They found equivalent rates of subsequent fistula surgery, less need for general anesthesia, and a shorter postoperative hospital stay when compared with patients treated with traditional incision and packing. [70] Beck and colleagues reported successful use of catheter drainage in 55 patients with ischiorectal abscess. [71] Due to the complexity of

ischiorectal abscesses, this technique is probably best left to the surgeon providing ongoing care.

Perirectal abscesses are currently recognized as a fairly common cause of fever in the granulocytopenic patient. These abscesses have a different bacteriologic profile: *Pseudomonas aeruginosa* organisms are isolated most frequently. These patients present later because pain develops later in the course, and fever may be the first manifestation. Therefore, any patients who are granulocytopenic with vague anorectal complaints, especially those with fever, should be examined carefully for perirectal abscesses. Any abscess that is found should be drained immediately under appropriate anesthesia, and extensive IV antibiotic coverage should be initiated.

**Infected Sebaceous Cyst**

A common entity that appears as a cutaneous abscess is the infected sebaceous cyst.

Sebaceous cysts may occur throughout the body and result from obstruction of sebaceous gland ducts. The cyst becomes filled with a thick, cheesy sebaceous material, and the contents frequently become infected. Sebaceous cysts may be quite large and may persist for many years before they become infected. When infected, they clinically appear as tender, fluctuant SQ masses, often with overlying erythema.

The initial treatment of an infected sebaceous cyst is simple incision and drainage. The thick sebaceous material must be expressed, since it is too thick to drain spontaneously (Fig. 40-14 *A*). An important difference exists between infected sebaceous cysts and other abscesses. *A sebaceous cyst has a definite pearly white capsule that must be excised to prevent recurrence* (Fig. 40-14 *B* and *C*). Traditionally, in the presence of significant inflammation, it is preferable to drain the infection initially and remove the shiny capsule on the first follow-up visit or a later visit, when it may be more easily identified. Alternatively, the entire cyst can be removed at the time of initial incision. At the time of capsule removal, the edges are grasped with clamps or hemostats, and the entire capsule is removed by sharp dissection with a scalpel or scissors. Following excision of the capsule, the area is treated in the same manner as a healing abscess cavity. Simple drainage without excision of the capsule often leads to recurrence.

Kitamura and associates reported a randomized study of 71 patients treated with either traditional incision and drainage or primary resection of the cyst, followed by irrigation and wound closure. In this study, the patients treated with primary resection had faster healing, fewer days of pain, and less scarring. [72]

**Paronychia**

A paronychia is an infection localized to the area around the nail root (Fig. 40-15) (Figure Not Available) . Paronychias are common infections probably caused by frequent trauma to the delicate skin around the fingernail and the cuticle. When a minor infection begins, the nail itself may act like a foreign body. Usually the infectious process is limited to the area above the nail base and underneath the eponychium (cuticle), but occasionally it may spread to include tissue under the nail as well, forming a subungual abscess. Lymphadenitis and lymphadenopathy are usually not seen. Generally, a paronychia is a mixed bacterial infection. *Staphylococcus* is commonly cultured from these lesions; however, anaerobes and numerous gram-negative organisms may be isolated. [73] Paronychias in children are often caused by anaerobes, and it is believed that this is the result of finger sucking and nail biting. Occasionally, a group A beta-hemolytic infection will develop in a paronychia if a child with a streptococcal pharyngitis puts his or her fingers in the mouth. [74]

A paronychia appears as a swelling and tenderness of the soft tissue along the base or the side of a fingernail (Fig. 40-16) . Pain, often around a hangnail, usually prompts a visit to the ED. The infection begins as a cellulitis and may form a frank abscess. If the nailbed is mobile, the infectious process has extended under the nail, and a more extensive drainage procedure should be performed. If soft tissue swelling is present without fluctuance, remission may be obtained from frequent hot soaks (6 to 8 times a day) and a short course of oral antibiotics (3 to 4 days). [73] Incision will be of no value at this early cellulitic phase. If a significant cellulitis is present, a broad-spectrum

antistaphylococcal antibiotic (cephalosporin or semisynthetic penicillin) may be tried. However, plain penicillin or erythromycin is often sufficient for limited inflammation. The digit should be splinted and elevated. [75] [76] One should never rely solely on antibiotic therapy once frank pus has formed.

**Technique**

When a definite abscess has formed, drainage is usually quickly curative. A number of invasive operative approaches have been suggested, but actual skin incision or removal of the nail is rarely required, and *neither procedure should be the initial form of treatment.* One can invariably obtain adequate drainage by simply lifting the skin edge off the nail to allow the pus to drain. This is usually curative, because a paronychia is not a cutaneous abscess per se, but rather a collection of pus in the potential space between the cuticle and proximal fingernail. Drainage may be accomplished without anesthesia in selected patients but frequently requires a digital nerve block. After softening the eponychium by soaking, a No. 11 blade, scissors, or an 18-ga needle is advanced *parallel to the nail* and under the eponychium at the site of maximal swelling (Fig. 40-17) . [76] [77] Pus rapidly escapes, with immediate relief of pain. A tourniquet placed at the base of the finger may limit bleeding and aid the physician in determining the exact extent of the infection during the drainage procedure.

If more than a tiny pocket of pus is present, one should fan the knife tip or needle or spread the scissors under the eponychium, keeping the instrument parallel to the plane of the fingernail. When a large amount of pus is drained, a small piece of packing gauze is slipped under the eponychium for 24 hours to provide continual drainage. Cultures are generally not indicated. Antibiotics are frequently prescribed, although they are not essential if drainage is complete or if the surrounding area of cellulitis is minimal. An alternative to systemic antibiotics is to keep the operative site bathed in antibiotic ointment. After anesthesia has worn off, the patient may be started on frequent soaks in warm tap water at home. In most cases the patient may easily remove the packing. At 24 to 36 hours, the finger is soaked in hot water and the gauze pulled out; a repeat visit to a physician is not required if healing is progressing. Once the packing is removed, the area is covered with a dry, absorbent dressing. An antibiotic ointment may be applied to the site for a few days. The benefit of antibiotic ointments in reducing infection is unproved, but instructing the patient concerning the use of the ointment may prompt soaking. In addition, the ointment helps to keep the bandage from sticking.

If the infection has produced purulence beneath the nail (subungual abscess), a portion of the nail must be removed or the nail trephined to ensure complete drainage. As an alternative to nail removal, a hole may be placed in the proximal nail with a hot paper clip. A large opening or multiple holes are required to ensure continued drainage. Most commonly the proximal portion of the nail is involved. This may be treated by bluntly elevating the eponychium to expose the proximal edge of the nail. The proximal one third of the nail is then elevated from the nailbed and resected with a scissors. The distal two thirds of the nail is left in place to act as a physiologic dressing and to decrease postoperative pain (Fig. 40-18) . If purulence is found below the lateral edge of the nail, the affected part may be gently elevated and excised longitudinally. [78] Care must be exercised during this procedure to avoid damage to the nail matrix. A wick of gauze

should be placed beneath the eponychium for 48 hours to ensure continued drainage.

Most paronychia resolve in a few days, and 1 to 2 postoperative visits should be scheduled to evaluate healing and reinforce home care. For compliant patients with a small paronychia, home care alone may suffice after the initial drainage. A well-known complication of even a properly drained paronychia is osteomyelitis of the distal phalanx. Clinical infection lasting longer than a few weeks should prompt evaluation for this complication.

Patients occasionally present to the ED complaining of a chronic, indolent infection of the paronychium. These seldom respond to ED intervention. Frank purulence is seldom present, and conservative treatments are often unsatisfactory. Many etiologies have been described for this frustrating condition, including fungal, bacterial, viral, and psoriatic conditions. Treatment modalities are varied, and controlled studies evaluating the various techniques are lacking. Meticulous hand care, oral and topical antimicrobial medications, and occasionally aggressive surgical intervention have been suggested. These patients should be referred to a dermatologist or hand surgeon because of the prolonged treatment required.

**Herpetic Whitlow**

Herpetic whitlow is an infection of the distal phalanx caused by the herpes simplex virus. Digital inoculation occurs through a discontinuity of the skin. [78] Health care providers and patients with other herpes infections are most commonly infected. The entity is recognized by the presence of herpetic vesicles, a burning or pruritic sensation, absence of frank pus, slow response to treatment, and a tendency to recur. In questionable cases, viral cultures can be obtained. Herpetic lesions are generally quite painful but are self-limited and resolve in 2 to 3 weeks. Surgical intervention is contraindicated, as this may potentiate a secondary bacterial infection and delay healing.  Treatment is symptomatic, consisting of splinting, elevation, and analgesia as needed. Antibiotics effective against herpes infections (acyclovir, famciclovir, and others) probably shorten the course of the disease if given early. Consideration must be given to preventing spread of the infection to other individuals. Although

an occlusive dressing may lessen the chance for viral transmission, any health care provider with this entity should refrain from patient contact until all lesions have crusted over and viral shedding has stopped.

**Felon**

A felon is an infection of the pulp of the distal finger (Fig. 40-19) . The usual cause is trauma with secondary invasion by bacteria. A felon may develop in the presence of a foreign body, such as a thorn or a splinter, but often a precipitating trauma cannot be identified. An important anatomic characteristic of this area is that there are many fibrous septa extending from the volar skin of the fat pad to the periosteum of the phalanx; these subdivide and compartmentalize the pulp area. When an infection occurs in the pulp, these same structures make it a closed space infection. The septa limit swelling, delay pointing of the abscess, and inhibit drainage after incomplete surgical

decompression. Pressure may increase in the closed space, initiating an ischemic process that compounds the infection. The infection can progress readily to osteomyelitis of the distal phalanx. Although the septa may facilitate an infection in the pulp, they provide a barrier that protects the joint space and the tendon sheath by limiting the proximal spread of infection.

The offending organisms are usually *Staphylococcus* or *Streptococcus,* although mixed infections and gram-negative infection may occur. A felon is one of the few soft tissue infections in which a culture may be helpful, since osteomyelitis and prolonged infection may occur. An initial culture may aid in the subsequent choice of antibiotics for complicated infections.

The patient developing a felon will describe gradual onset of pain and tenderness of the fingertip. In a few days the pain may be constant and throbbing and gradually becomes severe. In the initial stages, physical examination may be quite unimpressive, because the fibrous septa limit swelling in the closed pulp space. As the infection progresses, swelling and redness may become obvious. Occasionally one may elicit point tenderness, but frequently the entire pulp space is extremely tender. The patient characteristically arrives with the hand elevated over the head because pain is so intense in the dependent position. Cessation of pain indicates extensive necrosis and nerve degeneration.

Proper treatment of a well-developed felon consists of early and complete incision and drainage. [78] Antibiotics alone are not curative once suppuration has occurred. Delaying surgery may result in permanent disability and deformity. Most surgeons routinely administer broad-spectrum antibiotics to patients for 5 to 7 days following surgical incision.

**Technique**

The surgery can usually be performed as an outpatient procedure using a digital nerve block. A long-acting solution (bupivacaine) will prolong anesthesia. A tourniquet (1.25 cm Penrose drain) should be used to allow digital incision in a bloodless field.

Surgical drainage must be carefully performed to avoid injury to digital nerves, vessels, and flexor tendon mechanisms. Most commonly, a felon can be successfully managed with a limited procedure, but many surgical options have been advocated, none of which has been proven superior for all circumstances. [78] The preferred initial treatment is a simple longitudinal incision made over the area of greatest fluctuance, [87] which may occur laterally or along the volar surface (Fig. 40-20) . A potential drawback to an incision in the middle of the fat pad is the production of a scar in a very sensitive and commonly traumatized area. The incision must not extend to the distal interphalangeal crease because of the danger of injuring the flexor tendon mechanism. The SQ tissue is bluntly dissected using a hemostat to provide adequate drainage. A gauze pack may be placed in the wound for 24 to 48 hours to ensure continued drainage.

Recurrent or more severe infections may require a more aggressive approach. The following traditional incisions have a greater propensity for complications such as

sloughing of tissue and postoperative fat pad anesthesia or instability, [87] although they may provide for more complete drainage.

The hockey-stick incision is a well-accepted drainage procedure (Fig. 40-21) (Figure Not Available) . This incision is advantageous if the infection points to 1 side of the finger. The incision begins in the midline of the tip of the fat pad, just under the distal edge of the fingernail. It is extended to the lateral tip of the finger and proximally along the side of the distal phalanx (at the junction of the volar and dorsal skin markings) to 3 to 5 mm distal to the distal interphalangeal joint. The tip of the knife blade is inserted just under the bone to a depth corresponding to the opposite edge of the distal phalanx-- slightly more than halfway across the volar surface of the finger. A hemostat is inserted into the incision and is spread in the plane of the fingernail (perpendicular to the septa) to break open remaining septa and loculations. Necrotic tissue or any foreign matter is excised under direct vision, and the wound is irrigated. A small gauze pack is placed in the incision. Because the incision may produce partial numbness of the fingertip by associated digital nerve injury, the incision

**Figure 40-21** (Figure Not Available) Hockey-stick incision for the drainage of a felon. *Note:* An incision on the ulnar side of the index, middle, and ring fingers is appropriate. The little finger is best incised on the radial side. The site of the incision on the thumb is also preferably on the radial side, but this may depend on the occupation of the patient. *(From Chase RA: Atlas of Hand Surgery. Philadelphia, WB Saunders, 1973. Reproduced with permission.)*

should *not* be made on the radial aspect of the index finger or the ulnar aspect of the thumb or little finger.

An acceptable alternative to the hockey-stick, or median, incision is the through-and-through incision (Fig. 40-22) . This is basically a hockey stick-type incision (without the curved distal portion of the "hockey stick") that is carried through to the opposite side of the finger. A hemostat is used to break up loculations, and a rubber drain (Penrose) is placed through the incision for continual drainage. The through-and-through incision is probably the easiest procedure for most felons.

The fishmouth, or horseshoe, incision is basically 2 hockey-stick incisions that meet at the tip of the finger. A gauze pack is placed between the flaps and should be removed in a few days. This is a rather radical procedure but allows complete visualization and debridement of necrotic tissue (Fig. 40-23) . Some physicians advise against this incision, because it is extensive and may take a long time to heal. In addition, it produces a sizable scar and an unstable finger pulp. The fishmouth incision may be used if more conservative incisions are not successful, but it is not recommended for use initially.

No matter which incision is made, it must not be carried proximal to the closed pulp space because of the danger of entrance into the tendon sheath or the joint capsule. The patient should be rechecked in 2 to 3 days. A snug dressing, splinting and elevation, and adequate opioid analgesics are prerequisites for a successful outcome and a happy patient.

On the first postoperative visit, a digital block may again be performed and any packing

removed. The incision is irrigated copiously with saline, and any additional necrotic tissue is removed. At this time, the drain may be replaced for 24 to 48 hours if there is continued drainage, but usually it can be removed and a dressing reapplied. Soaking may be advised. At the first revisit, the sensitivities of the bacterial cultures are checked, and a decision to continue or change antibiotics is made. Most felons are empirically treated with antibiotics for at least 5 days. A broad-spectrum cephalosporin is a reasonable choice, pending cultures (if done).

A few additional points should be emphasized at this time. Frank pus may be encountered during incision, but usually only a few drops are expressed. One more often drains a combination of necrotic tissue and interstitial fluid. A careful search for a foreign body should be made even if the history is not known. Some physicians advocate radiographic evaluation for retained foreign bodies and a baseline evaluation of the bone for subsequent evaluation of osteomyelitis at the initial visit. Other physicians will reserve radiographs for wounds not showing significant improvement in 5 to 7 days. Evidence of osteomyelitis, however, may not be found radiographically for several weeks after the appearance of the lesion. More radical incision and drainage may be required in persistent infections. Following adequate drainage, osteomyelitis may respond surprisingly well to outpatient antibiotic therapy with almost complete regeneration of bone if incision and drainage have been adequate. Persistent cases may require IV antibiotics.

*Resistant fingertip infections are not uncommon.* Difficult or persistent cases require evaluation and care by a hand surgeon. In these cases, early consultation is advisable to avert catastrophic complications such as loss of function or amputation.

## Subungual Hematoma

Subungual hematoma is an injury that is frequently seen in the ED. Any digit may be affected. The hematoma often results from hitting the fingertip with a hammer or slamming it in a door. The main concern of the patient is relief of the terrible throbbing pain that accompanies the condition as the pressure of the hematoma increases. Pain relief can be accomplished quickly with nail trephination. Trephination may be performed with a large paper clip that has been heated until it is red hot. The instrument is applied to burn a hole at the base of the nail (Fig. 40-24) . Blood rapidly exits, and the blackened nail regains its normal color (Fig. 40-25) . The blood usually remains fluid for 24 to 36 hours and is easily expressed with slight pressure. Care should be taken to make multiple holes or a single hole that is large enough to allow continued drainage. An oversized paper clip is the simplest apparatus. Although a portable hot-wire electrocautery unit is available and is frequently recommended, it is difficult to obtain an adequate drainage hole without adapting the instrument and its use. One can modify the electrocautery device to burn a larger hole by "fattening" the end of the wire loop and rotating the device slowly as the nail is penetrated or by removing a small rectangle of nail with the cautery device. In addition to being convenient, the cautery device is desirable because the wire stays hotter longer, thus enhancing nail penetration. In the stoic patient, no anesthesia may be necessary, but a digital block affords painless trephination, and its routine use is suggested with the anxious patient.

The majority of subungual hematomas are painful but minor injuries. Complicated cases involve fractures of the distal phalanx. When the fingertip is unstable or the mechanism of injury suggests a significant distal phalanx fracture, a radiograph should be obtained. If a significant fracture is present, the digit should be splinted. A distal phalangeal fracture with a subungual hematoma is technically an open (compound) fracture. Such injuries usually heal without problems, although osteomyelitis of the tuft is a theoretical complication. The value of routine antibiotic prophylaxis in such cases is unproved, and their use is not standard in minor cases but may be of value in significant crush injuries. The presence of an underlying fracture does not contraindicate nail trephination for fear of changing closed fracture into an open one. It is difficult to predict the fate of the fingernail following drainage of a subungual hematoma. Some patients with subungual hematomas will lose the nail, but if the nail root or nailbed is not significantly disrupted and the nail remains implanted, a normal-appearing nail is the usual final result. If the nailbed is significantly lacerated or the edges of the nail are unstable, the nail should be removed and the nailbed repaired (see further discussion in Chapter 37) . Patients should be informed of possible future cosmetic problems.

# Chapter 41 - Burn Care Procedures

**Thomas J. Krisanda, Courtney A. Bethel**

Each year in the United States some 2 million people suffer a burn-related injury. Typical victims are children <5 years of age or young adults who are exposed to fire or hot or corrosive substances. [1] Fortunately, 95% of these burns are classified as minor and are amenable to outpatient management, with most patients completing their treatment course within 2 weeks.

The classification of burns is based on 3 criteria [2] : depth of skin injury, percentage of body surface area involved, and source of injury (thermal, chemical, electrical, or radiation). The *seriousness* of a burn injury is determined by the characteristics and temperature of the burning agent, the duration of exposure, the location of injury, the presence of associated injuries, and the age and general health of the victim.

The American Burn Association defines *minor* burns as uncomplicated partial-thickness burns of <10% of the total body surface area (TBSA) in children or the elderly or <15% TBSA in adults, or full-thickness burns of <2% TBSA. [3] *Moderate or major* burns include injuries that involve a greater TBSA, as well as burns to areas of specialized function, such as the face, hands, feet, or perineum. More serious burns also include those due to a high-voltage electrical injury or those with associated inhalation injuries or other major trauma.

The TBSA burned may be estimated in a number of ways. In adults, the "rule of nines" is a useful rule of thumb, but the formula is only a guide and *must be modified for children* who have proportionately larger heads and smaller legs (Fig. 41-1) . The Lund and Browder charts are another (more precise) guide to estimating the percentage of TBSA burned (Fig. 41-2) . For smaller or multiple burns, one can rapidly estimate the TBSA burned by using the area of the patient's palm as approximately 1.25% TBSA.

Throughout the course of history, physicians have experimented with burn therapies to relieve pain and promote healing. Before the latter half of the 19th century, the treatment of burns had little scientific basis. Accepted treatments consisted primarily of bleeding and purging the patient and placing substances on the wound that tended to promote infection or were toxic. Fortunately, the pathophysiology of burn injury and burn healing has gradually been elucidated, and the care of burns has evolved into its present form.

## WOUND EVALUATION

Emergency physicians should be aware that the depth of a burn wound cannot always be determined accurately on clinical grounds alone at the time of presentation and that burn injury is a dynamic process that may change over time, particularly during the 24 to 48 hours after the burning process has been arrested. It is common, for example, for a seemingly minor or superficial burn to appear deeper on the second or third return visit. This phenomenon is not a continuation of the burning process but is considered to be a

pathophysiologic event related to tissue edema, dermal ischemia, or desiccation. [4]

*First-degree burns* involve the epidermis only. The skin is reddened but is intact and not blistered. This injury ranges from mildly irritating or even pruritic to exquisitely painful. Minor edema may be noted. Causes include ultraviolet light (as in sunburn) and brief thermal "flash" burns. First-degree burns frequently blister within 24 to 36 hours, so the patient should be instructed appropriately. Often the skin begins to flake or peel within 5 to 10 days, but healing eventually occurs with no scarring.

*Second-degree burns* involve the entire epidermis and extend into the dermis to include sweat glands and hair follicles. *Superficial partial-thickness burns* involve only the papillary dermis. These burns are pink, moist, and extremely painful. Blisters may be present or the skin may slough. The burn blanches with pressure, and mild to moderate edema is common. Hair follicles are often noted to be intact. This is the most common depth of minor burn seen in the emergency department (ED). The usual causes are scalds, contact with hot objects, or exposure to chemicals. Barring infection or repeated trauma, these burns heal completely without scarring in about 2 weeks.

*Deep partial-thickness burns* extend into the reticular dermis and appear as mottled white or pink. There is obvious edema and sloughing of the skin, and any blisters are usually ruptured. Blanching is absent. These burns are generally not painful initially, but pressure can be perceived. Within a few days, however, these burns can become exquisitely painful. This type of burn can easily be converted to a full-thickness injury by further trauma or infection. Partial-thickness burns heal by re-epithelialization from dermal appendages, including hair follicles, sebaceous glands, and sweat glands.

In *full-thickness burns,* coagulation necrosis extends into the subcutaneous (SQ) tissues. These burns may appear a variety of colors but are usually dry, pearly white, or charred. They are initially painless, with a leathery texture. Marked edema and decreased elasticity may necessitate escharotomy when circulation is compromised. Exposure of the skin to temperatures in excess of 77 °C for more than 3 to 4 seconds generally causes a full-thickness injury. Although initially painless, in a few days these deep burns can become painful. Chemical burns often produce full-thickness injuries affecting a small or scattered surface area. Flame burns produce full-thickness injuries in <2 seconds if the temperature of the flame exceeds 500 °C. Generally, any burn wound that is not re-epithelialized or does not possess dense epidermal budding by 14 days post-burn should be considered a full-thickness injury. [4]

*Fourth-degree burns* extend deeply into SQ tissue, muscle, fascia, or bone. These burns are characteristically caused by contact with molten metal, flame, or high-voltage electricity.

## HISTOPATHOLOGY OF BURNS

One thermal wound theory describes 3 zones of injury in burns [5] :

1. *Zone of coagulation:* dead, avascular tissue that must be debrided.

2. *Zone of stasis:* injured tissue in which blood flow is impaired. Desiccation, infection, or mechanical trauma may lead to cell death.
3. *Zone of hyperemia:* minimally injured, inflamed tissue that forms the border of the wound. The hyperemia usually resolves within 7 to 10 days but may be mistaken for cellulitis.Histologically, full-thickness burns are characterized by confluent vascular thrombosis involving arterioles, venules, and capillaries. Edema due to loss of microvascular integrity results not only from the effects of direct thermal injury, but also from the release of vasoactive mediators. The increase in vascular permeability is linked to complement activation and histamine release. Histamine increases the catalytic activity of the enzyme xanthine oxidase, with resultant production of hydrogen peroxide and hydroxyl radicals. These by-products increase the damage to dermal vascular endothelial cells and result in progressive vascular permeability. [6] The cellular debris and denatured proteins of the eschar provide a substrate for the proliferation of microorganisms. The devitalized tissue (eschar) sloughs spontaneously, usually as a result of the proteolytic effect of bacterial enzymes. The greater the degree of wound bacteriostasis, the greater the delay in sloughing.Partial-thickness burns result in incomplete vascular thrombosis, usually limited to the upper dermis. The dermal circulation is gradually restored, usually over several days, resulting in a significant interval of relative ischemia. The eschar in deep partial-thickness burns is thinner than in a full-thickness burn and sloughs as a result of re-epithelialization rather than bacterial proteolysis.

## OUTPATIENT VS INPATIENT CARE

One of the first steps in minor burn care is to select patients for whom outpatient care is appropriate. Candidates for outpatient treatment are generally adults and children who meet the minor burn criteria detailed earlier. Persons who have deep burns of the hands, face, feet, neck, or perineum; burns resulting from abuse or attempted suicide; burns involving other significant trauma or inhalation injuries; or electrical burns should generally be managed as *inpatients*.

Poor candidates for outpatient care of even minor burns include those who have concomitant medical problems such as diabetes mellitus, peripheral vascular disease, congestive heart failure, and end-stage renal disease; patients who are using steroids or other immunosuppressive agents; patients who are very young or very old; those who are mentally retarded; alcoholics; those who are malnourished; and any individual with a suspect or unacceptable home support system. Inpatient treatment should be considered under these circumstances even though the burn might be considered "minor" by TBSA formulas.

## PROCEDURE

### Initial Care of the Minor Burn Victim

Prompt cooling of the burned part is an almost instinctive response and is one of the oldest recorded burn treatments, having been recommended by Galen (129 to 199 A.D.)

and Rhazes (852 to 923 A.D.). [4] Room-temperature tap water irrigation, immersion, or compresses (20 to 25 °C) are optimal in obtaining pain relief and providing some measure of protection for burned tissues without the problems of hypothermia that iced solutions can cause. [7] [8] First-aid telephone advice from the emergency physician includes immediately immersing the wound in room-temperature tap water. *Packing the wound in ice must be avoided*.

Emergency medical services (EMS) personnel should have a clear understanding of proper management of the minor burn victim. The benefits and details of early cooling should be understood and implemented. The victim should first be removed from danger. All involved clothing and jewelry, along with any gross debris, should be removed from the burned area. Chemical burns to the skin or eyes require prolonged tap water irrigation. The burn should be otherwise covered with a moist, sterile dressing-- nonmentholated shaving cream makes an excellent temporary covering for out-of-hospital use if a dressing is not available. [9] Home remedies such as butter, grease, or petrolatum should be avoided.

In the ED, the burned area should be immediately immersed in room temperature water or covered with gauze pads soaked in room-temperature water (Fig. 41-3) . The gauze must be kept cool and moist to provide continued pain relief; the patient will quickly let the physician know when additional cooling is required. Burns should be cooled or immersed until supplemental analgesia is effective and dressings are applied. Many physicians use sterile saline for cooling, but it has no proven benefit over tap water, even when the skin is broken. Immersion of burned tissue in ice or ice water should be avoided, because ice immersion increases pain and risks frostbite injury or systemic hypothermia.

The potential benefits of burn cooling are listed in Table 41-1 . With the exception of pain relief and removal of debris, the benefits of burn cooling are experienced only if the burn is cooled promptly, within the first 3 minutes after injury. [10]

Prompt burn cooling arrests cell death processes by inhibiting the release of toxic substances by the dying cells. If cooling is not performed, continued cell death results as oxygen free radicals are released, which can cause a "chain reaction" of cell membrane injury, arachidonic acid release, and increased local ischemia. [11]

The threshold temperature for cutaneous pain sensation is approximately 43 °C. The prompt alteration in capillary permeability and resultant edema induced by heat have been attributed to histamine release from stimulated or damaged mast cells. The tissue threshold for this phenomenon has been estimated at 52 °C. Cooling produces prompt and complete, but reversible, inhibition of histamine release. Tissue edema also results from damage to the membrane sodium pump, with resultant influx of sodium into tissue and loss of protein into the interstitial spaces. Unfortunately, this contribution to tissue edema is less responsive to local cooling. [1]

Minor burns are considered tetanus prone, and tetanus toxoid should be administered if the patient is unsure of his or her tetanus immunization status or when it has been more than 5 years since the last immunization. Nonimmunized patients should receive human

tetanus immune globulin, 250 units IM, along with tetanus toxoid, along with a booster injection of toxoid in about 3 weeks.

| TABLE 41-1 -- Advantage of Prompt Burn Cooling |
|---|
| Reduction or cessation of pain |
| Elimination of local hyperthermia |
| Inhibition of postburn tissue destruction |
| Decreased edema |
| Reduced metabolism and toxin production |

## Definitive Care of the Minor Burn

Few areas in medicine are fraught with as much mysticism, personal bias, and unscientific dogma as the care of the minor burn wound. Many physicians are rigidly committed to a specific ritual or approach merely because "it is the way it's done" in a specific institution or because the practitioner has had success with a particular therapy in the past. In reality, the plethora of successful regimens attests to the fact that almost any noninjurious approach results in a favorable outcome. Many misconceptions probably arise because the issues associated with major thermal injury are often erroneously extrapolated to the minor burn wound.

Minor burns are *not* associated with immunosuppression, hypermetabolism, or increased susceptibility to infection. [12] Many complications seen in minor burn care result from *overtreatment* of the injury rather than undertreatment. Examples include too-vigorous dressing changes that may peel off newly formed skin and secondary infections or pseudomembrane formation that results from topical or systemic antibiotic use.

**Burn Dressings**

**Open burn care.**

Burns are cared for using 2 general methods: open or closed. In the *open* method, a burn wound dressing is not used. The area is left open to the air and is washed 2 to 3 times per day, followed by application of a topical agent. This is the preferred method for managing burns of the face and neck and is an excellent way to manage hand burns, because it allows continuous inspection and range-of-motion exercises. The open method is impractical in young active persons, in children, or in other individuals in whom wound contamination is likely. Although many burns may be treated with this method, many patients prefer a dressing over a wound for cosmetic reasons.

**Simple closed dressing.**

The *closed* burn treatment method involves a dressing, of which there are various types. This is the method of choice for managing most minor burns treated in the ED. Wound preparation and basic bandaging should include the following steps (Fig. 41-4) :

1. The hair in the burn itself or around the wound should *not* be shaved. The burn is washed gently with a clean cloth or gauze pads and a mild non-alcohol-based soap or detergent (e.g., Ivory, Dreft, Hibiclens) and then flushed with normal saline. Adequate wound cleansing prevents further bacterial contamination, promotes early epithelialization in partial-thickness injuries, and aids the development of good granulation tissue in full-thickness injuries. [13]
2. Obviously sloughed skin should be debrided. This may be accomplished with scissors and forceps, but an expeditious and effective (and often painless) method is to use a dry 10-cm × 10-cm gauze pad (Fig. 41-5) to quickly debride loose skin. Meticulous and time-consuming instrument debridement is often quite stressful to the patient. Analgesia should be provided for any painful debridement.
3. Intact blisters are left alone in the absence of infection. Open blisters are debrided (Table 41-2) . All sloughed skin and blisters are debrided if infection is present.
4. A fine mesh gauze or a commercial nonadherent gauze such as Adaptic or Aquaphor is applied to the dry burn wound.
5. The burn is covered with loose gauze fluffs. If fingers and toes are included in the dressing, *the web spaces are padded and the digits are individually wrapped and separated with strips of gauze*. Failure to individually wrap fingers and toes may result in further injury (see Figure 41-4 *D*).
6. The entire dressing is wrapped snugly (but not tightly) with an absorbent, slightly elastic material such as Kerlix.
7. Antibiotic creams or ointments may be used as an option with this dressing. The topical antibiotic may be applied to the burned skin directly or impregnated into the gauze after step 3.Burn dressings should enhance healing. *The most important characteristic of a dressing is that it is capable of controlling fluid balance*. To accelerate healing, a burn dressing should be designed to keep the wound surface moist but avoid pooling of fluids. [14] The best material for this purpose is a generous amount of *simple dry gauze* applied over a nonadherent dressing or topical preparation. The outer dressing layer should be porous to permit the

evaporation of water from the absorbent dressing material.

**Biologic dressings.**

Biologic dressings are natural tissues, including skin, that consist of collagen sheets containing elastin and lipid. They are not routinely used in emergency care of minor wounds. Benefits of biologic dressings

---

**TABLE 41-2** -- General Approach to Blisters in Minor Burns [*]

If treated less than 48 hours after the burn:

  1. Leave all intact blisters alone.

  2. If blisters have ruptured, treat them as dead skin and debride them completely.

  3. Needle aspiration is generally not advised but may be used to decompress large burn blisters that appear ready to burst.

On follow-up, or more than 48 to 72 hours after the burn:

  1. Debride large (>5 cm in diameter) intact blisters and all blisters that have ruptured. Large, firm blisters of the palms and soles may be left intact longer. Do not aspirate blisters.

  2. Do not debride small or spotty blisters until they break, or until 5 to 7 days after the burn.

Five to 7 days after the burn:

| |
|---|
| 1. Debride all blisters completely . |
| *Note*: Intact blisters provide significant pain relief. Be prepared for an exacerbation of pain immediately after debridement. |
| Prophylactic analgesia is recommended. |

* All blisters and burned skin are debrided in the presence of infection.

include a reduction in surface bacterial colonization, diminished fluid and heat loss, prevention of further wound contamination, and prevention of damage to newly developed granulation tissue. Examples of biologic dressings include cadaveric human skin and commercially available porcine xenograft or collagen sheets.

**Synthetic dressings.**

Synthetic dressings are manufactured in various forms. Film-type dressings have a homogeneous structure and are usually polymers. Because these dressings are nonpermeable, there have been problems with retention of wound exudate. Some second-generation dressings have been developed that address these problems. These include the following:

1. *Tegaderm* (3M Inc., St Paul, Minn) pouch dressings consist of a thin polyurethane film coated with a water-resistant adhesive. The film is perforated to allow exudate fluid to pass into a pouch. An intact dressing is impermeable to liquids and bacteria. Although this dressing has been used on skin graft donor sites, it has not been studied as a primary burn dressing (C. D. Jones, written communication, 1993).
2. *Vigilon* (Bard, Inc., Berkeley Heights, NJ) is a hydrogel formulation of water and polyethylene oxide reinforced with a polyethylene support webbing. It is clear, conformable, and nonadherent and may be used along with topical antibiotic agents. Wound exudate is transmissible through the dressing and is absorbed by an overlying gauze dressing.
3. *DuoDerm* (Convatec, Inc, Arlington Heights, Ill) is a synthetic hydrocolloid dressing. The outer layer, consisting of polyurethane foam, is impermeable to gases, vapor, and fluids. The wound side of the dressing is a hydrocolloid polymer complex that adheres to the surrounding healthy skin via an approved acrylic adhesive. [15] Wound exudate converts the hydrocolloid complex into a gel, which creates a beneficial moist environment. The dressing may be left in place for up to 5 days. [16] DuoDerm is opaque and hence does not allow for wound inspection. It also has no antibacterial properties and should not be used on infected burns. [16]

4. *Biobrane* (Winthrop Pharmaceuticals, New York) is a

   biosynthetic, bilaminar membrane dressing that consists of a knitted nylon fabric mechanically bonded to a thin Silastic semipermeable membrane. Cross-linked collagen polypeptides coat the membrane and prohibit both desiccation and collection of serum. Biobrane is available with a variety of pore sizes to regulate wound transudation; these pores allow drainage of the exudate, which is absorbed by an overlying gauze dressing. Biobrane is generally well tolerated and permits the transmission of antibacterial activity from topical antimicrobial agents; the dressing itself has no inherent antibacterial activity. As long as the wound remains clean and there is no seroma, the collagen side of the dressing adheres to the burn surface, effectively sealing it. [17] Any fluid that accumulates beneath the fabric requires prompt removal by aspiration. Unfortunately, Biobrane often separates from the wound before healing is complete; these patients require complete removal of the dressing with alternative topical therapy. [18]

5. *Op-Site* (Smith and Nephew Medical, Massillon, Ohio) is a less than optimal membrane dressing, because fluid collections frequently occur beneath the barrier. Because this dressing is clear, however, it allows for ready wound inspection.

6. *Omniderm* (Jobskin, Jobst Institute, Inc., Toledo, Ohio) is a transparent polyurethane membrane that can be cut to any required shape or contour. [19] It provides an effective barrier dressing but is permeable to oxygen and antibiotic molecules. Omniderm is initially applied dry, but when wet, it becomes pliable and adherent. Pain relief is often remarkable, and the transparent dressing allows ready wound inspection without removal. Fluid accumulation may occur, usually within 1 to 2 days, and is treated with removal and reapplication of a new dressing, which is ultimately left in place for 5 to 10 days. The Omniderm dressing may be covered with flexible net tubular gauze to discourage tampering, especially in children.

7. *Sildimac* (Marion Laboratories, Kansas City, Kan) is an elastic, flexible, conformable sheet consisting of polyethylene glycol 400, poly-2-hydroxyethyl methacrylate, and dimethyl sulfoxide that contains a sustained-release delivery system for silver sulfadiazine. Sildimac is an opaque sheet that adheres to dry surfaces and conforms to body contours. The primary advantage of Sildimac lies in its ability to decrease the frequency of dressing changes while providing sustained-release antimicrobial activity that persists for up to 7 days, although dressing changes are recommended every 4 days. Thus far, Sildimac has been studied only in the management of small, full-thickness burns, but its efficacy seems comparable to twice-daily wound cleansing with application of 1% silver sulfadiazine cream. [20]

**Application of biologic and synthetic dressings.**

All of these dressings are best used on fresh *partial-thickness burns*; placement over a contaminated wound often results in nonadherence and infection. Biologic and synthetic dressings are readily available. These dressings provide immediate relief of pain and are the only dressing method that may actually promote faster wound healing. [2] In

addition, these dressings have the potential for a reduced number of dressing changes.

*Biologic dressings*, such as porcine xenograft, are applied as follows: The dressing is reconstituted as instructed by the manufacturer and is carefully "fit" to the wound. All fluid and air under the graft are pressed out. The dressing is secured with edge tapes and covered with coarse mesh gauze, and then the dressing is wrapped with absorbent gauze and a semi-elastic wrap. With healing, the biologic dressing dries, curls, and separates from the healed edge underneath. The loose edges should be trimmed frequently, any blisters debrided, and fluid accumulations drained.

*Synthetic dressings* are applied after standard wound cleansing. Blisters must be debrided before application of the synthetic dressings. The thicker membranes are cut to size and applied to the burn surface. The edge of the membrane should extend 2 to 3 cm beyond the burn onto the surrounding unburned tissue. Membranes such as DuoDerm can be wrapped about burned digits to permit continued function with limited motion during healing. [16]

Should fluid collect between the debrided burn and the dressing, one attempt at aspiration should be performed. If the fluid reaccumulates beneath the DuoDerm or Biobrane membranes after aspiration, the nonadherent portion of the fabric should be removed. For the first 5 to 8 days, the dressing should be checked at least every other day for adherence. After epithelialization is complete, the dressing begins to separate spontaneously and may be peeled away. [11]

If infection develops under a synthetic or biologic dressing, the dressing should be removed, the wound cultured, and treatment with topical (and possibly oral) antimicrobials instituted. Xenografts should not be used on superficial partial-thickness injuries, because the xenograft tissue may become incorporated into the healing wound in as many as 35% of patients so treated. [21]

Occasionally, application of a permanent dressing--or skin autograft--is appropriately performed in the outpatient setting. Appropriate patient selection is crucial; patients should be healthy and well motivated, with small (<2% TBSA), noncosmetic deep partial-thickness or full-thickness burns. These burns may initially be treated as outlined previously, with the use of a topical antimicrobial agent recommended. The wound should be reevaluated for excision and grafting within 4 days.

## Specific Clinical Issues in Minor Burn Care

### Analgesia

Pain is a much feared feature of any burn injury. Pain relief by the appropriate and judicious use of opioids is of paramount importance in the initial care of burn patients. Analgesia should be provided *before* extensive examination or debridement is performed. Inadequate analgesia is probably the most common ED error in the treatment of burn injuries. This error is most common in children.

Even with minor burns, patients often present with significant pain. Reassurance is important, but adequate analgesia is critical for gaining the patient's cooperation and ensuring comfort. Cooling may dramatically relieve pain temporarily, but parenteral opioids (meperidine, 1 to 2 mg/kg, or morphine, 0.1 to 0.2 mg/kg) are usually required, especially if painful procedures such as debridement and dressing changes are planned. We prefer to use IV opioids (occasionally supplemented with a short-acting benzodiazepine such

as midazolam) for all painful procedures. For complicated debridement or dressing changes, adequate analgesia and sedation (see Chapter 35) is strongly advocated.

Intramuscular (IM) medications following the procedure are helpful for prolonged analgesia. Regional or nerve block anesthesia is an excellent alternative when practical, and when feasible, nitrous oxide analgesia may be used. Oral opioids are inappropriate for initial treatment of significant pain but can be used for continued outpatient analgesia. Local anesthetics may be injected in small quantities when appropriate, such as for the debridement of a deep ulcer or other small burn. Topical analgesics have no role in burn care. A properly designed dressing will do much toward preventing further discomfort after release home; however, home burn care and dressing changes may be quite painful. For this reason an adequate supply of an oral opioid analgesic should be provided, and responsibility should be encouraged in analgesic use.

**Edema**

Minor burns lead to immediate inflammation mediated by the release of histamine and bradykinins, causing localized derangements in vascular permeability, with resultant burn wound edema. This edema is harmful in several ways. First, the increase in interstitial fluid increases the diffusion distance of oxygen from the capillaries to the cells, increasing hypoxia in an already ischemic wound. Second, the edema may produce untoward hemodynamic effects by a purely mechanical mechanism: compression of vessels in muscular compartments. Third, edema has been associated with the inactivation of streptococcicidal skin fatty acids, thus predisposing the patient to burn cellulitis. [22]

The successful management of burn edema hinges on *immobilization* and *elevation*. Most patients are unfamiliar with the medical definition of elevation and are not aware of or convinced of its value. Patient education in this regard is critical; however, certain burns (e.g., burns in dependent body areas) are prone to edema, despite everyone's best intentions. It is for this reason that lower extremity burns in general, and foot burns in particular, are prone to problems.

**Use of Topical Antimicrobials**

Minor burns result in insignificant impairment of normal host immunologic defenses, and burn wound infection is usually not a significant problem. Topical antimicrobials are often used; however, some believe these agents may actually impair wound healing. [23]

Although the procedure is of unproven value, many physicians routinely use antibiotic creams or ointments on even the most minor of burns.

Topical antimicrobials were designed for the prevention and care of burn wound sepsis or wound infection, and there is no convincing evidence that their use alters the course of first-degree burns and superficial partial-thickness injuries. As noted, the burn dressing is the key factor in minimizing complications in all burns. Nonetheless, topical antimicrobials are often soothing to minor burns, and their daily use prompts the patient to look at the wound, assess healing, perform prescribed dressing changes, or otherwise become personally involved in his or her care. Keep in mind that if a topical antimicrobial is used, its effectiveness is decreased in the presence of proteinaceous exudate, necessitating twice-daily dressing changes if the antimicrobial benefit of topical therapy is to be realized. In reality, once-daily dressing changes are more practical and are commonly prescribed, and there are no data to indicate that this regimen is inferior.

All full-thickness burns should receive topical antimicrobial therapy, because the eschar and burn exudate are potentially good bacterial culture media, and deep escharotic or subescharotic infections may not be easily detected until further damage is done. All deep partial-thickness injuries likewise benefit from the application of a topical antimicrobial. In deep partial-thickness injuries, re-epithelialization occurs from a few remaining deep epidermal appendages whose protection is important. Clinical studies and culture results support the hypothesis that surface destruction of dermal islands by bacterial enzymes and catabolic processes has the potential to convert a deep partial-thickness injury to a full-thickness injury. [24]

Initial topical therapy is prophylactic. [5] A burn wound infection that develops despite this therapy mandates a change to a different agent. Topical therapy, if chosen, should cover the usual bacteria responsible for burn wound infections (see later discussion of minor burn infections). Although topical agents are an important part of a burn treatment program, they are not substitutes for good local wound care or a careful program of management. Their successful use may prevent the conversion of deep thermal burns to deeper injury and allow better wound healing for earlier (and more successful) skin grafting.

Criteria for choosing a specific topical agent include in vitro and clinical efficacy, toxicity (absorption), superinfection rate, ease and flexibility of use, cost, patient acceptance, and side effects. Note that there are no firm scientific data that convincingly support the use of any specific topical antimicrobial.

**Specific topical agents**

**Silver sulfadiazine (Silvadene).**

This poorly soluble compound is synthesized by reacting silver nitrate with sodium sulfadiazine. It is the most commonly used topical agent and is well tolerated by most patients. It has virtually no systemic effects and moderate eschar penetration, and it is

painless on application.

Silver sulfadiazine is available as a "micronized" mixture with a water-soluble white cream base in a 1% concentration that provides 30 mEq/L of elemental silver. It does not stain clothes, is nonirritating to mucous membranes, and is easily washed off with water. It may be used on the face, but such use may be cosmetically undesirable for open treatment. Its broad gram-positive and gram-negative antimicrobial spectrum includes beta-hemolytic streptococci, *Staphylococcus aureus* and *Staphylococcus epidermidis*, *Pseudomonas* spp., *Proteus* spp., *Klebsiella* spp., Enterobacteriaceae spp., *Escherichia coli*, *Candida albicans*, and possibly *Herpesvirus hominis*.

Silver sulfadiazine often interacts with wound exudate to form a pseudomembrane over partial-thickness injuries. The pseudomembrane is often difficult and painful to remove. Except for term pregnancy and in newborns (i.e., due to possible induction of kernicterus), there are no absolute contraindications to the use of silver sulfadiazine. Allergy and irritation are unusual, although there is a potential cross-sensitivity between silver sulfadiazine and other sulfonamides.

**Mafenide acetate (Sulfamylon).**

Mafenide is another broad-spectrum antimicrobial that has excellent activity against *Pseudomonas* and other gram-negative organisms. It

has excellent eschar penetration but is quite painful when applied to sensate burns. Since mafenide is a carbonic anhydrase inhibitor, application to large surface wounds may result in a metabolic acidosis. This agent has been supplanted by other topical antimicrobials in minor burn care; its use should be limited to more serious burn wounds with or at high risk for invasive infection.

**Silver nitrate.**

Silver nitrate is an effective topical antimicrobial, but its popularity has decreased since the 1970s. It is painless on application, has a broad spectrum of antibacterial activity, and has no known bacterial resistance. It is available commercially as a 0.5% solution, but this is often clinically unavailable, necessitating custom compounding. Silver nitrate has several significant disadvantages: It is cumbersome to apply and tends to stain clothing and bandages; it has relatively poor tissue penetration; and it causes leaching of sodium, potassium, and chloride from the wound. Silver nitrate also requires increased nursing care in order to maintain moist bandages.

Silver sulfadiazine, mafenide acetate, and silver nitrate all tend to delay epithelialization and may actually slow burn wound healing. For this reason, these potent agents should be reserved for use in the treatment of extensive, infected, or full-thickness burns. [4]

**Broad-spectrum antibiotic ointments.**

Many nonprescription topical antimicrobials are used for minor burn therapy. Included

are bacitracin zinc ointment, polymyxin B-bacitracin (Polysporin), triple-antibiotic ointments such as polymyxin B-neomycin-bacitracin (Neosporin), and nitrofurazone (Furacin). These are all soothing, cosmetically acceptable for open treatment (such as on the face), and are effective antiseptics. Some researchers caution against agents containing neomycin because of a potential for sensitization.

### Povidone-iodine.

Despite the long record of safety and clinical efficacy this agent enjoys when used on *normal skin and mucous membranes*, its routine use on burns is not widely accepted. It is available commercially for topical use compounded in a water-miscible cream base. This combination is strongly acidic (pH 2.40), and its use may result in significant systemic absorption of iodine. In short, other safer and more readily available topical antimicrobials should be used routinely.

### Gentamicin sulfate.

Gentamicin sulfate is available for topical use as a 0.1% cream or ointment. It is readily absorbed when applied to open wounds and may result in the typical aminoglycoside-induced nephrotoxicity or ototoxicity. Burn specialists eschew its use for fear of the development of resistant strains of *Pseudomonas*.

### Chlorhexidine.

Chlorhexidine gluconate is a skin antiseptic that is widely available commercially in Hibiclens solution. Its prophylactic antibacterial effectiveness is comparable to silver sulfadiazine, but toxicity and absorption characteristics are not fully documented (Dr. Christine Ney, Zeneca Pharmaceuticals, personal communication, 1997). Chlorhexidine may be used as a skin or burn cleanser, but *it is not recommended as a topical agent under dressings*.

Chlorhexidine phosphanilate differs from other salts of chlorhexidine in that the phosphanilate moiety confers broad gram-negative antibacterial activity on the molecule that is not cross-resistant with silver sulfadiazine. [25]

### Aloe vera cream.

Aloe vera cream is commercially available in a 50% concentration with a preservative. It exhibits antibacterial activity against at least 4 common burn wound pathogens: *Pseudomonas aeruginosa*, *Enterobacter aerogenes*, *S. aureus*, and *Klebsiella pneumoniae*. Heck and colleagues compared a commercial aloe vera cream with silver sulfadiazine in 18 patients with minor burns. [26] Healing times were found to be similar, and there was no increase in wound colonization in the aloe vera group as compared with the patients treated with silver sulfadiazine. Aloe vera cream may be a viable, inexpensive option for open, home care of minor burns or skin graft donor sites.

# FOLLOW-UP CARE OF MINOR BURNS

The specifics of outpatient follow-up of minor burns are controversial and often based on physician preference and personal bias rather than on firm scientific data. Follow-up should be individualized for each patient and should be based on the reliability of the patient, the extent of the injury, the frequency and complexity of the dressing changes, and the amount of discomfort anticipated during a dressing change.

If a topical antibiotic agent is used, the dressing should be changed once or twice a day with reapplication of the antibiotic ointment. The wound should be rechecked by a physician after 2 to 3 days and periodically thereafter, depending on compliance, healing, and other social issues. If a dry dressing is opted for, follow-up every 3 to 5 days is usually adequate. The purpose of any burn dressing changes or home care regimen is defeated if the patient cannot afford the material or is not instructed in the specifics of burn care. Many EDs supply burn dressing material on patient release. (A complete pack includes antibiotic cream, gauze pads [fluffs], an absorbent gauze roll, a sterile tongue blade to apply cream, and tape.) Writing a prescription and merely stating that the dressing should be changed daily is often futile.

Daily home care can be performed by the patient with help from a family member or visiting nurse (Table 41-3) . The dressing may be removed each day and gently washed with a clean cloth or a gauze pad, tap water, and a bland soap. Sterile saline and expensive prescription soaps are not required. A tub or shower is an ideal place to gently wash off burn cream. The affected area may be put through a

| **TABLE 41-3** -- How to Change a Burn Dressing at Home: Patient Instructions |
| --- |
| 1. Take pain medicine ½ hour before dressing change if you find dressing changes a painful procedure. |
| 2. If the burn is on the hand or foot or other area difficult to reach, have someone else help you. |
| 3. Have all material available. Gloves may be worn. |

| |
|---|
| 4. Remove the dressing and rinse off all burn cream or ointment with tap water, under a shower, or in the bathtub. The area can be gently washed with mild soap and a clean cloth or gauze pads. |
| 5. Look at the burn and assess the healing, blistering, and amount of swelling. Note any signs of infection. |
| 6. Gently exercise the area through range of motion. |
| 7. Apply the burn ointment with a sterile tongue blade. |
| 8. Cover the cream with fluffed-up gauze. |
| 9. Wrap the area in bulky gauze. |
| 10. Repeat this dressing change daily. |

gentle range of motion during dressing changes. After the burn is cleaned, it is inspected by the patient. The patient is instructed to return if signs or symptoms of infection, significant blistering, or skin slough develop. Following complete removal of the old cream, a new layer is applied with a sterile tongue blade and covered with absorbent gauze.

If the undermost fine mesh gauze of a dry dressing is dry and the coagulum is sealed to the gauze, the patient should simply reapply the overlying gauze dressing. If the wound is macerated, the fine mesh gauze should be removed and the wound cleaned and redressed. The patient is instructed *not to remove a dry adherent fine mesh gauze from the underlying crust*. When epithelialization is complete, the crust will separate, and the gauze can be removed at that time. Dryness in healing skin may be treated with mild emollients such as Nivea (Beiersdorf, Inc., Norwalk, Conn) or Vaseline Intensive Care lotion (Chesebrough Ponds, Inc., Greenwich, Conn). Natural skin lubrication mechanisms usually return by 6 to 8 weeks. [12] Excessive sun exposure should be avoided during wound maturation, as this may lead to hyperpigmentation; a

commercially available sun block should be used. Exposure of the recently healed burned area to an otherwise minor trauma (chemicals, heat, sun) may result in an exaggerated skin response. Pruritus may be treated with oral antihistamines or a topical moisturizing cream.

Deep partial-thickness burns, along with small third-degree burns, may be initially managed in the outpatient setting. Topical antimicrobials are recommended; mafenide (Sulfamylon) cream may be useful in the care of small, full-thickness burns because it is capable of penetrating the entire eschar and is present in subjacent tissues at bactericidal levels. [13]

**Outpatient Physical Therapy for Burn Care**

When the hospital's outpatient physical therapy department is equipped to treat minor burns, it is prudent to consider this option. Many centers make available daily burn treatment, consisting of dressing changes, whirlpool debridement, and range-of-motion exercises. When patients are unable to handle their own burns at home, this can be an invaluable adjunct. An additional advantage is that medically trained personnel evaluate the burn daily, thereby decreasing physician visits and enabling identification of problems prior to the development of serious complications. Generally all that is required from the physician is to write a prescription for "burn care and dressing changes" and set up the appointment.

**Burn Healing**

Follow-up care will in part be guided by expectations of burn healing and observed healing. The following discussion is intended to serve as a general guide. However, burn healing is different from that of other wounds. [2] The timing is often variable, but it is proportional to burn depth. The inflammatory phase lasts 3 to 7 days (at times longer) and, if the burn is severe enough, is accompanied by the release of histamine and bradykinins, along with complement degradation. This degradation of complement may lead to immunologic, coagulation, and metabolic aberrations.

Within 1 to 3 weeks, neovascularization of the burn occurs, accompanied by fibroblast migration. Macrophages begin to replace the tissue neutrophils. Collagen production begins, but the molecules are often laid down in random fashion, leading to a scar. Re-epithelialization follows, but the presence of necrotic tissue and eschar impedes all aspects of wound healing. The amount of scar tissue produced is directly related to healing time. Burns requiring <16 days to heal generally do not scar excessively. [2]

Healing in superficial partial-thickness burns occurs within 10 to 14 days. After healing, the new epithelial layer tends to dry easily and crack. Using bland, lanolin-containing creams for 4 to 8 weeks following healing alleviates this problem. Deep partial-thickness burns heal by re-epithelialization from the wound edge and from residual dermal elements. Healing is slow and often unsatisfactory, frequently taking longer than 3 weeks, producing an unstable epithelium that is prone to hypertrophic scarring and contractures. This is a particular problem in burns that extend across joints. Burns that take longer than 2 to 3 weeks to heal are prone to infection; hence, topical

antimicrobials should be used. Because these burns often heal in complicated fashion, they should be considered for referral to expedite early excision, grafting, and physical therapy.

Full-thickness burns can heal only by contraction and epithelialization at the wound edge. Burns larger than 2 to 3 cm must be excised and grafted.

Cosmetic and functional recovery follows complete epithelialization of a partial-thickness injury or successful skin grafting of a full-thickness burn. The ultimate goal is to prevent scar thickening; achieve and maintain optimal range of motion; and prevent secondary environmental damage to the skin, particularly from sun exposure. [13] Nonscented skin lotions may be used after epithelialization to keep the burn scar soft. Compression dressings are especially helpful in preventing scar thickening. Repeated evaluations are important, because burn contractures can occur up to 12 months after the injury. Nighttime splinting is useful in maintaining full extension of joints.

## SPECIAL MINOR BURN CARE CIRCUMSTANCES

### Blisters

The management of blisters in minor burns is controversial. Management arguments are generally theoretic or emotional; the ultimate outcome of a minor burn is rarely determined by how one deals with blisters. Intact blisters do offer a physiologic dressing that rarely becomes infected; however, most large blisters spontaneously rupture after 3 to 5 days and eventually require debridement. When the integrity of the blister is breached, the fluid becomes a potential culture medium. Clinical choices include debridement, aspiration, or simply leaving the blister intact.

Some studies suggest that intact burn blisters may allow for reversal of capillary stasis and less tissue necrosis. [2] Madden and colleagues have shown that burn exudate (as contained within intact blisters) is beneficial for the stimulation of epidermal cell proliferation. [27]

Swain and colleagues demonstrated that the density of wound colonization with microorganisms was much lower in minor burns with blisters left intact. [28] They also found that 37% of patients with aspirated blisters experienced a

reduction in pain versus none of those whose blisters were unroofed. Other investigators believe that undressed wounds with debrided blisters have additional necrosis secondary to desiccation, which can convert a partial-thickness burn to a full-thickness injury. [3] Finally, intact blisters clearly provide some pain relief, as evidenced by a sudden increase in pain immediately following debridement. Increased pain should be anticipated and analgesia offered as appropriate when debridement is necessary. We suggest the guidelines in Table 41-2 as a general approach to burn blisters.

**Minor Burn Infections**

There are bacteria on the skin at all times--normal skin usually harbors nonvirulent pathogens such as *S. epidermidis* and diphtheroids. Therefore, all burns are *contaminated* but not necessarily *infected*. Thermal trauma results in a coagulative necrosis. Burn wounds therefore contain a variable amount of necrotic tissue, which, if infected, acts much as an undrained abscess, preventing access of antibiotics and host defensive factors.

The microbial flora of outpatient burns varies with time after the burn. Shortly after injury, the burn becomes colonized with gram-positive bacteria such as *S. aureus* and *S. epidermidis*. After this period of time there is a gradual shift toward inclusion of gram-negative organisms, 80% of which originate from the patients' own gastrointestinal tract. [4] Common organisms seen on days 1 to 3 include *S. epidermidis*, beta-hemolytic streptococci, *Bacillus subtilis*, *S. aureus*, enterococci, *Mima polymorpha*, *Enterobacter* spp., *Acinetobacter* spp, and *C. albicans*. One week after the burn, these organisms may be seen along with *E. coli*, *P. aeruginosa*, *Serratia marcescens*, *K. pneumoniae,* and *Proteus vulgaris*.

Anaerobic colonization of burn wounds is rare unless there is much devitalized tissue, as occurs in a high-voltage electrical injury. [29] For this reason, routine anaerobic cultures are generally unnecessary in an assessment of infective organisms that produce minor infections.

Most superficial wounds that have been treated properly do not get infected. However, it is sometimes difficult to differentiate wound infection from the normal healing process, as both involve pain, edema, and erythema. Early (days 1 to 5) burn infections are generally caused by gram-positive cocci, especially beta-hemolytic streptococci. Streptococcal cellulitis is characterized by marked, spreading erythema extending outward from the wound margins. Despite the plethora of organisms and the presence of some gram-negative pathogens noted in superficial burn cultures, first-line treatment in the normal host is oral penicillin, 1 to 2 g/day.

Effective topical treatment at the time of initial burn care and subsequent dressing changes is meant to delay bacterial colonization, maintain the wound bacterial density at low levels, and produce a less diverse wound flora. Because outpatient management of burns should be attempted only when the risk of infection is minimal, the use of systemic antibiotics is generally unnecessary for minor burns even in the setting of delayed treatment, diabetes, and steroid use. [30] Parenteral antibiotics in the management of minor burns have been recommended for patients undergoing an autograft procedure and for patients with a sore throat or other known streptococcal infection in whom penicillin is otherwise indicated. [31]

In minor burn care, wound cultures are not required or recommended. It is useless, for example, to culture blister fluid in the patient who presents for emergency care immediately after a thermal injury. Cultures are necessary only when overt infection develops, especially when this occurs while a topical or systemic antibiotic is being

used. Cultures may also be of benefit when the infected wound is old, when hygiene is poor, or when there are old abrasions nearby. [32] Swab surface cultures are generally eschewed. Although they may adequately reflect wound flora, falsely sterile cultures are relatively frequent. These cultures do not reflect deep burn flora and give no quantitative information.

Sterile wound biopsy for culture is most satisfactory for the assessment of intraescharotic, subescharotic, or invasive infections and allows for quantification of bacterial flora. If a wound culture is taken, it should be obtained from the deepest or worst-appearing area of the burn.

Surface bacterial densities >10 [5] /cm [2] or tissue bacterial densities >10 [5] /g correlate with invasive infection. Surface colonization may be treated with an alternative topical agent, but truly invasive infection warrants the administration of systemic antibiotics. Generally, the infectious process resolves in 24 to 48 hours.

## Foot Burns

Despite their relatively small surface area, foot burns tend to heal poorly, usually due to excessive edema; therefore they are formally categorized as major burns. Foot burns are the most common burn category to fail outpatient therapy and subsequently require admission and inpatient care. Zachary and coworkers reported on a series of 104 patients with foot burns. [33] No patient admitted on the day of injury developed burn cellulitis; in contrast, 27% of delayed admission patients had cellulitis. Their study also noted a higher incidence of hypertrophic scarring and need for skin grafting in the delayed admission group. Overall, fewer days of hospitalization were required for the initially admitted group.

Specific problems in the care of foot burns include pain, wound drainage, difficulty in changing dressings without help, inability of even motivated patients to comply with requirements for elevation, and prolonged convalescence. Hospital admission allows for splinting, intensive local burn care, physical therapy, and bed rest with elevation, which minimizes edema. For these reasons, initial admission for all but the most minor of foot burns is advised.

## Hand Burns

Because of their functional importance, hand burns can be a devastating injury, despite involvement of a relatively small TBSA. Hand function is critical, regardless of whether the patient is dealing with loss of use during healing, later limitation by scar contractures, a long-term appearance change, or loss due to amputation. [34]

As with other burns, the depth and extent of the burn determine the severity of the injury. The entire surface of one hand represents only 2.5% TBSA, yet even small burns can cause a disproportionate functional loss. Deep partial- or full-thickness hand burns, even if quite small, often warrant referral for early excision and grafting in order to limit scarring and maintain function. The skin on the dorsum of the hand is thinner than that

on the palm and is more susceptible to burn injury, but must remain flexible to allow

for finger motion. Any exposed tendon or bone, such as may be seen with an electrical burn, constitutes a true fourth-degree injury, which requires either flap closure or amputation in order to heal the wound. Many of the issues complicating outpatient management of foot burns are relevant to the care of hand burns. After initial burn cooling, the wound should be gently cleansed with mild soap. Any loose skin or ruptured blisters should be gently debrided, rinsed, patted dry, and covered with a topical antimicrobial agent and a nonadherent, bulky gauze dressing. The fingers should be carefully separated and bandaged individually. Small, intact blisters that do not interfere with hand function should be left intact to serve as a biologic dressing. Elevation of the hand is very important in the first few days after a burn injury in order to minimize edema. Deep partial- or full-thickness burns to the dorsum of the hand should be splinted after bandaging to avoid the development of contractures or a boutonniere deformity.

Hospital admission should be considered for all hand burns, particularly full-thickness injuries and circumferential burns involving the digits. If outpatient treatment is attempted, the patient must be given comprehensive instructions and should have the resources available to perform twice-daily dressing changes and range-of-motion exercises of the fingers and wrist during these dressing changes. An initial follow-up visit should be arranged in 48 to 72 hours, but the patient should be encouraged to return if there is development of a burn cellulitis, worsening pain, fever, or lymphangitis. Ideally, the patient should be seen twice in the first week after injury and once a week after that until the burn is healed.

**Facial Burns**

Facial burns commonly result from unexpected ignition flash burns (e.g., from a stove or charcoal grill) or from car radiator accidents. Facial burns often result in significant edema, which may compromise vision. Concurrent corneal injury can lead to the development of purulent conjunctivitis, with the risks of corneal ulceration and perforation. Fluorescein staining and slit-lamp examination should be used to confirm the diagnosis of suspected corneal injury. The treatment of a corneal injury involves irrigation, topical ophthalmic antibiotic ointment, and consideration of eye patching (see Chapter 67) . Facial burns are otherwise treated with an open technique. Patients are instructed to wash the face 2 to 3 times a day with a mild soap and then apply a thin layer of antibiotic ointment, such as bacitracin zinc. Neck burns are treated similarly. All patients presenting with head or neck burns should be carefully evaluated for a concomitant inhalation injury. Such patients may present with direct evidence of injury, such as oral burns, blisters, soot, or hyperemia, or with indirect evidence, such as dyspnea, wheezing, arterial hypoxemia, or an elevated carboxyhemoglobin level. The definitive diagnostic test for inhalation injury is fiberoptic bronchoscopy. [35] Inpatient care should be considered for all patients with significant facial burns.

Corneal contact burns, as from accidental contact with a curling iron, often present rather dramatically, with opacified, "heaped-up" corneal epithelium. Despite their appearance, the end result is usually excellent. Treatment is the same as for a corneal

abrasion. [36]

## Abuse of Children and Elderly Individuals

Recognition of the possibility of deliberate abuse by burning in the pediatric and geriatric populations is essential. In addition, children under 2 years old have a thinner dermis and a less well developed immune system than do adults. Elderly patients (>65 years old) likewise tolerate burns poorly, and these 2 populations are the most prone to abuse, often by family members. For these reasons, both groups of patients often require inpatient care. [8]

The majority of abused children are 18 to 36 months old, and for unknown reasons the majority are male. [23] Immersion burns are a common type of abuse. These are characterized by circumferential, sharply demarcated burns of the hands, feet, buttocks, and perineum. Cigarette burns and burns from hot objects such as irons should be obvious. Contact burns on "nonexploring" parts of the child also warrant suspicion.

## Burns in Pregnancy

There is little information in the literature concerning the special problems of the pregnant burn victim. Ying-bei and Ying-jie reported on 24 pregnant burn patients representing a wide range of burn severity. [37] Complications of the burn injuries included abortion and premature labor, although all patients in this series with burns covering <20% TBSA did well and delivered living full-term babies.

As the resistance of pregnant women to infection is lower than that of nonpregnant women, control of burn wound infection is paramount. Gestational age appears to have no direct bearing on prognosis. Silver sulfadiazine cream should be avoided near term because of the potential for kernicterus.

# SPECIFIC BURNING AGENTS

## Hot Tar Burns

Asphalts are products of the residues of coal tar commonly used in roofing and road repair. These products are kept heated to approximately 450 °F. When spilled onto the skin, the tar cools rapidly, but the retained heat is sufficient to produce a partial-thickness burn. Fortunately, full-thickness burns are unusual. Cooled tar is nonirritating and does not promote infection. When cooled tar is physically removed, the adherent skin is usually avulsed (Fig. 41-6) . Careless removal of the tar may inflict further damage on burned tissues. Agents such as alcohol, acetone, kerosene, or gasoline have been used to remove the tar, but these are flammable and may cause additional skin damage or toxic response secondary to absorption.

*There is no great need to meticulously remove all tar at the first visit.* Obviously devitalized skin can be debrided, but adherent tar should be emulsified or dissolved rather than manually removed (Fig. 41-7) . Polyoxyethylene sorbitan (Tween 80 or

polysorbate 80) is the water-soluble, nontoxic emulsifying agent found in Neosporin and several other topical antibiotic ointments. It is a complex mixture of ethers, esters, and sorbitol anhydrides that possesses excellent hydrophilic and lyophilic characteristics when used as a nonionic, surface-active emulsifying agent. With persistence, most tar may be removed (emulsified) on the initial visit.

Another household product (De-Solv-It multi-use solvent) also appears promising for topical ED use. [38] The De-Solv-It product has a surface-active moiety that wets the chemical's surface and emulsifies tar and asphalt. Since the latter product is itself a petroleum-based solvent, it should be applied only briefly, and the operator should wear gloves and protective eyewear during application. It should be used only for external exposure to tar or asphalt.

Many physicians prefer instead to emulsify the tar on an outpatient basis. A generous layer of polysorbate-based ointment can be applied under a bulky absorbent gauze dressing. The patient is then released home, and the residual is easily washed off after 24 to 36 hours (Fig. 41-8) . Once the residual tar is removed, the wound is treated like any other burn.

Shur-Clens, a nontoxic, nonionic detergent, also works well for tar burn wound cleansing, as do mineral oil; petrolatum; and Medisol (Orange-Sol, Inc, Chandler, Ariz), a petroleum-citrus product.

**Chemical Burns**

Chemical burns usually occur in the workplace, and the offending substance is usually well known. More than 25,000 chemicals currently in use are capable of burning the skin or mucous membranes. Commonly used chemical agents capable of producing skin burns are shown in Table 41-4 .

Injury is caused by a chemical reaction, rather than a thermal burn. [39] Reactions are classified as oxidizing, reducing, corrosive, desiccant, or vesicant or as protoplasmic poisoning. The injury to skin continues until the chemical agent is physically removed or exhausts its inherent destructive capacity. The degree of injury is based on chemical strength,

| **TABLE 41-4** -- Commonly Used Acids and Alkalis | |

| Chromic | |

concentration, and quantity; duration of contact; location of contact; extent of tissue penetration; and mechanism of action.

Immediate flushing with water is recommended for all chemical burns, with the exception of those caused by alkali metals. Flushing serves to cleanse the wound of

unreacted surface chemical, dilute the chemical already in contact with tissue, and restore lost tissue water. Leonard and colleagues clearly demonstrated that patients receiving immediate copious water irrigation for chemical burns showed less full-thickness burn injury and a 50% reduction in time of hospital stay. [40]

**Acid and Alkali Burns**

Alkalies cause saponification and liquefactive necrosis of body fats. Alkaline burns are *penetrating* and cause much tissue destruction. With acid burns, tissue coagulation produces a thick eschar that limits the penetration of the agent. Desiccant acids, such as sulfuric acid, create an exothermic reaction with tissue water and can cause both chemical and thermal injury. With extensive immersion injuries, acids may be systemically absorbed, leading to systemic acidosis and coagulation abnormalities.

Chemical burns may be excruciatingly painful for long periods of time. Discomfort can be out of proportion to what one might expect from the depth or extent of the burn.

The emergency care team should remove all potentially contaminated clothing. Any dry (anhydrous) chemical should be brushed off the patient's skin. The involved skin should be irrigated with large amounts of water under low pressure. Any remaining particulate matter should be carefully debrided during irrigation.

Strong alkali burns may require irrigation for 1 to 2 hours before the tissue pH returns to normal. Some recommend that *after extensive irrigation*, if the burn continues to feel "slippery" or tissue pH has not returned to normal, chemical neutralization may be helpful. [41] [42] Given that any heat of neutralization will be carried away with the irrigation solution, [43] prompt irrigation with a dilute acid (e.g., vinegar; 2% acetic acid) may hasten neutralization and patient comfort.

**Wet Cement Burns**

Portland cement is an alkaline substance whose major constituent is calcium oxide (64%), combined with oxides of silicon, aluminum, magnesium, sulfur, iron, and potassium. There is considerable variability in the calcium oxide content of different grades of cement, with concrete having less and fine-textured masonry cement having more. [40] The addition of water exothermically converts the calcium oxide to calcium hydroxide, a strongly corrosive alkali with a pH of 11 to 13. As the cement hardens, the calcium hydroxide reacts with ambient carbon dioxide and becomes inactive.

Both the heat and the $Ca(OH)_2$ produced in this exothermic reaction can result in significant burns. Because of its low solubility and consequent low ionic strength, a long exposure to calcium hydroxide is required to produce injury. This usually occurs when a worker spills concrete into his or her boots or kneels in it for a prolonged period. The burn wound and the resultant protein denaturation of tissues produces a thick, tenacious, ulcerated eschar. Concrete burns are insidious and progressive. What may appear initially as a patchy, superficial burn may in several days become a full-thickness injury requiring excision and skin grafting. [44] The pain of these burns is often severe

and more intense than the appearance of the wound might suggest (Fig. 41-9) . Interestingly, many workers are not warned of the dangers of prolonged contact with cement, and because initial contact with cement is usually painless, exposure may not be realized until the damage is done.

Treatment is as follows: Any loose particulate cement or lime is brushed off, contaminated clothing is removed, the wound is copiously irrigated with tap water (the pH of the effluent is tested and irrigation continued if the effluent is still alkaline), compresses of dilute acetic acid (vinegar) may be applied to neutralize the remaining alkali and provide pain relief after irrigation, and antibiotic ointment is applied to the eschar during the early postburn period.

Sutilains ointment (Travase, Flint Pharmaceuticals, Deerfield, Ill) is often recommended because it contains proteolytic enzymes and helps speed eschar separation, but any common topical burn preparation is acceptable. The depth of burns from wet cement can be difficult to assess in the first several days. If it becomes apparent that the burns are full-thickness burns, early excision and skin grafting are recommended.

Cement burns should be differentiated from cement dermatitis, which is far more common. The latter is a contact sensitivity reaction, probably due to the chromates present in cement. The contact dermatitis can initially be treated as a superficial partial-thickness burn.

**Air Bag Keratitis**

Recently enacted safety legislation has mandated increased use of air bags to protect automobile occupants in the event of collision. The automobile air bag is a rubberized nylon bag that inflates on spark ignition of sodium azide, yielding nitrogen gas, ash, and a small amount of sodium hydroxide. If the air bag ruptures, the alkaline contents of the bag are dispersed as a fine, black powder that usually causes no problems unless the eyes are exposed. Patients present with clinical evidence of a chemical keratoconjunctivitis, including photophobia, tearing, redness, and decreased visual acuity. The tear pH is usually elevated, and there may be a small amount of particulate material in the fornices. [45]

The severity of an ocular alkaline burn is related to the duration of exposure and the concentration and pH of the chemical. For this reason, prompt, copious irrigation of the eyes with frequent assessment of tear pH is essential to prevent or minimize the injury (see Chapter 67) . A rising pH suggests that trapped particulate matter is releasing additional chemical. Corneal edema and conjunctival blanching are signs of serious injury and necessitate immediate ophthalmologic consultation.

**Hydrocarbon Burns**

Hydrocarbons are capable of causing severe contact injuries by virtue of their irritant, fat-dissolving, and dehydrating properties. Cutaneous absorption may cause even more dangerous systemic effects. Gasoline, the usual agent involved, is a complex mixture of

C4 to C11 alkane hydrocarbons and benzene; the hydrocarbons appear to be the major toxic agent. Lead poisoning caused either by absorption through intact skin or burns from "leaded" gasoline exposure have been previously reported but are currently quite rare, as unleaded gasoline has virtually replaced the leaded version for most purposes. [46]

Depth of injury is related to the duration of exposure and concentration of the chemical agent. Gasoline immersion injuries resemble scald burns and are usually partial thickness. [47] Occasionally, gasoline-injured skin exhibits a pinkish brown discoloration, possibly related to dye additives. A common source of exposure is a comatose patient from a motor vehicle crash who had been lying in a pool of gasoline.

The lungs are the usual site of systemic absorption and are often the only major route of excretion. The resultant high pulmonary concentrations may lead to pulmonary hemorrhages, atelectasis, and adult respiratory distress syndrome (ARDS). Treatment of hydrocarbon burns includes the following: removal of contaminated clothing, prolonged irrigation or soaking of the contaminated skin, early debridement in significant burns caused by lead-containing gasolines (to reduce systemic lead absorption), and use of topical antibiotic ointments.

### Phenol Injury

Phenol is a highly reactive aromatic acid alcohol that acts as a corrosive. Carbolic acid, an earlier term for phenol, was noted to have antiseptic properties and was used as such by Joseph Lister in performing the first antiseptic surgery. Hexylresorcinol, a phenol derivative, is in current use as a bactericidal agent. Phenols, in strong concentrations, cause considerable eschar formation, but skin absorption also occurs and can cause systemic effects such as central nervous system depression, hypotension, hemolysis, pulmonary edema, and death. Interestingly, phenol acts differently from other acids in that it penetrates deeper when in a dilute solution than when in a more concentrated form. [39] Therefore, irrigation with water is suboptimal for phenol burns, but because water commonly is readily available, it is frequently used for irrigation.

Full-strength polyethylene glycol (PG 300 or 400) is more effective than water alone in removing phenolic compounds and should be obtained and used after water irrigation has begun. Polyethylene glycol is nontoxic and nonirritating and may be used anywhere on the body. When immediately available, polyethylene glycol can be used to remove the surface chemical before water irrigation (and chemical dilution) is begun.

### Hydrofluoric Acid Injury

Hydrofluoric acid (HFA) is one of the strongest inorganic acids known; it has been widely used since its ability to dissolve silica was discovered in the late 17th century. [48] Currently, HFA is used in masonry restoration, glass etching, and semiconductor manufacturing; for control of fermentation in breweries; and in the production of plastics and fluorocarbons. It is also used as a catalyst in petroleum alkylating units. It is available in industry as a liquid in varying concentrations up to 70%. It is also found in

many home rust-removal products, and in aluminum brighteners and heavy-duty cleaners in concentrations of <10%.

Although HFA is quite corrosive, the hydrogen ion plays a relatively insignificant role in the pathophysiology of the burn injury. The accompanying fluoride ion is a protoplasmic poison that causes *liquefaction necrosis and is notorious for its ability to penetrate tissues and cause delayed pain and deep tissue injury.* This acid can penetrate through fingernails and cause nailbed injury. With home products, the unwary user does not realize that the substance is caustic until the skin (usually the hands and fingers) is exposed for a few minutes

to hours, at which time the burning begins and becomes progressively worse. At this point the damage is done, and the absorbed HFA cannot be washed off. With higher-strength industrial products, symptoms are almost immediate.

The initial corrosive burn is due to free hydrogen ions; secondary chemical burning is due to the tissue penetration of fluoride ions. Fluoride is capable of binding cellular calcium, resulting in cell death and liquefaction necrosis. The ionic shifts that result, particularly shifts of potassium, are believed to be responsible for the severe pain associated with HFA burns.

In high concentrations, the fluoride ions may penetrate to the bone and produce demineralization. Skin exposure to concentrated HFA involving as little as 2.5% TBSA can lead to systemic hypocalcemia and death from intractable cardiac arrhythmias; it has been calculated that exposure to 7 mL of anhydrous HFA (HFA gas) is capable of binding *all* of the free calcium in a 70-kg adult. [49] [50] If the hands are exposed, the acid characteristically penetrates the fingernails and injures the nailbed and cuticle area. As with most caustics, *the pain is generally out of proportion to the evident external physical injury.* HFA burns produce variable areas of blanching and erythema, but rarely are blisters or skin sloughing seen initially. Skin necrosis and cutaneous hemorrhage may be noted in a few days.

Immediate treatment should begin with copious irrigation with water. Another approach is to wash the area with a solution of iced magnesium sulfate (Epsom salts) or a 1:500 solution of a quaternary ammonium compound such as benzalkonium chloride (Zephiran) or benzethonium chloride (Hyamine 1622). Magnesium and calcium salts form an insoluble complex with fluoride ions, preventing further tissue diffusion. Unfortunately, topical preparations are often ineffective in limiting injury or controlling pain.

If there is no or only minimal visible evidence of skin injury and minimal pain, the burn may be dressed with topical calcium gluconate paste. This is not commercially available in the United States but is easily compounded in the pharmacy by mixing 3.5 to 7.0 g of pulverized calcium gluconate with 5 oz of a water-soluble lubricant such as K-Y jelly. This will form a thick paste with a calcium gluconate concentration of 2.5 to 5.0%. Some have suggested dimethyl sulfoxide (DMSO) as a vehicle to aid in skin penetration of the calcium. Plastic wrap (e.g., Saran wrap) is used over a standard dry burn dressing to cover the calcium paste on the limbs; a vinyl or rubber glove is used over the paste

when used on the hands. The wound should be completely redressed and the paste reapplied every 6 hours for the first 24 hours. A digital or regional nerve block with long-acting bupivacaine is an excellent way to provide prolonged pain relief if the hands are involved. Otherwise, oral opioids are generally required. If bullae or vesicles have formed, these should be debrided to decrease the amount of fluoride present, and the wound should then be treated as any partial-thickness burn. Burns with HFA of <10% strength will heal spontaneously, usually without significant tissue loss, but pain and sensitivity of the fingertips may persist for 7 to 10 days. In addition, the fingernails may become loose.

The presence of significant skin injury or intense pain implies penetration of the skin by fluoride ions. This scenario is particularly common with exposure to HFA solutions in concentrations of 20%, but tissue injury can occur with prolonged exposure to less concentrated products.

Initial treatment of a more concentrated exposure begins as described above and includes immediate debridement of necrotic tissue to remove as much fluoride ion as possible. Following this, a 10% solution of calcium gluconate *(note: avoid calcium chloride for tissue injections)* is injected intradermally and subcuticularly with a 30-ga needle about the exposed area, using about 0.5 mL/cm [2] of burn. Pain relief should be almost immediate if this therapy is adequate. Since the degree of pain is a measure of the effectiveness of treatment, the use of anesthetics, especially by local infiltration, may be deleted if the burn is on the arm or leg. HFA can penetrate fingernails without damaging them. Soft tissue can be injected without prior anesthesia, but if the fingertips or nailbeds are involved, they may be injected after a digital nerve block has been performed (Fig. 41-10) . Before anesthesia and prior to injecting calcium, the patient can outline the affected areas with a pen to ensure accurate injection of the antidote (see Fig. 41-10 *B*). Although some investigators recommend that the fingernails be removed routinely, we strongly advise *against* this unless the nails are very loose or there is obvious necrosis of the nailbed. Fingers are best injected with a 25- or 27-ga needle (a tuberculin syringe works well). [51] Nails frequently become loose in a few days, but often they return to normal and do not require removal, particularly when lower concentration nonindustrial products are involved.

Although calcium gluconate infiltration is effective, the technique has certain limitations. Injections are painful, and the calcium gluconate solution itself causes a burning sensation. Because of the volume restrictions, not enough calcium may be delivered to bind all the free fluoride ions present. For example, 0.5 mL of 10% calcium gluconate contains 4.2 mg (0.235 mEq) of elemental calcium, which will neutralize only 0.025 mL of 20% HFA.

Several authorities have advocated intra-arterial calcium infusions in the treatment of serious HFA burns of the extremities. [49] [52] Although very effective, this technique is not recommended for burns secondary to dilute HFA (i.e., concentrations <10%), because morbidity is usually quite mild. When using this technique, 10 mL of 10% calcium gluconate are diluted in 50 mL of a 5% dextrose-and-water solution. The dilute solution is given by a slow infusion into an arterial catheter. If only the radial 3 digits are involved, only the radial artery need be cannulated. Otherwise, a percutaneous catheter

is inserted into the brachial artery, and *the solution is slowly infused over 4 hours.* At this point, the catheter is left in place, and the patient is observed. If pain returns at any time over the next 4 hours, the infusion is repeated. If the patient is pain free over the 4-hour observation period, the burn is dressed, and the patient is released home.

Advantages of the intra-arterial method are elimination of the need for painful SQ injections and avoidance of the volume limitations of the SQ route while providing substantially more calcium to neutralize the fluoride. Both the chloride and gluconate salts of calcium have been used intra-arterially. A volume of 10 mL of 10% calcium gluconate contains 4.7 mEq of calcium, whereas the same volume of 10% calcium chloride contains 14 mEq of calcium. Thus, intra-arterial calcium chloride may provide nearly 3 times as much neutralizing calcium equivalent as the gluconate salt; however, because calcium chloride can irritate tissues, it is not recommended for SQ use. Disadvantages of intra-arterial calcium therapy include the possibility of local arterial spasm (which can be treated with vasodilators such as phentolamine or removal of the catheter), local arterial injury or thrombus, and the long duration of treatment required.

HFA burns to the eye are a potentially devastating injury that deserves special mention. Ocular exposure to liquid or gaseous HFA will result in severe pain, tearing, conjunctival inflammation, and corneal opacification or erosion. Complications include decreased visual acuity, globe perforation, uveitis, glaucoma, conjunctival scarring, lid deformities, and keratitis sicca. Optimal therapy for ocular HFA burns, other than initial irrigation, is unknown. Irrigation may be performed with water, isotonic saline, or magnesium chloride. [53] Anecdotal reports have described promising results using a 1% solution of calcium gluconate in normal saline, with instillation of 2 to 3 drops into the injured eye every 3 hours for 2 days. Topical antibiotics and cycloplegics, along with light pressure patching, are also recommended. The use of topical steroids has been advocated by some in order to lessen corneal fibroblast formation, but other attempted therapies such as subconjunctival injections of calcium gluconate and ocular irrigation with quaternary ammonium compounds have been associated with additional injury. [54]

**Chromic Acid Injury**

Chromium compounds are used extensively in industry, mainly in metallic electroplating. Chromic acid is commonly used in concentrated solutions containing up to 25% sulfuric acid. It causes sufficient skin damage to allow absorption of the toxic chromium ion if intensive irrigation is not undertaken immediately. Heated (60 to 80 °C) chromic acid makes the problem of chromium absorption much worse.

Dichromate salts containing hexavalent chromium are the most readily absorbed and the most toxic because they can cross cell membranes. The mortality rate from these burns is very high if the burn exceeds 10% TBSA. Chromium absorption leads to diarrhea, gastrointestinal bleeding, hemolysis, hepatic and renal damage, coma, encephalopathy, seizures, and disseminated intravascular coagulation.

Treatment includes immediate excision of the burned tissues to lessen the total body dichromate burden. Wounds should be washed with a 1% sodium phosphate or sulfate

solution and dressed with bandages soaked in 5% sodium

thiosulfate solution. These actions reduce the hexavalent chromium ion to the less well absorbed trivalent form. [55]

Chelation therapy with ethylenediaminetetra-acetic acid (EDTA) should be instituted, and IV sodium thiosulfate and ascorbic acid given. Hemodialysis, peritoneal dialysis, or exchange transfusion may be indicated.

**Phosphorus Burns**

White phosphorus is a translucent, waxy substance that ignites spontaneously on contact with air. For this reason, it is usually stored under water. It is used primarily in fireworks, insecticides and rodenticides, and military weapons.

Phosphorus causes both thermal burns from the flaming pieces and acid burns, which result from the oxidation of phosphorus to phosphoric acid. The burns classically emit a white vapor with a characteristic garlic odor. [56]

These burns are treated first with immersion in water, followed by debridement of any gross debris. The wound is then washed with a 1% copper sulfate solution, which reacts with the residual phosphorus to form copper phosphate; the latter appears as black granules and allows for easy debridement. Following debridement, the residual copper is removed by a thorough water rinse, and the wound is dressed and treated as any other burn.

**Elemental Alkali Metal Burns**

The commonly encountered alkali metals (sodium, lithium, and potassium) are highly reactive with water and with water vapor in air, producing their respective hydroxide with liberation of hydrogen gas. Therefore, water should never be used for extinguishing or debridement of the metal. A class D fire extinguisher or plain sand may be used for smothering the fire, followed by application of mineral oil or cooking oil to isolate the metal from water and allow safe debridement. The burn is then treated as an alkali burn.

Magnesium burns in a less intense fashion but otherwise acts as do other alkali metals. These burns may be particularly injurious, however, because if all of the metallic debris is not removed, the small ulcers that form will slowly enlarge until they become quite extensive.

# EMERGENCY ESCHAROTOMY

Full-thickness burns result in an eschar that is inelastic and may become restrictive. During fluid resuscitation and as a direct result of transcapillary extravasation of fluid from thermal injury, intracellular and interstitial edema progresses. As the soft tissues become edematous and pressure rises under the unyielding eschar, first venous and

then lymphatic, capillary, and ultimately arterial flow to the underlying and distal unburned tissue may be compromised. Full-thickness and extensive partial-thickness circumferential extremity burns are most likely to impede peripheral blood flow. Circumferential chest burns may restrict chest wall movement, impairing ventilation, and circumferential neck burns may result in tracheal obstruction. In such cases immediate escharotomy may be indicated.

On occasion, because of high-volume fluid resuscitation, noncircumferential and even unburned limbs may develop progressive tissue edema and ischemia requiring surgical decompression to prevent complications of nerve or muscle damage. Early elevation of the limb and active range-of-motion exercises every 15 minutes may minimize tissue edema, but once signs and symptoms of vascular impairment are present, the clinician must act quickly to prevent tissue hypoxia and cellular death. This pathophysiology may manifest itself within a time frame that mandates that the emergency physician must intervene. The reluctance of non-burn specialists to perform an adequate escharotomy is illustrated by the report of Brown and colleagues, [57] who found that 44% of pediatric burn cases were inadequately decompressed prior to arrival at a referral burn unit.

**Indications**

The indications for escharotomy are based on clinical examination, compartment pressure, or both. A high index of suspicion and a low threshold for intervention are essential for a successful outcome. Skin temperature and palpation of pulses are unreliable and imprecise indicators of adequacy of circulation because of peripheral vasoconstriction and local edema. The patient with circulatory embarrassment significant enough to warrant escharotomy may complain of deep aching pain, progressive loss of sensation, or paresthesias, but these parameters are difficult to quantitate in the severely burned, sedated, or mechanically ventilated patient. In the awake and cooperative patient, alteration in vibratory sensory testing with a 256-cps tuning fork may be a reliable indicator of increased compartment pressure. [58] However, gross motor activity and peripheral pulses may remain intact despite severe underlying muscle ischemia. In the series by Brown and colleagues, [57] peripheral pulses were present in 74% of the limbs that required decompression. Serial assessment of capillary refill, arterial flow (with the use of Doppler technique), arterial oxygen (with peripheral oximetry ), and compartmental pressures (using the technique described in Chapter 58) are sensitive indicators to monitor. Muscle compartments with pressures in excess of 30 mm Hg should be decompressed. Measurements should be taken before and after escharotomy to ensure adequate decompression.

In the patient with absent distal arterial flow (as determined by Doppler ultrasonic flowmeter) but an otherwise adequate blood pressure, immediate escharotomy is indicated. Bardakjian and colleagues suggest that an oxygen saturation below 95% in the distal extremity as demonstrated by pulse oximetry (in the absence of systemic hypoxia) also is a reliable indicator of the need for emergency escharotomy. [60]

**Technique of Escharotomy**

Because full-thickness burns are insensible to pain and involve coagulation of

superficial vessels, no general or local anesthesia is necessary, although sedation is highly recommended in the awake patient. A properly executed escharotomy releases the eschar to the depth of the SQ fat only. This results in minimal bleeding, which can be controlled by local pressure or electrocautery. These incisions, although limb- or life-saving, are potential sources of infection for the burn patient and should be treated as part of the burn wound. The wounds should be loosely packed with sterile gauze impregnated with an appropriate topical antimicrobial such as silver sulfadiazene cream. Fasciotomy, which involves a deeper incision, may be needed for thermal or electrical burns.

### Limbs

Under sterile conditions the lateral and medial aspects of the involved extremity are incised with a scalpel or electrocautery 1 cm proximal to the burned area, extending to 1 cm distal to the involved area of constricting burn (Fig. 41-11) (Figure Not Available) . The incision is carried through the full thickness of skin only and results in immediate separation of the constricting eschar to expose SQ fat. Because joints are areas of tight skin adherence and potential vascular impingement, incisions should cross these structures (Fig. 41-12) (Figure Not Available) . Care must be taken to avoid vital structures, such as the ulnar nerve at the elbow, the radial nerve at the wrist, the superficial peroneal nerve near the fibular head, and the posterior tibial artery at the ankle. The incision should extend to the great toe medially and the little toe laterally in circumferential burns of the feet, and to the thenar and hypothenar aspects of the hands (see Figs. 41-11 (Figure Not Available) and 41-12) (Figure Not Available) . Improvement in color, sensation, Doppler flow signal strength, and oximetry values indicate adequate release.

### Chest

Full-thickness circumferential chest or upper abdominal burns may impair respiration. For release of this eschar, the incision should extend from the clavicle to the costal margin in the anterior axillary line bilaterally and may be joined by transverse incisions, resulting in a chevron-shaped escharotomy.

### Neck

Neck escharotomy should be performed laterally and posteriorly to avoid the carotid and jugular vessels.

### Penis

Penile escharotomy is performed midlaterally to avoid the dorsal vein.

## Complications

Complications of escharotomy include bleeding, infection, and damage to underlying structures. Complications of inadequate decompression include muscle necrosis, nerve

injury (such as foot drop), and even amputation of the limb. Systemic complications of inadequate decompression include myoglobinuria and renal failure, hyperkalemia, and metabolic acidosis

## CONCLUSION

Patients with circumferential or nearly circumferential burns should be evaluated for deep tissue ischemia. Emergency physicians should not hesitate to perform an escharotomy prior to transfer of the patient to the burn center if there is evidence of reduced perfusion.

# Chapter 42 - Esophageal Foreign Bodies

**Steven A. Pace, Gary P. Young**

The presentation of a patient with an esophageal foreign body (FB) can range from the adult with dysphagia and a history of acute ingestion to the child with signs mimicking acute epiglottitis or chronic respiratory symptoms such as asthma. Four groups of patients are prone to have FBs lodge in the esophagus: patients with esophageal pathology; older patients with dental prostheses who ingest poorly chewed food (although this belief has been questioned [13] ); small children with oral retentive behavior; and adults with functional or organic impairment, including suicidal, psychotic, mentally retarded, incarcerated, and alcoholic patients. The type of esophageal FB usually depends on the patient's age and underlying condition--for example, coins in children, fish bones in adults, food boluses in the elderly, and almost anything in impaired adults.

The esophagus has three normal anatomic sites of narrowing where impactions are most common: the cricopharyngeus muscle, the crossing point of the aorta, and the lower esophageal sphincter (LES). In addition, pathologic strictures may develop elsewhere because of intrinsic lesions. Most impactions occur at the cricopharyngeus muscle, and patients are better able to localize the site of an esophageal impaction when the FB is above the cricopharyngeus. [14]

*Impacted esophageal FBs must be removed or dislodged.* Although the urgency of removal depends on many factors, FBs cannot be left in the esophagus for prolonged periods to dissolve or "pass by themselves." This approach courts disaster. After acute airway compromise, [15] esophageal perforation is the most serious complication of esophageal FBs. [16] Blunt objects lodged for any extended period of time can cause pressure necrosis and esophageal perforation. Small button batteries should be removed immediately; they are of special concern, because they can cause perforation in as little as 18 hours. [17] Although 80 to 90% of esophageal FBs cause transient symptoms and pass spontaneously, often within minutes, [18] approximately 10 to 20% require endoscopic removal, and approximately 1% require surgery. [19] In-hospital observation of small, round FBs or food boluses while awaiting spontaneous passage should be limited to no longer than 24 hours. [4] Conners [20] reported that 9 of 15 children with distal esophageal coins spontaneously passed the coins without intervention. Button batteries and sharp, angulated, or large FBs (2 cm in diameter or longer than 5 cm) are best removed immediately. This chapter focuses on the diagnosis and management of esophageal FBs.

## BACKGROUND

Both the diagnostic workup and the treatment of esophageal FBs are procedure oriented. In 1937, Jackson and Jackson published a classic monograph on the management of FBs of the upper airway and esophagus that was based on the use of the rigid endoscope in 3266 patients. [21] In 1945, Richardson reported the use of papain (a technique currently discouraged) in the successful treatment of meat obstructions of

the esophagus. [22] In 1966, Bigler reported the use of the Foley catheter to extract blunt radiopaque FBs from the upper gastrointestinal tract. [23] More recently, medications and solutions have been used to relax the LES. [18] Although otolaryngologists and thoracic surgeons continue to use the rigid esophagoscope for FB extraction, gastroenterologists began to use the flexible endoscope during the 1970s. [19]

To prevent morbidity and mortality from esophageal FBs, the emergency physician must first rapidly diagnose the presence and site of an FB, often with radiographic assistance. [24] Then the emergency physician must choose the best method of removal, often with the assistance of an otolaryngologist, a gastroenterologist, or both. [19] The anesthesiologist, thoracic surgeon, and operating room crew may also be called on to assist in the definitive management of these patients.

Cohen analyzed the reasons for the failure to diagnose esophageal FBs. [25] Among the explanations for retained FBs being missed are (1) the absence of a positive history, (2) the omission of the possibility of an FB from diagnostic consideration, and (3) the absence of positive radiologic findings. The last may be due to inadequate x-ray studies or to the characteristics of the FB itself. Although complications may occur with attempts to remove esophageal FBs, [16] long-term complications are more common with retained esophageal FBs. Children are more prone than adults to such complications.

## RADIOLOGY OF ESOPHAGEAL FOREIGN BODIES

### Background

The radiographic examination of the patient suspected of harboring an esophageal FB is usually straightforward and

accurate, assuming proper patient selection. Chaikhouni and colleagues [4] diagnosed esophageal FBs in 67 of 79 patients with standard chest radiographs only. Haglund and coworkers [24] reported a series of 264 patients with suspected esophageal FBs who were studied with plain film radiographs and contrast esophagograms. All patients received esophagoscopy, and only 1 of 195 patients with an FB detected by endoscopy had normal radiographic findings, although 43 patients (18%) had false-positive radiographic findings.

Some esophageal FBs are not so readily diagnosable by radiographs (e.g., radiolucent FBs). Food, wood, plastic, and aluminum cannot be seen on standard radiographs. Occult esophageal FBs can cause chronic respiratory symptoms. Children with previously unrecognized esophageal perforation caused by a pop-top from an aluminum can (which is radiolucent on plain radiographs) may present in this manner. [29] Unrecognized esophageal FBs may simulate asthma or epiglottitis, and symptoms may even improve when treatment is instituted for the wrong diagnosis. [30] Ros and Cetta has described the use of a metal detector to locate coins in children.

### Indications

Some investigators believe that the presence of ingested FB impaction is often overestimated by physicians, parents, and patients. Boothroyd and coworkers [33] found that if radiographic workups were limited to children with a clinical history suggestive of esophageal FB impaction or FB aspiration following a button battery ingestion, half of their pediatric patients would have been spared the expense of and exposure to x-rays. Whether patients (especially children) with a history of FB ingestion should routinely receive radiographs is a controversial issue. [ Whereas older patients may be able to localize the hypopharyngeal or esophageal FB by pain, pressure, or FB sensation, preschool children often cannot. Hence, *any preschool child, with or without symptoms, with a history of FB ingestion should be radiographed.*

It is axiomatic that a complete radiographic study include the areas from the "nose to the anus." In a small child this is often accomplished with a single radiograph taken with a large cassette. An ingested FB may end up in the nasopharynx of an infant and be missed if only a chest or abdominal film is obtained. Plain films of the neck are indicated in the patient with FB symptoms localized to the hypopharynx or upper chest, unless the hypopharyngeal FB can be visualized directly by the physician or there is a reliable history that a radiolucent FB (e.g., food without bones) was ingested. Plain films of the chest are indicated in the symptomatic patient who has ingested a radiopaque FB. Abdominal radiographs may also help locate a radiopaque FB, especially if the neck or chest films are negative and the physician or patient and family would be reassured by finding the FB. Plain radiographs may be necessary even after "removal" of an FB in an unreliable adult or a child who may have ingested more than one FB. Two ingested coins, for example, may overlap and appear as a single FB if only an anteroposterior film is obtained. Contrast esophagograms may be indicated if an FB ingestion or impaction is suggested by the history or examination but the plain films are negative or equivocal (e.g., radiolucent FBs).

Radiographic studies may also identify complications from esophageal FBs. For example, plain films may identify retropharyngeal air or pneumomediastinum caused by esophageal perforation, and contrast studies can demonstrate the site of perforation or obstruction. Conversely, if the patient recently ingested a poorly chewed meat bolus and is currently complaining of FB symptoms in the lower chest or epigastrium, it may be possible to relieve the distal esophageal impaction with or without benefit of prior x-ray contrast studies. Subsequently, these patients will require either contrast esophagograms or esophagoscopy to rule out any underlying pathology. If the FB has moved into the stomach or is found to be in the stomach, clinical follow-up (e.g., checking the stools of an infant) should be adequate to verify movement of the FB through the alimentary tract. Follow-up plain x-ray films are indicated after a reasonable period of time (e.g., 4 to 7 days, or sooner when symptoms ensue) if passage cannot be documented. Infrequently, there may also be indications for other radiographic studies, such as computed tomography (CT) and xerograms (described later). The following discussion presents an approach to the use of radiographic studies in patients with presumed esophageal FBs.

**Procedures**

The diagnostic methods to be discussed include plain film radiographs of the neck and chest, contrast esophagograms, CT, and xeroradiography. Soft tissue-intensity radiographs or xeroradiographs enhance the visualization of weakly radiopaque FBs.

Lateral and anteroposterior views of the neck are among the most commonly ordered films to evaluate the presence of FBs of the neck, because the majority of FBs are located at the level of the cricopharyngeus constrictor muscle. [24] Soft tissue technique should be routinely requested, and the technician should include the nasopharynx to the seventh cervical vertebra. (Note that FBs of the nose and those ingested and propelled into the nasopharynx are not uncommon and may be missed if only the neck is examined.) If slight hyperextension is performed, the clavicles are projected away from the lower esophagus. Having the patient phonate "Eeeeee" during the exposure traps air in the pharynx to enhance soft tissue landmarks and prevents swallowing, an activity that produces motion and blurs the anatomy. The upper esophagus, vallecula, and retropharyngeal area deserve special attention when reading the film.

Plain radiographs are somewhat difficult to interpret in the elderly. The physician must be cognizant of the anatomy and aware that soft tissues (ligaments, glands) and cartilage calcify as aging occurs. It is common to misidentify calcified structures as a possible FB (Fig. 42-1 (Figure Not Available) *A- C*).

Posteroanterior and lateral views of the chest are necessary for examination of the remainder of the esophagus. Both projections should be made, because small objects may be visible in only 1 plane, or multiple objects may be recognized in different x-ray planes. [30] Positive radiographic findings include the presence of radiopaque FBs, air-fluid levels, soft tissue swelling, intraesophageal air, subcutaneous (SQ) emphysema, or free air in the mediastinum. A chest radiograph may reveal infiltrates consistent with aspiration pneumonitis resulting from total esophageal obstruction or a tracheoesophageal fistula.

Contrast esophagograms can be used to pursue the suspicion of an FB in the absence of positive findings on plain x-ray films (Fig. 42-2) (Figure Not Available) . The type of FB, its precise location, the degree of obstruction or perforation, and possible underlying anatomic abnormalities can all be delineated by contrast studies. Several controversial choices arise at this point. Should a cotton pledget soaked in contrast agent be used initially? Which contrast agent should be used? Are fluoroscopy and radiologic consultation necessary? What is the risk of aspiration of contrast material or other complications?

A cotton ball or cotton pledget soaked in contrast can be swallowed, followed by x-ray exposures of the neck and chest during and after the swallow. [36] Total obstruction will impede the cotton, partial obstruction may do the same, and on occasion small pieces of cotton will lodge on irregular or sharp surfaces, thus indicating the presence of an FB. Advantages of this maneuver are that fluoroscopy is not necessary, and very little contrast material is required, which minimizes interference with follow-up endoscopy should it be required. However, the diagnostic accuracy of this technique is poor, [24] and

if negative, this technique does not definitely rule out an FB with incomplete obstruction.

The contrast agent of choice is debated among radiologists. In general, it is suggested that if a perforation is suspected, a water-soluble material (diatrizoate [Gastrografin]) should be used because it is less reactive on serosal surfaces than barium. Small perforations, however, may be missed with a diatrizoate study. In all other situations, barium compounds should be chosen, because imaging is better and tracheal aspiration of barium is less injurious.

Fluoroscopy and radiologic consultation are not always necessary. Allen [1] described excellent results in a series of 22 patients using barium solutions and spot films. The technique involves asking the patient to swallow the contrast solution, and after 4 to 5 swallows (approximately 50 mL), frontal, lateral, and perhaps oblique exposures are made. Should total obstruction be suspected despite the absence of an air-fluid level, the patient should be told to ingest only a small amount of barium initially to minimize the risk of aspiration. Positive findings include either positive or negative imaging of the FB in the column of barium and obstruction. In difficult cases, fluoroscopy performed by a radiologist presumably increases diagnostic accuracy and perhaps precludes the necessity for further diagnostic evaluation of possible underlying anatomic or motility disorders. Computed tomography (CT) is most useful in diagnosing suspected esophageal perforation in which the previously described modalities have been normal or inconclusive. The high resolution of CT may detect small FBs not apparent with plain films, barium swallow, or esophagoscopy. CT evaluation with soft tissue and bone windows may replace the barium swallow because of its better detection of thin, small, minimally calcified FBs that are often obscured by overlying tissues in the usual x-ray studies. Xeroradiography also may have some limited utility in this setting. The technique can also identify low-density materials such as aluminum or wood in the cervical esophagus.

In summary, assuming proper patient selection, the radiologic diagnosis of esophageal FBs can often be carried out successfully with plain radiographs alone. Contrast esophageal studies can delineate radiolucent objects and define the degree of obstruction. CT and xeroradiography have limited application in this setting.

## ESOPHAGEAL PHARMACOLOGIC MANEUVERS

Unsatisfactory pharmacologic alternatives for removing or resolving esophageal FB impactions include the use of diazepam, meperidine, and atropine. [43] These agents, alone or in combination, have success rates below 10%, which is no better than observation alone. [4] The pharmacologic alternatives described later (glucagon, nitroglycerin, nifedipine, and gas-forming agents [Table 42-1]) are most effective for distal esophageal food impactions. Most patients with this problem have underlying pathologic abnormality; a benign fibrotic stricture or Schatzki-type ring is more common than esophagitis with spasm, motility disturbances, or carcinoma. [18] If therapy with pharmacologic agents does not relieve the distal esophageal obstruction, the patient remains a candidate for other recommended therapy for the removal of an esophageal FB. In general, nonfood items (especially angulated, abrasive, or sharp FBs) should not be treated with pharmacologic modalities but instead should be removed by

esophagoscopy.

## Glucagon

**Pharmacology**

Glucagon is the prototype for the spasmolytic agents.  Its use has been advocated for enhancing the passage of esophageal FBs since 1977, and there have been several isolated reports of dramatic relief.  Glucagon relaxes esophageal smooth muscle and decreases LES pressure. However, it has no effect on the upper third of the esophagus, where striated muscle is present and some voluntary control is operative. It only minimally affects the middle third of the esophagus, although the successful use of glucagon to dislodge food in the middle third of the esophagus has been reported. Peristalsis is not affected by glucagon.

**Indications and Contraindications**

Glucagon is most useful for meat impactions at the LES that are suspected because of the patient's complaint of pain or "something stuck" in the lower chest or epigastrium. The clinical diagnosis is usually straightforward. Nevertheless, some clinicians recommend that the FB be localized first with contrast radiographs to establish that the impaction is at the LES and to serve as the baseline study for comparison following glucagon administration. [45] However, with a classic history and physical examination, most investigators agree that an initial contrast study can be omitted. Glucagon is successful in approximately 30 to 69% of lower esophageal obstructions, although reported case series generally involve small numbers.  Glucagon is not effective in upper and middle esophageal obstructions, and it is not yet recommended for use in children. Glucagon also is usually not effective in patients with fixed fibrotic strictures or rings at

| **TABLE 42-1** -- Recommended Pharmacologic Therapies for Esophageal Foreign Bodies | | | |

* May be repeated once or used in conjunction with nitroglycerin.
1-2 inches of paste applied under an occlusive dressing may be an alternative.
A capsule is punctured, chewed, held in the mouth for 3 minutes, then swallowed.
§ Alternatively, dissolve 2 to 3 g tartaric acid and 2 to 3 g sodium bicarbonate in 30 mL water.

the gastroesophageal (GE) junction. [18] Glucagon is contraindicated if the patient has an insulinoma, a pheochromocytoma, Zollinger-Ellison syndrome, a hypersensitivity to glucagon, or a sharp esophageal FB.

**Use of Glucagon**

Some reports recommend a small test dose to check for hypersensitivity to glucagon. The therapeutic dose is 1 to 2 mg administered intravenously over 1 to 2 minutes in the sitting patient. The patient is given water orally after the injection of glucagon to stimulate normal esophageal peristalsis to help push the food through the relaxed LES into the stomach. [18] Glucagon has rapid onset and short duration of action. Gastrointestinal smooth muscle relaxes within 45 seconds, and the duration of action is about 25 minutes. If there are no results within 10 to 20 minutes, a second administration of 2 mg may be tried. Some clinicians combine nitroglycerin with glucagon therapy.

**Complications**

Glucagon is associated with a few minor side effects. If administered too rapidly, glucagon causes nausea and vomiting, so the adult patient must be alert and mobile enough to avoid aspiration. Occasionally the vomiting will dislodge the impacted food bolus. Theoretically, there is a risk of rupture of the obstructed esophagus during induced emesis, so slow injection is preferred. [18] The administration of glucagon is also associated with dizziness. Mild elevation of blood glucose levels is also common but is not of clinical concern. No fatalities have been reported.

**Further Evaluation and Therapy**

If glucagon should fail to produce symptom relief or resolve radiograph findings, its use does not preclude another method from being used subsequently. If the patient experiences symptom relief, follow-up contrast radiographs or esophagoscopy at that time or later, depending on the clinical concern for perforation or severe obstruction, should be obtained to rule out coexistent esophageal pathology. Esophageal pathology was demonstrated in all but 1 such patient in a study of 19 patients. [44]

## Nitroglycerin and Nifedipine

**Pharmacology**

Both sublingual nitroglycerin and nifedipine have been used in a manner similar to that of glucagon to relieve LES tone to allow the passage of a distal esophageal FB. Although these 2 agents have been used less than glucagon for the treatment of esophageal FBs, both agents are useful for the relief of chest pain associated with esophageal smooth muscle spasm [42] and may be administered concurrently with glucagon. Manometric and radiographic studies after the administration of nitroglycerin reveal abolition of repetitive high-pressure wave contractions characteristic of esophageal spasm, whereas nifedipine significantly reduces LES pressure without changing contraction amplitudes in the body of the esophagus. Thus, nitroglycerin may relieve partial or complete obstruction of the middle or lower esophagus secondary either to intrinsic esophageal disease or to simple FB impaction. However, nifedipine is

most likely to succeed when the bolus is lodged at the GE junction.

**Indications and Contraindications**

As is true for the clinical indications for the use of glucagon, any patient presenting with an impacted esophageal FB, especially a food bolus, may be a candidate for nitroglycerin and/or nifedipine. Also, similar to the mode of action of glucagon, neither of these agents is expected to relax a fixed fibrotic stricture or ring at the GE junction. [18] Nevertheless, because both agents have a relatively benign side effect profile, if the patient has no contraindication to their use, they may be tried with or without previous documentation of the distal esophageal obstruction by contrast study. Contraindications to their use include a history of allergic reactions, a sharp esophageal FB, and hypotension.

**Use and Complications**

Doses of 1 to 2 (0.4 mg) sublingual nitroglycerin tablets or 1 to 2 inches of nitroglycerin paste, or 10 mg of nifedipine (the capsule is punctured, chewed, held in the mouth, then swallowed) have been reported. A case report of the administration of a 10-mg dose of sublingual nifedipine to an elderly man with a 3-day history of a distal esophageal

FB led to an almost immediate but transient increase in chest pain and pressure followed by the relief of all symptoms. [43] It should be remembered that some patients with esophageal FBs may present with some degree of dehydration due to the inability to swallow liquids or their own saliva. These patients may be prone to hypotension from the vasodilation associated with the use of either agent. Ideally, rehydration should precede therapy with these agents.

**Further Evaluation and Therapy**

If treatment is successful, follow-up barium swallow or esophagoscopy should be performed to rule out underlying disease, as mentioned following the use of glucagon. Unsuccessful symptom relief should also be followed up with further study of the distal esophagus. [44] The use of either nitroglycerin or nifedipine does not contraindicate the use of any other method for the treatment of an esophageal FB.

# Gas-Forming Agents

**Pharmacology**

The use of gas-forming agents for the treatment of distal esophageal food impactions, especially for meat boluses, was first described in 1983. [53] The combination of tartaric acid solution followed immediately by a solution of sodium bicarbonate or even carbonated beverages has been reported. In theory, the use of this acid-base mixture or of a carbonated beverage may produce sufficient carbon dioxide to distend the esophagus, relax the LES, and push impacted food through the GE junction into the stomach. Radiologists use similar gas-forming solutions for upper gastrointestinal

contrast studies.

**Indications and Contraindications**

Gas-forming agents are indicated for the relief of distal esophageal food impactions, with or without prior FB confirmation by a contrast radiograph study. Although gas-forming agents are more likely to succeed with distal esophageal food impactions, they have also been used successfully in obstructions in the proximal esophagus. One author recommends that this modality be used first when a food bolus impaction is suspected at the GE junction, [16] because a fixed lower esophageal stricture or ring is more common than LES spasm. Concurrent administration of spasmolytic agents may improve the effectiveness of the gas-forming agents, which presumably distend the esophagus and "push" the food into the stomach.

**Use and Complications**

In one study, [53] patients were administered 15 mL of a solution of tartaric acid (18.7 g/100 mL), followed by 15 mL of a sodium bicarbonate solution (10 g/100 mL). In this study, Rice and coworkers achieved success in all 8 patients. In another study, [54] 1.5 to 3.0 g of tartaric acid and 2 to 3 g of sodium bicarbonate were each dissolved in about 15 mL of water. In this study, Zimmers and coworkers observed symptomatic relief in 17 of 26 cases (65%). A study involving the use of carbonated beverages in 28 patients found that 8 patients responded to the ingestion of barium sulfate suspension alone, and 16 of the remaining 20 patients (80%) responded to the ingestion of about 100 mL of a carbonated beverage. [55] Coca-Cola has been used with some success. [56] Most patients with esophageal FB impactions have been noted to retch after receiving gas-forming agents, which theoretically puts patients with FB impactions at risk for esophageal trauma. The only reported complication with the use of gas-forming agents for this indication was a mucosal tear of the esophagus (requiring surgical exploration to rule out mediastinitis) in a 66-year-old patient with an 18-hour-old esophageal impaction. [54] Because of this complication and the reduced effectiveness in prolonged FB impactions, the investigators recommended that gas-forming agents not be given to patients with impactions of more than 6 hours' duration or to patients with chest pain that might be indicative of an esophageal injury. [54]

**Further Evaluation and Therapy**

As with the use of glucagon, nitroglycerin, or nifedipine, even if administration of the gas-forming agent is successful, as judged by relief of symptoms, further evaluation is necessary for determining the underlying esophageal abnormality that potentially led to the FB impaction.

## Papain

Papain is *not* a recommended treatment for an esophageal FB. It is a proteolytic enzyme that has been touted for dissolving meat impactions. [57] Papain is available commercially as Adolph's meat tenderizer. This therapy has never been submitted to

clinical trial. In vitro studies suggest that the commercial preparation may have no intrinsic proteolytic activity. [58] Although it is harmless when in brief contact with the normal esophagus, if it is left too long in the obstructed esophagus, papain may begin to dissolve the abnormal esophageal mucosa underlying an FB.  This is likely to occur when the esophageal wall is ischemic owing to FB impaction, when esophageal injury results from small bony spicules in the FB, or when an underlying lesion is responsible for the obstruction. The subsequent rupture and leakage of the proteolytic enzymes result in a self-perpetuating mediastinitis, which can be followed by great vessel rupture. [54] Patients with esophageal FBs are at increased risk for aspiration, and pulmonary aspiration of papain results in acute hemorrhagic pulmonary edema. [55] In general, papain is not currently recommended because of the 2% mortality rate associated with its use and the fact that perforation has occurred in 2 of 90 cases reported in the literature.

## FOLEY CATHETER MANIPULATION OF ESOPHAGEAL FOREIGN BODIES

Some esophageal FBs can be safely managed with balloon-tipped catheters (e.g., Foley or Fogarty). Blunt esophageal FBs that are not believed to have resulted in total obstruction, perforation, or other esophageal injury may be amenable to Foley catheter manipulation. The classic patient for this technique is a small child who is brought to the hospital shortly after swallowing a coin documented by radiograph. FB extraction or dislodgment into the stomach with this technique are both therapeutic. An 80% or better success rate can be expected.  One serious complication and no deaths have been reported in >1000 cases in the literature.

Foley catheter extraction costs less than endoscopy under general anesthesia. [63] Emergency physicians, radiologists, otolaryngologists, and surgeons have all described this technique. In McGuirt's survey of otolaryngologists, thoracic surgeons, pediatric radiologists, and pediatric surgeons, [69] 50% of the pediatric specialists stated that they use the technique. However, few of the otolaryngologists and thoracic surgeons used this technique, instead preferring endoscopy. [69] Fluoroscopic assistance may be preferable, but it is not essential. Whether the procedure is performed in the emergency department or the radiology department, equipment and personnel capable of emergency pediatric airway management must be present.

### Background

In 1966, Bigler [72] first described the use of a Foley catheter for esophageal FB extraction. In 1972, Henry and Chamberlain [74] reported that 14 of 16 children were successfully treated with this technique. Campbell and Foley [65] reported a series of 100 children in which 91 FBs were extracted and 7 were dislodged into the stomach. No complications were reported. Nixon [71] reported the successful use of this technique in 12 of 15 patients with radiolucent FBs. The literature abounds with other reports of successful Foley catheter extractions.  The largest series reported includes 415 fluoroscopic Foley catheter extractions in children with an overall 91% success rate. [75] The success rate was 96% if the duration of impaction was 3 days or less, compared

with 50% if the duration was longer.

**Indications and Contraindications**

It is important that the patient not be combative during the procedure. Some researchers believe that the presence of an uncooperative patient precludes the use of a Foley catheter. [43] Many investigators use various combinations of topical anesthesia and parenteral sedation. Others report restraining children but not sedating them.

*Recently ingested smooth, blunt objects that are radiographically opaque are the only FBs suitable for balloon catheter extraction.* Coins are physically amenable to Foley manipulation, and their frequent presentation has resulted in numerous successful reports. Food boluses have also been extracted successfully, as have button batteries. [76] Even patients with preexisting esophageal disease have been treated with Foley catheter manipulation. [71] Recently ingested FBs carry little likelihood of causing pressure necrosis, perforation, or other significant injury. Recommendations for the maximum duration of impaction before treatment range from 24 hours to 2 weeks with inert objects, although most reports cite 48 to 72 hours as the upper limit. However, potentially reactive FBs such as button batteries have caused second-degree mucosal burns in as few as 4 hours [79] and esophageal perforations in less than 24 hours. [17] Animal studies have shown mucosal burns occurring within 1 hour and transmural penetration occurring in as little as 4 hours with button batteries. [17]

Radiographically opaque objects are most easily located by plain film radiograph. Radiolucent objects can be manipulated, [71] but uncertainties about location mandate contrast esophagograms. Fluoroscopy can be very helpful, and some believe the procedure should not be performed without it. Conversely, many practitioners describe manipulation by traction and tactile stimulation alone. Given the potential for airway obstruction, it is imperative to perform the procedure with airway equipment and suction available.

Contraindications to catheter removal of esophageal FBs include total esophageal obstruction, as manifested by an air-fluid level on plain radiograph or by contrast esophagography. The presence of a total obstruction prevents passage of the catheter tip distal to the FB. Esophageal perforation, as recognized by the typical symptoms and signs, requires immediate surgical consultation and precludes any blind esophageal manipulation. *Sharp, irregularly shaped FBs should not be removed with this technique*, because esophageal perforation or laceration can result, and the balloon may burst during the procedure.

**Equipment**

The equipment necessary is basic and present in most emergency departments (Table 42-2) . Although never reported, airway obstruction during the procedure is the most feared potential complication. Thus, the proper equipment and personnel capable of managing airway obstruction must be present, including suction devices. Clamps and forceps (bayonet and Magill) of various sizes should be available to extract the FB from the pharynx. Foley catheters ranging in size from No. 8 Fr with 3-mL balloons to No. 26

Fr with 30-mL balloons have been used.  In settings in which both children and adults may be treated, sizes ranging from 10 Fr to 16 Fr with 5- to 10-mL balloons should suffice. Child restraint devices (e.g., papoose board), topical anesthetics, and parenteral sedation may be used.

**Procedure**

Every patient should be appropriately coached concerning the procedure and cooperation. Young children must be gently restrained. Conscious sedation and nasopharyngeal topical anesthesia may be used, although some argue that the use of topical anesthesia and parenteral sedation depresses physiologic airway reflexes and increases the risk of aspiration. [73] The patient is then placed in a *head-down* Trendelenburg, lateral decubitus, or supine position during preparations. Some operators prefer to place the child prone during the procedure to facilitate oral expulsion of the FB.

Assuming the procedure is being performed in a young child, a 12 Fr Foley catheter may be the correct choice. After checking for symmetric balloon inflation, the catheter is most frequently inserted through the nose for patient comfort

| **TABLE 42-2** -- Equipment for Foley Catheter Extraction of Esophageal Foreign Bodies |

* Optional equipment.

(Fig. 42-3) (Figure Not Available) . Some reports [65] argue that oral insertion is preferred to allow removal of the inflated catheter and FB with 1 smooth, uninterrupted pass. When using fluoroscopy, the catheter is visually passed distal to the FB. If performed without fluoroscopy, the distance from nose or mouth to FB is estimated, and the catheter is inserted accordingly. On occasion, the operator feels the catheter tip pass the object. The balloon is *slowly* filled with 3 to 5 mL of saline or contrast agent (if fluoroscopy is used). *Balloon inflation should be stopped if the patient complains of increased pain*; the catheter should be repositioned before an attempt at reinflation. Fluid is preferable to air, as it is less compressible. Overdistention of the balloon is undesirable; *in children no more than 5 mL of fluid should be used.*

The catheter is then withdrawn with steady, gentle traction. Contact with the object can be sensed as the friction of withdrawal increases. Significant impedance to traction requires termination of the attempt. Should the catheter slide by the object without dislodging it, the balloon can be enlarged and another attempt made. Often when the object reaches the hypopharynx, the balloon and gravity act in concert to fully externalize the FB, especially if the patient can be instructed to spit it out. The operator can also grasp the object with the fingers, forceps, or a clamp.

A follow-up radiograph may be necessary to exclude the possibility of multiple objects. [68] If fluoroscopy is not used and no FB is retrieved, another radiograph should be obtained, because 10 to 20% of the time, the FB will pass distally into the stomach. [10] This is considered therapeutic, because once a blunt FB has traversed the esophagus, only rarely will the FB not eventually pass per rectum. Such an occurrence has only been noted with objects longer than 6 to 7 cm. Multiple attempts should not be required if catheter size, placement, and balloon inflation are correct. Failed attempts are best followed by a change in one of the aforementioned parameters or repeat x-ray studies to confirm the continued presence of the esophageal FB before esophagoscopy.

**Complications**

No deaths have been reported. One esophageal rupture has occurred. [75] Nosebleeds, nasopharyngeal displacement of the FB with impaction, and a case of laryngospasm have been described. [80] Failure to move the object at all can be estimated to occur in approximately 15 to 20% of cases. Endoscopists who object to this technique argue that (1) an underlying disease or multiple FBs may be missed, (2) blind

manipulation may perforate the esophagus, (3) radiation exposure is prolonged when fluoroscopy is used, and (4) airway obstruction can occur. In the large series (415 catheter extractions) reported by Schunk, [75] minor complications occurred in 2% of the episodes, and major complications (i.e., esophageal rupture requiring surgical repair, mucosal laceration followed by 24 hours of fever, and 2 cases of transient respiratory distress) were noted in 1%.

**Disposition**

If the patient is asymptomatic and the extraction was successful, or if the FB is in the stomach, the patient may be released. If the FB is in the stomach, clinical follow-up should be adequate to verify movement of gastric FBs through the alimentary tract. Follow-up plain x-ray films are indicated after a reasonable period of time (e.g., 4 to 7 days, or sooner if symptoms ensue) if passage is not documented. Instructions should include warnings about gastrointestinal obstruction, perforation, and hemorrhage. Parents of children who swallow coins can be instructed to watch for any coins ("change in the stools"). Adults with esophageal FBs that have been removed successfully must be referred for evaluation of possible esophageal pathology. Should an FB remain lodged in the esophagus, immediate referral to an endoscopist is necessary.

## NASOGASTRIC TUBES

Several case reports describe the use of nasogastric (NG) tubes to manage esophageal FBs. Before insertion, the NG tube must be modified by cutting off the end of the tube at the level of the last side hole to allow maximal negative (suction) pressure to be exerted at the tube-FB interface. The initial technique is to place the tip of the catheter just proximal to a totally obstructing object (e.g., a food bolus) to aspirate oropharyngeal secretions. Then maximal suction may be applied directly to the esophageal FB itself in an attempt to lift it out proximally. Other modifications of this technique include the use of larger bore NG tubes or magnets and insufflation of air above the FB. Although gentle pushing of the FB through the GE junction is a tempting procedure to consider, *the technique of blindly pushing an impacted FB distally may injure the esophagus and is strongly discouraged*. This technique may be appropriate if performed under direct visualization during endoscopy (see later discussion).

Henry and Chamberlain [74] described the case of a steel ball obstructing the pylorus that was lifted into the esophagus with an NG tube and magnet, after which it was removed with a Foley catheter. Jaffe [80] used a similar method to remove button batteries from the stomachs of 6 patients. The batteries could not be extracted beyond the cricopharyngeus, and Foley catheters were used for ultimate removal. Chaikhouni and colleagues [4] reported a patient who had a needle removed from the lower esophagus under fluoroscopy with an NG tube and a magnet. Kozarek [81] described the use of a 34 Fr gastric evacuation tube and a syringe to successfully aspirate a meat bolus. Zalev [82] used air insufflation just above a meat impaction to negotiate the esophageal FB through the GE junction in 1 patient. Binder [2] described 1 patient whose dysphagia resolved after NG intubation. In summary, NG tubes may have limited usefulness in treating esophageal FBs.

## ESOPHAGOSCOPY

Esophagoscopy is the definitive diagnostic and therapeutic procedure for impacted esophageal FBs. [19] With esophagoscopy the physician can document the presence and location of the FB along with any underlying lesion, then remove the object and

reevaluate the esophagus after FB removal to rule out perforation or underlying pathology. Although it is not a procedure performed by the emergency physician, its proper role must be understood by the emergency physician (Table 42-3) . Esophagoscopy may be necessary even if a radiologic contrast study does not reveal complete obstruction, because x-ray studies are not always conclusive. Esophagoscopy may be necessary to rule out predisposing pathology or resultant perforation, even if the symptoms presumed to be due to an esophageal FB resolve.

## Indications and Contraindications

Endoscopy is the preferred method for removal of sharp or pointed objects such as bones, open safety pins, and razors. [83] [84] However, sharp, pointed FBs may require surgery. Toothpicks and bones require surgery more often than nails,

* Mortality is primarily related to the risk of general anesthesia.

needles, pins, blades, and dental prostheses. [83] In the case of sharp objects prone to causing esophageal perforation, IV antibiotics should be administered before any removal procedure. It is important to regard button batteries impacted in the esophagus as a true emergency because of their potential to cause perforation secondary to liquefaction necrosis.  Once button batteries pass the stomach, surgery may be necessary if serial radiographs indicate that the batteries have not continued to move or if they become symptomatic. In terms of the most common esophageal FBs, coins can cause pressure necrosis and perforate with prolonged impaction. Meat impactions may pass overnight, so endoscopy need not be performed immediately in these patients,

although it would be necessary eventually to assess for esophageal pathology.

### Equipment

Currently the flexible endoscope is more commonly used than the rigid esophagoscope for several reasons. [19] There are more gastroenterologists and others trained in the use of the flexible endoscope than in the use of the rigid endoscope. The latter remains the tool of surgeons, especially otolaryngologists and thoracic surgeons. Flexible esophagoscopy is easier to use and more mobile and has magnified visibility. Flexible endoscopic procedures are usually performed without general anesthesia, even in most children. [85] Because of this fact, Webb argued that flexible endoscopy is more cost-effective compared with either rigid endoscopy or surgery. [19] Berggreen and colleagues [86] reported a success rate of 96% using flexible endoscopy and 100% using rigid endoscopy in 192 patients with esophageal foreign bodies. Overall, rigid esophagoscopy had a higher complication rate (10% vs 5%, $P > .05$), but this trend did not reach statistical significance.

Rigid endoscopy is still favored by some clinicians, because it is superior to flexible endoscopy in containing and removing esophageal FBs. [19] Despite the advantages discussed, some reports contend that flexible endoscopy too often fails to remove the FB. Instead, the FB may become impacted, making subsequent extraction with the rigid endoscope more difficult or impossible. The main danger of flexible endoscopy that is not associated with the use of rigid endoscopy is the accidental loss of the FB into the airway during extraction in the unintubated patient. The requirement for general anesthesia and airway protection is both the main advantage and the drawback to rigid endoscopy.

## SPECIAL SITUATIONS

### Fish Bones in the Throat

It is common to evaluate patients who complain of sharp pain in the throat on swallowing after they have eaten fish. This symptom is perceived by the patient as evidence of a fish bone lodged in the throat.

Because an impacted fish bone can produce serious sequelae [87] if not removed, efforts should be undertaken in the emergency department to diagnose and treat retained bones. It is important to note that a bone is identified in only 20 to 30% of such patients, and symptoms may be due to minor mucosal trauma (abrasion, laceration) simulating the retained FB. Ngan and colleagues [88] described the outcomes for 358 patients with a history of fish bone ingestion: 117 bones were found, 21 on oral examination alone.

A plain radiograph (soft tissue technique, lateral neck projection) may identify some bones in the throat. However, even though cod, haddock, and halibut bones tend to be radiopaque, this technique is generally unreliable in ruling out retained bones, because many commonly eaten fish (e.g., mackerel, trout, salmon) have a radiolucent skeleton. [89] Evans and associates [90] reported 100 cases of proven fish bone impaction in which

lateral neck radiographs yielded a sensitivity of only 25%, a specificity of 86%, and a positive predictive value of 73%. These results suggest that plain radiographs are not useful in the diagnosis of fish bone impaction. Other radiographic techniques, such as swallowing a contrast-laden cotton ball, are also unreliable in identifying small bones.

Although pharyngoscopy is the most accurate method to diagnose a retained fish bone, *simply looking in the mouth and pharynx with the use of a tongue blade may identify many impacted bones.* Knight and Lesser reported a series of 71 patients who complained of the sensation of a fish bone in the throat; they noted that in 56 cases (79%), no bone was ultimately identified after careful follow-up. [91] Of significance, 14 of the 15 retained fish bones (93%) were visible on the initial examination of the oropharynx or hypopharynx. Derowe and Ophir reported 22 negative endoscopy examinations in 98 patients with a suspected esophageal FB; 20 of the 22 negative examinations were performed for suspected bones (mostly fish). [92] Most commonly these bones were instead found lodged in the base of the tongue, tonsil, or posterior pharyngeal wall (Fig. 42-4) . All were easily removed under direct vision. Saliva strands may mimic or obscure a bone, so care should be taken when extracting possible retained fish bones.

Although any patient persistently complaining of a retained fish bone ultimately should be referred for endoscopy (usually within 48 hours), many patients with the annoying symptoms do not have an esophageal FB. If a fish bone is present, however, many may be diagnosed and removed on the initial visit if one merely looks in the mouth and throat with a good light source and a tongue blade or with indirect laryngoscopy or with fiberoptic pharyngoscopy. Local anesthetic sprays may aid in the evaluation and removal of a bone, or they may be used for temporary relief of dysphagia. If a fish bone is not identified and the patient has no SQ emphysema, soft tissue swelling, hemoptysis, or inability to swallow, then referral for outpatient follow-up within 24 to 48 hours is acceptable. Note that retained fish bones do not "dissolve" and rarely pass spontaneously once lodged in the mucosa.

**Button Battery Ingestion**

Small disc batteries, such as those used in cameras, watches, and hearing aids, present a distinct type of esophageal FB because of the potential for serious morbidity and mortality. [93] Litovitz and Schmitz [94] reported on 2382 patients with battery ingestion, 2 of whom suffered serious esophageal injury. Batteries range in size from 7 to 25 mm and are radiopaque. Batteries appear as round densities, similar to an impacted coin, but some batteries may demonstrate a "double contour" configuration. [93] It is important to distinguish between a coin and a button battery, because button batteries require immediate removal (Fig. 42-5) (Figure Not Available) . The devices consist of 2 metal plates joined by a plastic seal. Internally the batteries consist of an electrolyte solution (usually concentrated sodium or potassium hydroxide) and a heavy metal, such as mercuric oxide, silver oxide, zinc, or lithium.

If ingested, these batteries often lodge in the esophagus. The mechanisms of injury include electrolyte leakage, injury from an electrical current, heavy metal toxicity, and pressure necrosis. Of particular concern is the development of a corrosive esophagitis

(occasionally fatal) or esophageal stricture or perforation as a result of caustic injury and prolonged mucosal pressure. Although relatively harmless in the stomach and intestines, batteries lodged in the esophagus should be considered an emergency situation, because even new batteries demonstrate corrosion, leakage, and mucosal necrosis within a few hours of contact with the esophagus.

Esophageal impaction mandates immediate removal. The Foley catheter technique may be successful, but it is less ideal than endoscopy. Endoscopy allows for direct esophageal evaluation and a more controlled extraction. In addition, the "invasive" nature of batteries may lead to rapid edema, making the catheter technique technically more difficult. Glucagon or gas-forming agents have no role in the extraction of button batteries. It is particularly dangerous to delay treatment in hopes that the FB will pass spontaneously.

A survey of British endoscopists and pediatricians revealed variable approaches to the child with a history of button battery ingestion. Forty-eight percent of 312 respondents indicated that under some circumstances batteries should be removed from the GI tract; 78%, 72%, and 48% extracted them from the esophagus, stomach, and duodenum, respectively, within 24 hours of ingestion. [95] However, *when in the stomach*, batteries do not require immediate removal. They may be followed radiographically to demonstrate passage, with little risk of gastrointestinal injury or heavy metal poisoning, even if the battery opens.  Some advise cathartics or metoclopramide (Reglan) if the battery is in the stomach. Ipecac is best avoided, as it has been reported to move a battery from the stomach to a more dangerous position in the esophagus.

**Childhood Coin Ingestion**

Coins are among the most commonly ingested objects in preschool-age children. In most cases the ingestion is quickly realized by a caretaker, and in the majority of cases, the coins pass uneventfully. [98] Rarely, an esophageal coin can be clandestine for many weeks or months, producing a variety of vague respiratory or gastrointestinal symptoms. Byard and colleagues described a case of supposed sudden infant death syndrome that at autopsy was found to be due to an obstructing esophageal coin. [99] Most coins pass from the esophagus to the stomach with only transient symptoms. The child may be in pain for a few minutes as the coin migrates, but on arrival in the emergency department, the child is often

asymptomatic. Coins that remain in the esophagus are likely to, but do not always, produce continued symptoms (e.g., drooling, pain, dysphagia, or refusal to eat or drink). Rarely, esophageal coins can produce airway distress by external compression of the trachea, simulating an asthmatic attack. Coins below the diaphragm are generally asymptomatic. Coins in the trachea produce immediate and obvious respiratory distress.

The decision regarding whether to obtain a radiograph during evaluation of the child with a possible coin ingestion is controversial. Some authors recommend that *asymptomatic* children not be radiographed. [35] However, because up to 44% of children with esophageal coins may be asymptomatic, it seems prudent to perform a

film on all children with a suggestive history. [100] In most cases a single film that includes the pharynx, esophagus, and stomach will suffice to prove or exclude an ingested coin. Previous mention has been made of the possibility of multiple coins stacked on top of each other simulating a single coin on an anteroposterior radiograph.

Once a coin's presence has been documented, a decision concerning removal must be made (Fig. 42-6) (Figure Not Available) . Schweich suggests that an impacted coin may be safely observed for 24 hours without risk in the asymptomatic or minimally symptomatic child. [101] Others recommend quick removal if the child is symptomatic, if the coin is in the upper third of the esophagus, or if the child has a history of gastrointestinal abnormalities. A few hours of observation in the child with minimal symptoms and an upper esophageal coin seems reasonable, as does a repeat film just prior to attempts at removal. Although coins in the upper and middle third of the esophagus are less likely to pass spontaneously, coins in the distal esophagus often pass spontaneously within a few hours.

Schweich suggests that all asymptomatic children, regardless of coin location, can be followed and re-radiographed in 24 hours. Anxious children and those in pain will benefit from the prudent use of sedation and analgesia. Conners and colleagues suggest that healthy children with coins *at the gastroesophageal junction* for <24 hours be allowed to eat and drink, with reevaluation for coin passage a few hours later. [20] Medical interventions (nitroglycerin, nifedipine, glucagon) may be appropriate at this juncture. If asymptomatic, reliable patients may be released home to return for follow-up evaluation. If the child fails the test of eating and time, he or she is then a candidate for a removal procedure. With this approach, attempts at removal may have to be further delayed until normal gastric emptying occurs.

About half of ingested coins are in the stomach at the time of first investigation, and such patients can be safely released home to allow for almost certain spontaneous passage with normal diet. Spontaneous passage of a coin from the stomach to the anus usually requires 5 to 7 days; there is no need for routine cathartics. Parents should be advised to check the stool for the coin and return for repeat radiographs if the coin is not found in 1 to 2 weeks. Most coins are passed unknowingly by the patient. Any abdominal discomfort or distention warrants reevaluation in the emergency department. If a follow-up radiograph demonstrates a persistent coin in the intestines for more than 3 to 4 weeks, an obstructive lesion may be present, and surgical referral is warranted.

## CONCLUSION

Esophageal FBs should be approached with great clinical respect because of their potential to produce serious injury or death. Esophageal FBs can be difficult to diagnose (e.g., in children and neurologically impaired adults), difficult to locate (e.g., when radiolucent or asymptomatic), and difficult to remove (e.g., requiring the services of radiology and specialty consultation).

# Chapter 43 - Nasogastric and Feeding Tube Placement

**Leonard E. Samuels**

A wide variety of patients require nasogastric intubation, including those with obstructed, preoperative, or potentially hemorrhaging upper gastrointestinal systems. Although the initial placement of feeding tubes is rarely the province of emergency physicians, patients with feeding tube complications frequently present to the emergency department (ED). Therefore, the emergency physician must be familiar with the different types of enteral tubes, as well as with their care, cleansing, and means of replacement.

## PROPERTIES OF NASOGASTRIC AND FEEDING TUBES

Enteral tubes are made of various materials. Polypropylene is the most common material used for Levin and Salem sump nasogastric tubes (Fig. 43-1) , but it is too rigid for long-term use for a feeding tube. Although they are less likely to kink than others, polypropylene tubes are more capable of creating a false passage during placement. Latex (rubber) tubes are moderately firm, require greater lubrication for passage, are relatively thick-walled, and induce a greater foreign body reaction than tubes of other commonly used materials. Latex, especially in latex balloons, deteriorates more rapidly than other materials. [1] Silicone tubes are thin-walled, quite pliable, and nonreactive. However, the walls of silicone tubes are less strong and may rupture if fluid is introduced into a kinked tube. [2] Polyurethane tubes are quite nonreactive and relatively durable. Rigidity varies from manufacturer to manufacturer, depending on tube thickness. A stylet may aid in the passage of polyurethane and silicone tubes, but its use increases their rigidity and capability of tissue dissection, especially in tubes that have a small distal end bulb. [3] Some feeding tubes have weights, usually made of tungsten, which are nontoxic if released into the gastrointestinal tract.

## NASOGASTRIC TUBE PLACEMENT

### Indications and Contraindications

The simplest nasogastric tube is the Levin tube, which has a single lumen and multiple distal "eyes." The advantage of the Levin tube is its relatively large internal diameter in proportion to its external diameter. The theoretical disadvantage is that a Levin tube should not be left hooked up to suction after the initial contents of the stomach have been drained, because the suction will cause the stomach to invaginate into the eyes of the tube, blocking future tube function and potentially causing injury to the stomach lining. Levin tubes are useful for diagnostic aspiration of stomach contents or for simple instillation of therapeutic agents. Tubes with lumens larger than 16 Fr are preferred for lavage procedures if large particulates are anticipated (see Chapter 45) .

In practice, the Levin tube is no more prone to bleeding complications than the Salem sump tube, provided that the *intermittent* suction setting for the Levin tube is 40 mm Hg.4 The Salem sump tube is preferred to the Levin tube for more chronic use as a

drainage device because of the presence of a separate channel (blue colored) that vents the distal main lumen to the atmosphere (Fig. 43-2) (Figure Not Available) . When extended gastric drainage is desired, Salem sump tubes should be placed on intermittent suction, even though the vent generally will prevent excessive vacuum at the tube tip. Note that potentially both intermittent suction and wall unit vacuum can exceed the venting capacity of the second lumen; for intermittent suction, the vacuum setting should be 120 mm Hg.4

The major indication for nasogastric intubation is to aspirate the stomach contents (see also Chapter 45) . Aspiration may be useful in the management of upper gastrointestinal bleeding, particularly to differentiate upper from lower gastrointestinal bleeding. Except when frankly bloody fluid is obtained, the sensitivity and specificity of aspiration to detect upper intestinal bleeding are not good. Use of Hemoccult or guaiac cards to detect bleeding in gastric aspirates is unreliable, because false-positive tests are obtained frequently. [5] Although variceal rupture has occurred during insertion of instruments into the esophagus, several studies suggest that nasogastric tube passage is generally safe, even in the presence of esophageal varices. [8] [9] Nasogastric suction is indicated in cases where vomiting is likely to be recurrent or dangerous, such as with a paralytic ileus or intestinal obstruction, or to relieve acute gastric dilation. The trauma patient may need a nasogastric tube as part of the evaluation for gastrointestinal injury or to decompress the stomach prior to surgery or peritoneal lavage. A radiopaque nasogastric tube may help delineate transdiaphragmatic hernia of the stomach after trauma.

Nasogastric tubes are contraindicated in a few groups of patients with special predispositions to injury from tube placement. Patients with facial fractures who have a cribriform plate injury may suffer intracranial penetration with a blindly placed nasal tube. [10] Patients who have esophageal strictures or a history of alkali ingestion, especially recent alkali ingestion, may suffer esophageal perforation. Comatose patients may vomit during or after nasogastric tube placement; their airways should be protected prior to placing the nasogastric tube. Gagging will decrease venous return and increase cervical and intracranial venous pressure, which may be clinically significant in selected trauma patients with cervical or intracranial bleeding and in the presence of significantly elevated intracranial pressure.

Despite their traditional use, *nasogastric tubes are not routinely required in patients with mild to moderate pancreatitis*. Extended irrigation of the stomach with water in a patient with upper gastrointestinal hemorrhage can lower serum potassium levels, [13] and animal studies suggest that cold water lavage can cause rather than control bleeding. [14] [15] No study has shown irrigation to be effective in the control of bleeding, and vigorous lavage with cold water may lower the body temperature. However, a nasogastric tube may be used to instill air into the stomach for documentation of a suspected gastric perforation by enhancing visualization of free air under the diaphragm on an upright chest film.

**Equipment**

Nasogastric passage of standard nasogastric tubes or feeding tubes can be messy and

may be accompanied by coughing, retching, sneezing, bleeding, and spilled water or stomach fluid. Both patient and physician should be gowned; cleanup may be reduced if the bib area is covered with a towel and a supply of tissue or washcloths is available. The physician requires gloves; the appropriate nasogastric or feeding tube; a penlight or other light source; a tongue blade; an emesis basin; a glass of water with drinking straw (or an extra syringe if the patient is uncooperative); water-soluble lubricant; a stethoscope; a safety pin; a rubber band; topical anesthetic jelly, spray, or ointment; and vasoconstrictor nasal spray or liquid. For standard nasogastric tube placement, a piston or bulb syringe (with a catheter slip-tip) should be available. Nasogastric feeding tubes should have a compatible 50- or 60-mL syringe (some are Luer compatible and others are slip-tip compatible).

Tape torn in 4-in. strips or a commercial nasogastric tube holder (e.g., Suction Tube Attachment Device, Hollister, Libertyville, Ill) should be handy for securing the tube after placement. Cotton-tipped applicators and tincture of benzoin may be helpful if the skin is greasy. Depending on the indication, other equipment may be needed (e.g., saline for irrigation or Magill forceps in an uncooperative or anesthetized

patient). Make sure the feeding tube is designed for duodenal passage if that is desired--such tubes are usually longer than regular feeding tubes.

An antireflux valve (Keith Antireflux Valve, Sherwood Medical Industries, St Louis) is a one-way valve used on the vent port of the Salem sump tubes. One study found the device to be cost-effective by reducing the need for gown and linen changes during inpatient nasogastric tube use. [17] Placement of this device in the ED should be considered if extended use is anticipated.

**Procedure**

Explain the procedure to the patient. If the patient is alert, the head of the bed should be raised so that the patient is in the high Fowler position or upright. A towel is placed over the patient's chest to protect the gown, and an emesis basin should be available on the patient's lap. [18] The tube (typically a 16 or 18 Fr sump) should be positioned so that insertion distance can be estimated, and this distance should be marked with tape or noted using the markers printed on the proximal tube. A simple method is to extend the tube from the xiphoid to the earlobe and then from there to the tip of the nose and *then add 15 cm* (6 in.) (Fig. 43-3) . [19] While other techniques of estimating appropriate nasogastric tube insertion distance using formulas may be more accurate than the nose-ear-xiphoid method, the formulas are difficult to memorize and calculate. [20] [21] It is a common error to fail to estimate the proper length of the tube prior to passage.

The nares should be checked for obstruction and the tube passed down the more patent naris. Patency can be assessed by direct visualization or by having the patient sniff while first one and then the other nostril is occluded. The selected naris and the distal 5 cm of the tube should then be lubricated with a liberal amount of water-soluble lubricant, viscous lidocaine, or lidocaine jelly. Lubrication of the naris can be facilitated using a syringe (without needle) filled with 5 to 10 mL of lubricant (Fig. 43-4) . Alternatively, the nostrils can be lubricated and anesthetized with a pair of cotton swabs soaked in the

desired anesthetic/lubricant. A 10% lidocaine spray also can provide excellent (and rapid) anesthesia of the nose. Additional topical pharyngeal anesthesia using benzocaine (Cetacaine) or lidocaine spray in the pharynx prior to the procedure will significantly reduce gagging and aid tube passage. The mucosa should be anesthetized *prior to tube passage*. It is insufficient to put anesthetic jelly on the tube and expect anesthesia during the tube's passage.

The tube is inserted into the naris along the floor of the nose and not toward the nasal bridge (Fig. 43-5) (i.e., directed posteriorly and not cephalad). Mild resistance may occur in the posterior nasopharynx, but only gentle pressure should be required to overcome this resistance. Bleeding or dissection into retropharyngeal tissue may occur if force is used, and it is better to try the other nostril or an oral tube if significant resistance is encountered. Once the tube passes into the oropharynx, a pause may help the patient regain composure and enhance the chances for cooperation with the rest of the procedure.  Have the patient, if he or she is alert and cooperative, sip water from a straw and swallow while the tube is advanced into and down the esophagus. This often helps ease passage of the tube. Flexing the neck also tends to direct the tube into the esophagus rather than the trachea. Excessive choking or gagging or any coughing, change in voice, or the appearance of condensation on the inner aspect of the tube should alert the clinician to the possibility of tracheal tube position, prompting withdrawal of the tube into the oropharynx. The tube may be inspected through the mouth to detect coiling or respiratory passage. A tube position lateral to the midline suggests correct position in the esophagus. [22] Once the tube is in the esophagus, it should be *advanced rapidly* to the previously determined depth. Slow passage of the tube prolongs discomfort and may precipitate more gagging. [18]

**Confirmation of Tube Placement**

Before the nasogastric tube is secured, nonradiographic confirmation of its successful placement should be obtained. All confirmation methods have some possibility of error, so it is wise, when in doubt, to use more than 1 method.

Insufflation of air into the nasogastric tube is simple and quick. The requirement of increased pressure to instill air or the absence of borborygmi with instillation should raise concern about tube malposition or kinking. If the patient immediately burps on air instillation, an esophageal tube position should be suspected. [23]

Unfortunately, passage of nasal tubes into the lungs is frequent, especially in comatose or demented patients, and insufflation is often insufficient to detect this type of malpositioning. The insufflation test also is unreliable in detecting whether the tube has advanced past the stomach into the small bowel. [26]

Aspiration of stomach contents, especially if pH tested, is more reliable. If the pH is less than 4, the nasoenteral tube has an approximately 95% chance of having its tip in the stomach. Furthermore, nonrespiratory placement is almost guaranteed. [31]

Aspirated fluid can occasionally be obtained from the lung or pleural space, but the pH should be 6.0 or higher. Approximately 2% of patients have an alkaline stomach pH. [33]

Causes include duodenal reflux, antacids, H2 blockers, or recent instillation of formula or medications.

Ask the patient, if he or she is awake and cooperative, to talk. If the patient can't speak, respiratory placement is likely. Note that with small-bore tubes, patients may still be able to speak despite tracheal placement. [34]

Once correct tube position is tentatively confirmed, the tube should be secured. If the tube is radiopaque, radiographic confirmation of tube position can then be obtained. If the patient requires abdominal or chest radiographs for other diagnostic purposes, it is best to place the nasogastric tube prior to obtaining the films.

**Securing the Tube**

The nasogastric tube is generally secured to the patient with tape attached to both tube and nose. A butterfly bandage (or tape on each side of the nose) that then coils around the nasogastric tube is a typical approach. The tube should be clean and possibly prepped with tincture of benzoin, as should the nose. If a tape should let go or require repositioning, both the tape and the tincture of benzoin must be replaced. It is wise to also secure the tube to the patient's gown, so that a tug on the tube will encounter this resistance before pulling on the material securing the tube to the patient's nose. A rubber band tied around the tube with a slip knot (Fig. 43-6 *A* and *B*) and pinned to the gown near the patient's shoulder is effective. It is critical to ensure that the tube is not secured in such a way that it presses on the medial or lateral nostril. Necrosis or bleeding can result if a tube is not secured correctly.

When a Salem sump is used, the blue pigtail must be kept above the level of the fluid in the patient's stomach, or stomach contents may leak back through the vent lumen. If a patient needs to ambulate with a sump tube in place, the blue pigtail can be fitted into the plastic connector at the end of the suction lumen, creating a closed loop that should not leak. For a Levin tube, a syringe can be attached to the lumen and taped to the patient's gown. Alternatively, a commercial antireflux valve may be attached.

**Placement Issues**

Nasogastric tube placement in the unconscious patient can be attempted using the same technique as in the conscious patient, omitting those steps requiring patient cooperation. If the patient is intubated, the balloon of the endotracheal tube should be deflated briefly to allow passage of the nasogastric tube. The nasogastric tube is easily misplaced into the pulmonary tree in the unconscious patient, a complication that may be missed during the procedure, because gag and cough reflexes may be suppressed and the patient cannot talk. In addition, the absence of swallowing may prevent successful passage of the tube. Several techniques may be used to successfully pass a nasogastric tube in a difficult unconscious patient.

The nasogastric tube may be placed initially through a naris into the oropharynx. The tip of the tube is then visualized with a laryngoscope, grasped with Magill forceps, and

pulled out of the mouth. An endotracheal tube with an internal diameter that is slightly larger than the external diameter of the nasogastric tube is selected and is slit along its lesser curvature from its proximal end to a point 3 cm from its distal end. The slit endotracheal tube (generally 8 mm ID [internal diameter]) is then passed through the mouth into the esophagus. [35] Alternatively, a 7-mm ID slit endotracheal tube may be passed directly through the nose into the esophagus. [36] Passage into the esophagus is facilitated by the stiffness of the larger endotracheal tube and does not require active swallowing. The tip of the nasogastric tube is then threaded into the endotracheal tube and advanced into the stomach (Fig. 43-7) (Figure Not Available) . The slit endotracheal tube is then removed from the esophagus. When the distal part of the endotracheal tube is visible, the unslit 3-cm distal part is slit with scissors. The endotracheal tube is removed, and the nasogastric tube remains in place. [37] Any slack tubing is then advanced with the forceps or pulled back nasally, depending on the final depth required for the nasogastric tube. The technique can also be performed by passing the slit endotracheal tube nasally, which also saves the trouble of orally advancing or nasally retracting any slack tubing.

In particularly passive or toothless patients, guiding the nasogastric tube with the fingers is occasionally successful. [38] Displacing the larynx forward by manually gripping and lifting the thyroid cartilage has aided tube insertion, [39] as has simple jaw elevation. A soft nasopharyngeal airway, well lubricated, is at times easier to pass nasally than the nasogastric tube, and then the lubricated nasogastric tube can be passed through it. In addition, it affords some protection to the nasal mucosa if multiple attempts to pass the nasogastric tube are necessary, or if it is particularly important to minimize bleeding or trauma. Cooling a nasogastric tube increases its rigidity, and coiling it can increase the tube curvature, both of which may help pass the tube. Note that a cooled tube is more likely to dissect into tissue.

Ultimately, if all other methods fail, a flexible fiberoptic bronchoscope or esophagoscope can be placed under direct vision into and through the esophagus. [40] A guide wire is threaded into the stomach. The nasogastric tube can be placed over the guide wire into the stomach; the guide wire is then removed.

### Complications

Complications of standard nasogastric tube placement are similar to problems noted with nasogastric feeding tube placement. The complications related to tube misplacement are discussed in that section. In addition, the physician placing the nasogastric tube in the patient with neck injuries should be cautious of potentiating cervical spine injuries with excessive motion during passage (especially in association with coughing and gagging in the awake patient). Furthermore, passage of a nasogastric tube in the awake patient with a penetrating neck wound may exacerbate hemorrhage, should coughing or gagging result. Particularly serious forms of tube misplacement are pulmonary placement (Fig. 43-8) (Figure Not Available) and intracranial placement (Fig. 43-9) (Figure Not Available) .

## NASOENTERIC FEEDING TUBES

**Indications and Contraindications**

The most common indication for feeding tube replacement in the ED is unintentional removal of a preexisting feeding tube. In 1 prospective study, 38% of tubes were removed unintentionally. Although some of these tubes had fallen out or been coughed out, more than half had been pulled out by the patient. [42] Tube rupture, deterioration, or clogging may also necessitate replacement. Management of the clogged or nonirrigating feeding tube is discussed in the section Clogged Feeding Tubes.

Enteric feeding tube replacement is contraindicated in the presence of vomiting, intestinal obstruction, severe ileus, upper gastrointestinal bleeding, distal enteric anastomoses, and conditions in which bowel rest is desired. [43] Occasionally, the patient whose feeding tube is displaced does not require nasoenteric feeding tube replacement because oral intake is adequate for nutritional needs. Patients suffering erosions or discomfort may be candidates for percutaneous endoscopic gastrostomy (PEG) placement.

**Choice of Feeding Tube Site**

Three major classes of enteral feeding tubes are currently in common use; classification is according to site of insertion. Tubes can enter through the nares, a cervical ostomy, or an abdominal ostomy. The mode of nutritional support is determined by the patient's physiologic requirements and degree of debilitation, the disease process, the anticipated duration of inadequate oral intake, and the facilities and equipment available to initiate and maintain delivery of nutritional support.

Tube feeding may be either a temporary or a permanent means of nutritional support and may have supplemental or complete responsibility for meeting the patient's nutritional needs. Enteral nutrition is less expensive and easier to use than total parenteral nutrition [45] and probably safer.  Enteral nutrition is indicated when oral intake is less than two thirds of the patient's requirement, despite a functioning gastrointestinal system. Nasoenteric feedings are appropriate when fewer than 4 weeks of feeding are required, [43] although in some cases a pharyngostomy may be preferred because it is less irritating and cosmetically easier to conceal. Cervical or abdominal ostomies are recommended when more than 4 weeks of feeding are necessary. [43] Oral ingestion may continue with gastrostomy tubes and may be possible with nasogastric and cervical ostomy tubes with a gauge of 12 or lower.

Enteral tubes may terminate in the stomach or the small intestine. Gastric feeding results in better digestion than intestinal feeding. Normally about 20% of gastric antral contents pass into the duodenum, with 80% refluxing back into the body of the stomach for further mixing. [20] If the feeding tube is placed in the antrum of the stomach or in the small bowel, enteral feeding solution passing into the small bowel may not be tolerated, resulting in diarrhea and paradoxical decreased nutrition.

The most common rationale for small intestinal feeding is to reduce regurgitation and

aspiration. Disagreement exists concerning the clinical significance and frequency of regurgitation-induced aspiration.  Nevertheless, the emergency physician should attempt to ensure that the terminal end of a replaced tube is in the same viscus as the original.

External inspection may or may not reveal where a feeding tube should terminate. A de Pezzer (mushroom) or Foley gastrostomy tube is designed only for intragastric termination. Some tubes have 2 lumina, 1 terminating in the stomach for decompression and the other in the small bowel for feeding. These can be confused with tubes that have 2 entrances to 1 lumen (1 for continuous feeding, the other for medications) and tubes that have a second lumen leading to an inflatable balloon. Review of the medical record or communication with the surgeon is often necessary when external inspection does not reveal the specific type of feeding tube or indicate where a feeding tube should terminate.

**Procedure**

Nasoenteric feeding tube replacement requires greater time and effort if the patient is uncooperative or has a physically obstructing lesion. Nasoenteric feeding tube migration into the duodenal bulb generally requires patient positioning in the right decubitus position for about an hour after successful intragastric passage. [50]

The physician should explain the procedure to the patient before tube passage. The patient's assistance with esophageal passage can be enlisted in 2 ways. First, the patient can assist with swallowing the tube. Second, the patient can vocalize when requested to confirm that the tube is not passing down the trachea. Many patients find it helpful to develop a signal to indicate to the physician when they need a temporary reprieve and rest. It is generally advisable to restrain the hands of demented, impaired, or otherwise uncooperative patients.

The nares should be prepared before passage with generous application of a lubricant and local anesthetic. A local vasoconstrictor will dilate the nasal passages slightly and help prevent bleeding. Viscous lidocaine or water-soluble jellies (e.g., Surgilube) are excellent lubricants. A small amount of lidocaine with epinephrine can be squirted from a syringe into the nares a few minutes before lubrication. Application of lidocaine with epinephrine, application of the lubricant, or both, can also be accomplished with soaked cotton-tipped applicators. Alternatively, viscous lidocaine can be introduced into the nose with a gloved finger. The physician should be prepared and garbed for the inevitable sneeze that this will provoke. Patients with a hyperactive gag reflex should gargle with viscous lidocaine or with benzocaine (Cetacaine) or lidocaine (Xylocaine) spray before the placement attempt.

The feeding tube stylet should be lubricated and inserted into the feeding tube before the insertion of the feeding tube into the nares. Tube stylets can be lubricated with water-soluble jelly. Dobbhoff, EntriFlex (Biosearch), and several other tubes have a preapplied lubricant that must be activated with a 5-mL flush of water. Frying pan lubricant sprays (e.g., Pam) also may work well on the stylet. Other types of lubricants may have greater potential for pulmonary complications or may damage the substance

of the tubes. *The stylet should never protrude beyond the end of the feeding tube*, because these stiff, small-diameter wires have the capacity to scratch the esophagus and can encourage the creation of a false passage. The stylet may lock into position on the tube at the proximal end and should be properly secured.

An upright patient position is more comfortable for the physician during nasogastric passage. The distal end of the feeding tube should be moistened or lubricated and then passed down the more patent of the 2 nasal passages. Most persons' nostrils are fairly symmetric, but in some cases, growths or old trauma may narrow the passage. The tube

should be inserted into the nostril and then directed toward the ear. A common mistake of the inexperienced practitioner is to continue directing the feeding tube in a cranial direction. If the first nostril is impassable, the opposite side may permit tube passage. In particularly difficult cases, it may be desirable to first pass a lubricated nasal airway (trumpet) and then pass the feeding tube through it, reducing nasal and nasopharynx stimulation.

The tube's passage into the nasopharynx can usually be detected by a lessening of resistance. One can then proceed with esophageal passage. Topical anesthesia of the pharynx may be required to ameliorate any excessive gagging that may occur at this point. Cough should warn of incipient respiratory placement of the tube. If the patient can vocalize, the tube has not yet passed through the vocal cords. The patient should bend the head forward if possible. This encourages the tube to pass into the esophagus and aids airway closure. If the patient is gagging or choking, it may be because the tube is beginning to coil in the oropharynx. Look in the mouth with a penlight to see if this is occurring. If the tube is coiled on entering the airway, temporarily pulling the tube back should relieve the problem. When pulling back, some resistance is again felt as the thicker end bulb of the tube begins to enter the posterior nasal passages; at that point, the tube has been pulled back far enough for a fresh try at esophageal intubation. The cooperative patient should swallow ice chips or take small sips of water with a straw to facilitate tube passage down the esophagus. In some cases it may be impossible to avoid coiling when the tube is advanced, unless the patient is swallowing. When the patient is uncooperative, the introduction of 5 to 15 mL of water into the mouth or into the proximal end of the feeding tube with a syringe may induce swallowing, facilitating tube passage. Although the patient may not swallow for several minutes, waiting for the swallow may mean the difference between a coiled or pulmonary tube placement and successful passage.

Another technique for passing soft feeding tubes involves attaching the distal end to a Salem sump tube by means of a gelatin cap (one half of a size 0 gelatin capsule, as used for a large medication capsule). Lubricate the joined tubes, avoiding lubrication of the soluble capsule. The Salem sump-soft tube complex is passed nasogastrically. Once the tubes are positioned in the stomach, both tubes are irrigated several times with 10 to 20 mL of water. After about 5 minutes the gelatin capsule should have dissolved, allowing independent removal of the Salem sump tube (Fig. 43-10) . [2]

**Placement Confirmation**

Auscultatory confirmation of tube placement can be misleading.  The proper technique for auscultation is to inject 20 mL of air into the tube rapidly while listening with a stethoscope in the left upper abdomen. Air insufflation should occur without resistance and without delay in borborygmi. If the sound is muffled, faint, or delayed, the physician may reinject another 20 mL of air and listen over the lower lung. If the sound is clearer, the tube may be in the lung. The injected air should be aspirated from the stomach after placement is confirmed so that the patient is less likely to burp or regurgitate.

Proper placement of nasogastric feeding tubes should be confirmed with a radiograph. Tubes should be secured with tape before taking the radiograph. Tincture of benzoin applied to the tube and the patient makes the tape stick better. Commercial tube fixation devices may also be used. The position before and after the radiograph is taken is more likely to be the same if the tube is secured before filming.

Gordon suggests that radiographs are not necessary to check nasogastric feeding tube placement if the following criteria are met in order. [2] The tube must be passed beyond the 50-cm mark in a normal-sized adult; palpation and visual inspection confirm that the tube is not coiled in the mouth or oropharynx; air insufflation occurs without resistance and without delay in epigastric borborygmi; 10 mL of water advances through the tube without difficulty; and some water can be retrieved with aspiration. Do *not* inject water into the tube if any of the preceding criteria suggest that placement may be in the lung or upper esophagus. A risk of delivering water into the airway exists. [43]

Aspirated pleural or pulmonary fluid contents can be mistaken for return of intragastric fluids. [3] In addition, radiographic confirmation of tube placement may be misleading. In viewing the radiograph, it is particularly important to study the area around the carina. An esophageal tube shows at most a mild change in course, whereas a tracheally placed tube usually deviates significantly as it travels into the right or left main stem bronchus. The end of a nasogastric tube may appear to be in the stomach yet be in the left lung behind and below the top of the diaphragm. [51] When a stylet has been used for passage, the stylet should be left in the feeding tube for the radiograph, because the tube's course is not always visible without it. The stylets of most tubes are designed to allow insufflation and aspiration while in place. Even when stomach entry is certain, the intestinal location may be misleading on radiograph: A nasoenteric tube may lie completely to the left of midline and yet have its tip in the duodenum, or it may have a position overlying the right abdomen yet not have entered the duodenum. A contrast study is necessary to ascertain duodenal position when pulmonary placement has been ruled out.

The radiograph should also be examined for the presence of mediastinal air and a pneumothorax, which may suggest pulmonary or esophageal puncture. An esophageal puncture should be evaluated with endoscopy and may require surgery, depending on the size of the rent.

The end bulb of most nasoduodenal tubes will pass into the duodenum after patient

positioning in the right decubitus position for an hour. Some researchers recommend pretreatment with metoclopramide to enhance gastric emptying. One investigator found that metoclopramide enhances duodenal passage of nasogastrically placed feeding tubes in diabetic, but not in nondiabetic, patients. [50] Gastric antral motility in diabetics is often impaired; metoclopramide helps restore normal synchronized activity in these patients but has little effect on emptying in subjects who have normal antral function. The usual dose of metoclopramide is 10 mg administered IV. Also, 3 mg/kg of erythromycin lactobionate given IV over 1 hour works similarly and may be effective even if metoclopramide fails. [55] Endoscopy or fluoroscopy may be necessary if positioning and metoclopramide are not successful. [56]

## Complications

Pulmonary intubation is an uncommon but well-known and potentially fatal complication of nasal feeding tube insertion (see Fig. 43-8) (Figure Not Available) . Coughing and respiratory distress are the most common symptoms of respiratory passage of a nasogastric tube, but there may be relatively few symptoms in a demented or comatose patient. [57] Decreased mentation and an absent cough reflex are predisposing factors for unrecognized nasopulmonary intubation with nasogastric tubes. [3] A small end bulb, e.g., 2.7 mm diameter, can slip past a tracheal high-volume, low-pressure cuff and pass easily to the lung periphery.

To prevent nasopulmonary feeding tube intubation, one may choose to use the wire stylet only for initial tube passage. This will prevent pulmonary parenchymal penetration but not tracheobronchial intubation. It also will make passage of tubes positioned in the esophagus more difficult. [3] Esophageal entry of the feeding tube can be checked with the use of a laryngoscope. The metal stylet can be left in the tube during esophageal tube passage when an esophageal position has been confirmed by laryngoscopy. [59] A stylet should never be reinserted into a tube already in the patient. The stylet may puncture the tube at a kink or exit the side holes and puncture the esophagus. [60]

A pneumothorax may result when a nasogastric tube dissects into or is withdrawn from the pulmonary parenchyma. [30] Bloody aspirate from a tube should heighten awareness of tissue damage.

A clogged or nonfunctional nasogastric tube may prove difficult to remove. Fluoroscopy may allow careful insertion of a guide wire or stylet into an in situ tube to facilitate removal. Fluoroscopy also may identify the mechanical problem interfering with the removal. Bent-double segments are probably the most common; knots are uncommon but do occur. Excessive force should not be used in the removal of a nasogastric tube, because serious injury to the patient may result.

Premature removal of the nasogastric tube is the most frequent complication of feeding tube use. To help prevent removal by the uncooperative patient, the nasogastric tube may be secured to a loop anchor passed in the same naris. The anchor works by aversive stimulation of the soft palate and nose with distraction of the nasogastric tube, rather than by mechanical stabilization of the tube.

Sax and Bower recommend a technique for creating a separate nasogastric tube anchor. [61] A soft weighted nasoenteric tube is cut approximately 12 in. from the top. A heavy (2-0) silk suture is passed through the tube to exit the side hole. The guide wire is inserted with care, as it must not protrude from the cut end. The patient should be sedated if uncooperative. The tube is inserted through the anesthetized naris into the nasopharynx, grasped with Magill forceps, and pulled to exit from the mouth (Fig. 43-11 A). The excess tube is trimmed without cutting the silk suture. A closed loop is made by tying the silk suture in front of the nose. The loop must be slack enough that it does not apply continuous pressure to the nose or palate at rest. The nasal feeding tube is passed through the same nostril and secured to the loop (see Fig. 43-11 B). This anchor is simpler to construct and more comfortable than anchors passed through the opposite nostril. [61]

Complications of properly placed nasoenteric tubes include nasopharyngeal erosions, esophageal reflux, tracheoesophageal fistulas, gagging, rupture of esophageal varices, and otitis media. [43] One survey of nasogastrically fed patients found that the most distressing features of nasogastric feeding tube use were deprivation of tasting, drinking, and chewing of food; soreness of the nose; rhinitis; esophagitis; mouth breathing; and the sight of other patients who were eating. [62]

Checking feeding tolerance is difficult with small-gauge feeding tubes. Aspiration of tubes to check for residual is not recommended with tubes of 9 Fr or smaller. Aspiration is likely to clog the tubes, because they collapse under pressure and because relatively small particles can occlude the tube. For the same reasons the residual is likely to be inaccurate. [46]

**Patient Instructions**

Patient instructions should include a proscription against aspiration in small tubes. To maintain catheter patency, small tubes should be flushed with 20 to 30 mL of tap water at least 2 to 3 times daily and after administration of medication.  Water is a more effective irrigant than cranberry juice. [63] Medications should be in liquid form or be completely dissolved, or they may clog the tube. Methods of dealing with a clogged tube are discussed below.

The tube should be anchored to the nose and face in such a way that it is not in contact with the skin at the nasal opening. This reduces tube discomfort and prevents necrosis of the alae, nares, and distal septum. Patients who exhibit a tendency to pull on their tubes need adequate restraints. Patients receiving tube feedings should have their heads elevated to at least 30 degrees above the horizontal.

# PHARYNGOSTOMY AND ESOPHAGOSTOMY FEEDING TUBES

### Indications

Cervical pharyngostomy and cervical esophagostomy both have been developed

relatively recently. Cervical esophagostomy was first described by Klopp in 1951, [65] and cervical pharyngostomy was described in 1967 by Shumrick. [66] Cervical esophagostomies are generally performed at the time of cervical or maxillofacial operations. Malignant growths of the proximal esophagus, head, or neck are the primary indications for esophagostomy. Cervical esophagostomies may eventually evolve a permanent sinus, allowing the feeding tube to be removed between meals.

As with an esophagostomy, a pharyngostomy may be either a simple ostomy or a permanent tract formed by suturing pharyngeal mucosa to the skin. [66] [67] [68] The more common version is a simple opening that closes very rapidly (within a few hours) if it is not stented with a tube (Fig. 43-12) . Pharyngostomy is a simple procedure and does not require general anesthesia. It is useful when nasogastric feeding tubes are contraindicated or when prolonged tube feeding is anticipated. [44] Patients with traumatic or congenital anomalies of the maxillofacial region who are undergoing an operation and patients with impaired swallowing from neuromuscular disorders are potential candidates for cervical pharyngostomy. [68] A pharyngostomy is also indicated to bypass obstructing lesions for feeding, to assist healing after head or neck surgery for malignancy, and to feed the unconscious patient. A pharyngostomy can also be used for gastric decompression if it is required for more than 3 days. [67] Cervical pharyngostomy tubes produce only mild discomfort. Patients do not usually complain about pharyngostomy tubes, as they do about a nasogastric tube. The additional comfort and ease of productive coughing are especially important in critically ill and elderly patients.

**Technique of Tube Passage**

The feeding tubes commonly used for esophagostomy and pharyngostomy feeding are the same as those used for nasogastric feeding. Polyurethane feeding tubes are the most frequently used. The large (>3 g) bolus weights on some feeding tubes may be inconvenient to pass through the ostomy. Tubes that are approximately 90 cm (3 feet) long are appropriate for gastric feeding; tubes that are longer--108 to 112 cm (43 or 45 in.)--are used for duodenal feeding.

The feeding tube replacement technique is the same for pharyngostomy and esophagostomy. The outside of the tube tip can be lubricated with a small amount of water-soluble lubricant jelly. Mineral oil, which irritates the airways if aspirated, should never be used. The tip of the tube is inserted into the ostomy and directed caudally to ensure that it enters the esophagus and does not pass upward into the nasopharynx or mouth (Fig. 43-13) . The patient may be able to assist by attempting to swallow. The length of feeding tube required varies depending on the position of the ostomy and is several centimeters longer than the distance from ostomy to xiphoid. For duodenal feeding, the tube should be advanced about 20 cm beyond the distance from ostomy to xyphoid.  If the feeding tube persistently exits the mouth during attempts at passage instead of passing down the esophagus, the following 2 techniques may prove useful. After insertion of the feeding tube a short distance into the ostomy, a flashlight is used to visualize the tube in the pharynx. The feeding tube is grasped slightly proximal to the end bulb using Magill forceps, and the end bulb is directed toward the esophagus in the posterior inferior pharynx. Once the tube is properly directed, it may be possible to advance the remainder of the tube through the external ostomy. Sometimes it is

necessary to use the forceps to advance the entire length of the feeding tube. An alternative method is to allow the feeding tube placed through the ostomy to exit the mouth for the entire distance that must be passed down the esophagus. The end bulb of the tube is then directed into the posterior pharynx, and the patient is directed to swallow as for an orogastric tube. Toward the end of tube passage, it may be necessary to use a Magill forceps or to pull back the tube slightly at the ostomy to eliminate a short loop of extra tubing in the oropharynx.

Tube replacement is more difficult in the first week after the creation of a pharyngostomy or an esophagostomy. A tract forms after the first week and helps prevent tissue dissection by the tube. The angle of a well-formed tract also encourages appropriate esophageal passage. A well-formed tract closes more slowly than a new ostomy, although in some people even a long-term ostomy may begin sealing within a few hours. If an ostomy is too narrow for the replacement tube, the ostomy should be stented with a narrower tube and the patient's surgeon contacted.

**Complications**

Complications of pharyngostomy and esophagostomy include local soft tissue irritation, accidental extubation because of excess length of the external tube, pulmonary aspiration from vomiting, arterial erosion with exsanguination, and esophagitis or stricture of the esophagus from reflux. Accidental pulmonary intubation is less common with cervical ostomy tubes than with nasogastric tubes, at least partially because patients with cervical ostomies are more likely to be alert and have functioning cough reflexes. Auscultation and aspiration are still advisable techniques to check tube placement. Radiographic evaluation may also be necessary and is essential to confirm duodenal feeding.

## GASTROSTOMY, GASTROENTEROSTOMY, DUODENOSTOMY, AND JEJUNOSTOMY TUBES

The mid-19th century physician Sedillot described the first functioning gastrostomy, which formed as a complication of a war wound. The gastrostomies performed by Sedillot on 2 patients resulted in peritonitis and death. The jejunostomy procedure was first performed by Surmay in 1879. It was not until the 1890s that further innovations in surgical technique allowed the gastrostomy to be popularized. The Witzel serosal-lined gastric tunnel technique (Fig. 43-14) (Figure Not Available) and the Stamm procedure of concentric pursestring sutures placed around the gastrostomy tube were developed in the 1890s. These 2 techniques prevent significant intraperitoneal gastric fluid leakage, a complication that had frequently resulted in the deaths of gastrostomy patients. Both Witzel and Stamm gastrostomies tend to close rapidly without a stenting gastrostomy tube. In the early 1900s the tubular gastrostomy (Depage-Janeway) was developed. The Depage-Janeway gastrostomy results in the creation of a permanent mucocutaneous ostomy. Since the turn of the century, more than 30 different operative techniques have been described for tube gastrostomy. [44]

**Operative Indications and Contraindications**

Neurologic diseases constitute the most frequent indication for a gastrostomy tube. [47] Facial fractures, oropharyngeal trauma, and tracheal and laryngeal injuries may be indications for placement of a temporary feeding gastrostomy. Rare indications for gastrostomy include enhancement of nutrition by continuous feeding in severely debilitated patients who still are capable of oral intake, provision of a route for bile replacement in patients with an external biliary fistula, and the need for long-term gastric decompression. Indications for gastrostomy tube placement in children include neurologic diseases, facial reconstructive surgery for congenital deformities, and maxillofacial trauma. Young children who require long-term administration of unpalatable medications or dietary components may also require a gastrostomy. Tube duodenostomies are created almost exclusively for duodenal decompression after partial gastrectomy with Billroth II anastomoses. [68] Permanent jejunostomies are rarely used. Tube jejunostomy is indicated when the proximal bowel has a fistula or is obstructed, when recovery of small bowel motility is anticipated long before recovery of gastric motility, and after a gastrectomy.

Contraindications for gastrostomy feeding include severe gastroesophageal reflux, upper gastrointestinal fistulas, repeated aspiration of gastric contents, and intestinal or gastric outlet obstruction. [44] Jejunal feeding is contraindicated if the highly osmolar feeding solutions required for jejunal feeding are poorly tolerated and cause copious diarrhea.

**Indications and Contraindications for Tube Replacement**

The nursing home patient with a nonfunctioning or displaced feeding tube represents a common ED presentation. When available, details regarding the type of tube, details of placement (when, where, and how), and its most recent use can help guide the physician. If the tube has been removed, often the information on the tube can guide acquisition of an appropriate replacement tube. When unclear, a Foley catheter (16 Fr or larger) is generally a reasonable temporary replacement. Information should be sought from the patient's medical record, nursing home record, and private physician, when available.

If the tube is nonfunctioning yet still in place, the physician must make a judgment as to the risk versus benefit of removal and replacement versus an attempt at unclogging the tube (see subsequent section on unclogging). *The major concern is that a new tube may be misplaced (i.e., into the peritoneal cavity)*. If it appears that a skin incision was used to place the tube, it is unlikely that the patient has an easily removable tube. If the patient has signs of a complication (e.g., infection, ileus, or intestinal obstruction), surgical consultation is warranted.

Ease and safety of transabdominal feeding tube replacement depend on the surgical procedure performed and the length of time since placement of the feeding tube. For a simple gastrostomy, the insertion site of the tube through the gastrointestinal wall is sealed by either annular or plication sutures. The gastrointestinal wall is approximated

to the peritoneum around the site of penetration to provide a further leakage barrier. The tube is then secured outside the abdominal wall. A Witzel tunnel is a serosal tunnel created when the feeding tube is placed alongside the viscus for a distance after exiting the viscus, and the bowel is pulled up over it along this distance and secured with sutures (see Fig. 43-14) (Figure Not Available) . In 1 type of Hickman catheter jejunostomy, the tube passes through a Dacron cuff and a Witzel tunnel. [71] Reinsertion of a Hickman catheter through a tortuous, rough Witzel tunnel is unlikely to be simple. [72] A percutaneous gastrostomy may have been placed without any attempt to affix the stomach to the abdominal wall.

Nonoperative tube replacement techniques are safe only through an established tract between the skin and the bowel. Catheter replacement should not be attempted in the immediate postoperative period. A simple gastrostomy takes about a week to form a tract. [67] A Witzel tunnel may take up to 3 weeks after the operation to mature sufficiently for safe nonoperative tube replacement. A nonfunctional tube can still serve as the stent for the gastrostomy tract and should not be removed if it cannot be promptly and safely replaced.

## Equipment

Gastrostomy tubes come in an unusually varied selection of styles and materials. Rubber, silicone, and polyurethane tubes are all in common use. Many gastrostomy tubes are designed with a flange or a crossbar (bumper) to anchor them in the stomach (Fig. 43-15) .

Equipment for feeding tube insertion includes gloves, stethoscope, feeding tube, external bolster, lubricant, basin, and a syringe that fits the tube. Tincture of benzoin, tape, and absorbent dressing material may be used to dress the wound, although many are better left undressed. [73] Some feeding tubes require special plugs or connectors. Others need to be pinched with a clamp when not in use to prevent leakage. Some tubes are placed with the aid of accompanying guide wires or stents. For still others, it is necessary to use a clamp or hemostat, endotracheal tube stylet, urinary or uterine sound, laryngeal dilator (No. 14), guide wire, or other appropriate rod or support as an aid to tube passage (Fig. 43-16 A and B).

A stylet to assist introduction of de Pezzer catheters can be fashioned by cutting half the stylet from a 9 Fr pediatric chest tube inserter. The tip can be filed smooth. The device will be 10 to 12 cm long and can be inserted alongside the de Pezzer catheter and into its tip to distend and flatten the mushroom (Fig. 43-17) .

## Transabdominal Feeding Tube Removal

A feeding tube may have to be removed because it is irreversibly clogged, leaking, or broken; persistently developing kinks; too large or too small; causing a hypersensitivity reaction; associated with an abscess; or not the appropriate length for feeding into the desired viscus. Before a new transabdominal feeding tube is inserted, the old tube must be removed. Most, but not all, tubes can be removed without endoscopy. It is imperative to know whether the tube in place is safe to remove before attempting to remove it.

Standard de Pezzer or mushroom catheters that have been modified with bolsters or rings at the time of endoscopic or surgical insertion may no longer be safe to remove with traction. Tubes are occasionally secured with sutures or rigid internal bumpers or stays. Recently placed feeding tubes may need to be left in until a tract has formed (1 to 2 weeks depending on the procedure) even if the tube is nonfunctional. *The externally visible tube does not always reveal the internal stabilization* (see Fig. 43-15) .

A simple Foley catheter gastrostomy is easiest to remove. Once the Foley balloon is deflated, the tube should slide right out. If the Foley balloon cannot be deflated, cutting the tube may allow the balloon to deflate. The catheter must not be cut so close to the abdomen that it will be impossible to maintain a grip on it for a traction removal if the balloon still does not deflate. The balloon also may be punctured to cause it to deflate. To puncture a Foley balloon, traction is applied to the catheter to draw the balloon up against the ostomy. Using the taut feeding tube as a guide, an 18- or 19-ga needle is passed along the tube to puncture the balloon. It may be necessary to try again on the other side of the catheter, because the balloon may be asymmetrically inflated, and contact with the needle may be established on 1 side and not the other. The clinician should be careful not to track away from the ostomy into the patient's abdominal wall or to cause separate punctures of the stomach. The balloon is allowed a minute to deflate before another attempt is made at traction removal. Large balloons should probably be punctured, whereas small balloons may be removed with traction.

Traction is an acceptable removal technique for feeding tubes that are secured by a small mushroom. A towel is placed over the orifice, and the physician applies counterpressure with the flat part of the hand against the abdominal wall as the tube is placed under tension (Fig. 43-18) . This causes the tube and end mushroom to narrow, and the tube should come out easily. The inner crossbar, if present, may remain in the stomach when the rest of the feeding tube complex is removed by traction. Obstruction from the crossbar, which will pass in the stool, has yet to be reported for adults. In small children, obstruction is a possibility, and the crossbar should be removed by endoscopy.

A local anesthetic may be useful in selected cases of feeding tube removal, especially when the tube is in some way secured subcutaneously--for example, by a Dacron cuff. [71] It may be difficult to remove a catheter accidentally caught by a fascial suture during operative closure. [75]

Removal of gastrostomy tubes with moderate to large mushrooms may be easier if the mushroom is distended with a sound or stylet. The length of the gastrostomy tube should be known so that the sound may be inserted to the correct depth. Firm resistance should be noted at that point. Firm resistance at deeper depths represents pressure on the viscus wall and can result in viscus puncture. [53] The premeasured stylets that come with feeding devices are useful instruments for assisting in removal. This is particularly true of gastrostomy "buttons," whose ends resemble de Pezzer catheters. Because buttons come in a variety of lengths, it is important to have the proper stylet. Following elective permanent removal of a gastrostomy tube, a pressure dressing should aid in closure of the fistula. [53]

If it is not possible to pull the inner bolster or mushroom out through the ostomy, it may

be acceptable to cut the tube at the skin, push the remaining short stump into the stomach, and rely on later rectal passage. Although obstruction or impaction is infrequent, it can occur, and this alternative should not be chosen with children or patients who have had previous impaction, potential for bowel obstruction, or stool-passing problems. Rigid or large internal mushrooms and bolsters, the very kind that cause the most difficulty with percutaneous removal, also are more likely to cause difficulty with rectal passage. In no case should a device be released into the gut with a long length of tubing attached. Remember that double-part tubes may have an additional length of tubing for duodenal or jejunal feeding that extends far past the inner bolster. Korula and Harma reported the successful intestinal elimination of 63 of 64 gastrostomy tubes that were cut at the skin entrance and advanced into the stomach through the stoma. [76] These cases included tubes with internal bumpers, and success occurred regardless of the nature of the patient's underlying medical disorder, age, or method of original tube placement. However, no patient had suspected obstruction or potential for obstruction (e.g., no prior radiotherapy, inflammatory bowel disease). The 1 lodged tube required endoscopic removal from the pylorus. In most cases tube passage was documented by sequential radiographs, with a mean interval to passage of 24 days (range, 4 to 181 days).

Some physicians and surgeons may strongly condemn cutting off the tube at the skin, even when the risks posed by the procedure are very low. It is always advisable to contact the patient's private physician before cutting the tube. In some cases endoscopic retrieval of the tube remnant will be preferred to allowing rectal passage, and the tube should not be cut until just before or during endoscopy to ensure that migration does not occur before endoscopy.

**Transabdominal Feeding Tube Replacement**

A Foley catheter is a simple gastrostomy tube to replace. After the tract opening and distal Foley catheter are lubricated, the Foley balloon's integrity is checked by inflation. The catheter is then inserted into the tract. Good placement can be recognized by easy passage, prompt borborygmi with 20 mL of air insufflation, and rapid return of stomach juices with aspiration. The balloon is then inflated with saline (30-mL balloons are best), and gentle traction is applied to draw the balloon against the stomach wall. *Always inflate the Foley balloon with saline*, because balloons inflated with air deflate more easily. Tube replacement is usually successful if the tube has not been dislodged for more than 4 to 6 hours. If passage is impossible, a radiologist may be consulted to advance the tube over a guide wire that has been passed through the tract using fluoroscopy.

An external bolster may be threaded onto the catheter. The external bolster is a ring or bar of material threaded onto a tube that creates a large bulge on the tube and prevents inappropriate ingress of the tube into the ostomy on the side of the bolster. The anchor must adhere strongly to the tube so that mild stress on the tube does not cause the bolster to migrate up the tube. The bolster can be salvaged from the old tube or constructed in a number of ways. An anchor may be made from the end nipple of a de Pezzer catheter. The ring from a 24 Fr catheter, taken off at its junction with the end nipple, fits snugly over a 22 Fr Foley catheter when the balloon is distended slightly. The

nipple can be pushed forward to an anchoring position near the stoma. The nipple can be fixed in this position by fully distending the Foley balloon and applying a circle of adhesive tape just adjacent to the nipple on the stem on the side away from the body. [77] Adhesive tape sticks better if the lubricant is removed and the stem is prepared with tincture of benzoin.

An external anchor may be made from a segment of tube from a large rubber catheter (Fig. 43-19) . A segment approximately 3 cm in length is cut to form the bolster. Two diamond-shaped openings can be formed on both sides of the segment by bending the segment and clipping it with scissors on either side of the bend. The diameter of the holes should be slightly smaller than the catheter. A hemostat or a Kelly clamp can be inserted through both holes to grasp the external end of the gastrostomy tube, which can be bent in half--with some difficulty--to narrow its diameter (Fig. 43-20) . The hemostat can then pull the tube through the bolster, which can be threaded down the tube and anchored with tape as described previously (Fig. 43-21) . The outer crossbar should be located 1 cm away from the skin. [78] Contact between the crossbar and the skin promotes moisture entrapment and maceration. Too much tension on the gastrostomy tube can result in necrosis of the gastric wall where it abuts the inner mushroom or balloon. Proper placement of the external bolster helps avoid this complication (Fig. 43-22) .

Many physicians prefer mushroom or de Pezzer gastrostomy tubes, which are more difficult to replace than Foley catheters. The advantage of these catheters over Foley catheters is that the mushroom nipple keeps its shape more reliably than the Foley balloon, which tends to deflate. [62] Foley catheters also have a greater tendency to migrate internally and block the pylorus. [44] A Kelly clamp or other stylet can be placed through a side hole into the tip of a gastrostomy mushroom and used to elongate the end for easy passage through the gastrostomy (see Figs. 43-16 and 43-17) . Lubrication of the mushroom may make it more difficult to maintain the stylet's position in the mushroom. Some stylets are suitable for passage down the catheter lumen to elongate the end. Tubes should never be forced through a stoma for replacement, because this can cause separation of the viscus from the external stoma and lead to viscus leak or tube misplacement. [53]

The replacement tube provided in the ED does not have to be--and in a few cases should not be--the same type placed at surgery. The tube must be compatible with the feeding system, terminate in the same viscus, and fit through the ostomy. When a Witzel tunnel jejunostomy is created, the catheter most frequently used is a Broviac catheter. An appropriate replacement is a lubricated polyurethane tube shortened to a total tube length of 30 to 40 cm. Although the polyurethane tube is strong enough to be used for tube replacement through the Witzel tunnel without a guide wire, Broviac (silicone) catheters are too pliant to be coaxed through the resistive tunnel. [70] Jejunal feeding tubes are generally advanced 20 to 30 cm into the jejunum.

Jejunal feeding tubes may be placed through or alongside a decompressing gastrostomy. Original placement of the jejunal feeding tube is endoscopic. Replacement of these tubes also generally requires endoscopic assistance.  Fluoroscopic techniques can be used to help guide these tubes; however, these techniques are out of the realm

of emergency practice. [43] Occasionally, feeding tubes are placed in the jejunum because of gastric ileus.  If gastric ileus is no longer present, a gastrostomy tube may suffice. The rationale for jejunal feeding, risk of aspiration, and acceptability of gastric feeding to the primary physician should be established before changing from a jejunal feeding tube to a feeding gastrostomy tube. Techniques discussed in the nasoenteric feeding section of this chapter (metoclopramide and right decubitus position) may in selected cases coax gastrostomy-placed feeding tubes into the small bowel. Gastric decompression tubes are either clamped or put at continuous drainage. [80]

Verification of tube placement can be made radiographically using a fluoroscope or with a small amount of contrast material passed into the tube (Figs. 43-23 and 43-24) . In the latter scenario, a catheter-tip syringe is used to introduce water-soluble contrast solution (e.g., diatrizoate meglumine-diatrizoate sodium [Gastrografin]) into the tube. *Barium is contraindicated.* Generally 20 to 30 mL of water-soluble solution is adequate for documenting the intraluminal tube position. A supine abdominal film should be taken within 1 to 2 minutes of dye instillation to optimize gut visualization. *If the contrast material does not flow freely into the tube, the procedure should be terminated immediately and the position of the tube questioned.* With proper positioning, contrast will outline the gut containing the tube (e.g., stomach with gastrostomy tube). An irregular or rounded blotch with wispy edges or streamers suggests peritoneal leakage. In questionable cases, dye injection can be performed under fluoroscopy.

### Transabdominal Low-Profile Feeding Tube Replacement

Low-profile feeding tubes are almost flush with the skin, held in place with a preformed plastic external bolster. Commonly called *feeding buttons*, they are only slightly more difficult to place than a Foley catheter. The key to replacing a low-profile gastrostomy is to select the correct-length tube, which can be done by measuring the length using the stoma measuring device included with the tube. The stoma measuring device is inserted through the stoma and has a retaining hook or balloon on the end and markers on the portion protruding out of the abdomen. By counting the number of markers, the physician determines whether a long, medium, or short tube is appropriate. Once the appropriate tube is selected, the enclosed pre-sized obturator will distend the tube's end bulb, which can then be passed through the well-lubricated stoma for insertion of the tube.

### Complications

If the ostomy is not a mucocutaneous type, it will close rapidly without a stenting tube. Often the stoma begins to contract within hours of feeding tube removal. The physician may be presented with a very narrow ostomy and a tract that is difficult to identify or thread. A sound or blunt stylet can be passed down the tract more easily than a tube. This procedure can identify the opening and direction of the tract for easier tube passage. When a guide wire passes easily

down a narrow tract but the needed feeding tube does not, it may be possible to dilate the tract with dilators or a dilation catheter. [83] Viscus puncture, viscus abdominal wall separation, and false tract creation with subsequent tube misplacement are risks of

dilation procedures. Such procedures should generally be left to the surgeon. If tube replacement will be delayed, maintain the narrow tract with the largest available easily placed stent, usually a Foley catheter. Always secure the stent against internal migration.

The position of the gastrostomy tube should be checked by air insufflation and aspiration of gastric fluid, as is done with nasoenteric tubes. It is wise to document the results of this testing in the medical record. Air should enter the stomach without resistance and should produce immediate borborygmi. Gastric fluid should return with aspiration. It may be necessary to insert a small volume of water to get good return. Water pooling in the soft tissue may be aspirated back through a misplaced catheter. Good tube placement is indicated when more fluid returns with aspiration than was originally placed into the catheter. If replacement of the gastrostomy or jejunal tube required the overcoming of any resistive force or if either the air or the aspiration test yields uncertain results, a radiographic study with contrast should be performed. Peritoneal infusion of feeding solution can be fatal.

Complications of gastrostomy include wound infections around the catheter, performance of an unnecessary laparotomy for suspected leakage, gastrocolic fistula, pneumatosis cystoides intestinalis, bowel obstruction, peritonitis, and hemorrhage. [74] Jejunostomies can cause most of these complications, as well as other types of fistulas and small bowel obstruction from adhesions or volvulus around the jejunostomy site. The most common complications of gastrostomy and gastroenterostomy are local skin erosions from leakage, wound infections, hemorrhage, and tube dislodgment. [46] Peritonitis and aspiration are the most critical complications of gastrostomy feedings. Jejunostomies are less prone to stomal leakage and cause less nausea, vomiting, bloating, and aspiration than do gastrostomies.

Dislodgment of gastrostomy and jejunostomy tubes is most common in the 2 weeks following ostomy creation. [85] Extrusion of the gastrostomy tube is usually caused by excessive tension applied to the tube. Only gentle contact of the gastric and abdominal walls is desirable. Uncooperative patients should be restrained, and mittens are often particularly helpful. Sutures and large mushrooms or balloons do not prevent purposeful removal of the gastrostomy tube by the uncooperative patient.

A small amount of drainage is to be expected at the tube entry site. Local leaks of gastric juices may macerate and irritate the skin, predispose to local infections and abscesses, and encourage the development of small granulomas.  Granulomas are particularly common in children. They can be treated with silver nitrate at the time of dressing changes. Any dressing used around the entry site of an enteral nutrition tube should absorb fluid and not encourage persistent moisture. [73] An unusually large stoma may promote a leak. Although insertion of a larger tube or firmer traction on the tube may be transiently effective, these measures often result in further stomal enlargement. Rigid gastrostomies promote leakage by widening the stoma as they pivot. Insertion of a soft, pliant feeding tube through the widened stoma is often easy and allows later contraction of the stoma. [1] If these techniques are ineffective, temporary removal of the feeding tube may allow the stoma to shrink. Large amounts of drainage around the stoma site may occur with high residual volumes. [79] The residual should be checked

and feedings withheld until residuals are <100 mL. Feeding residual should be checked every 4 hours when a patient is on continuous drip feeding. [82]

Pneumoperitoneum after percutaneous gastrostomy is neither unusual nor dangerous. Benign pneumoperitoneum may be present as long as 5 weeks after percutaneous endoscopic gastrostomy. Pneumatosis cystoides intestinalis can occur through the defect in the bowel wall created for the enterostomy tube. Although often clinically insignificant, its occurrence suggests air under pressure in the small bowel. Nasogastric suction and diet change generally permit resolution of the problem. Catheter or feeding tube removal is usually not required. [75]

Clinically significant pulmonary aspiration can occur with gastrostomy feeding. Methods of checking for silent pulmonary aspiration include checking tracheal aspirates with a glucose oxidant reagent strip or placing methylene blue in the formula and monitoring tracheal aspirate for pigmentation.

A Foley balloon accidentally inflated in the small bowel or esophagus can lead to perforation or obstruction. [87] Careful inflation of the balloon soon after it has entered the stomach prevents viscus perforation. A gastrostomy tube may migrate in the stomach and obstruct the gastric outlet. This complication manifests itself clinically with vomiting and high residuals of feeding solution. Volvulus and jaundice may also occur as a result of balloon migration. This problem can be alleviated by gently pulling back the tube. If the balloon of a Foley catheter has migrated into the small bowel, deflation of the balloon before pulling it back further reduces the risk of intussusception. An outer crossbar will prevent distal migration.

Gastrocolic fistula usually manifests itself as copious diarrhea. Once it is confirmed, treatment consists of removal of the gastrostomy tube. Later creation of a gastrostomy in a different location may be possible. The patient may require hospital admission for nutritional support and monitoring of fluid and electrolyte status.

An external bolster that is snugged down too tightly may result in a short stoma and embedding of the internal bolster into the abdominal wall. An abscess may result. Overly tight external bolsters should be loosened. The correct position is 1 cm from the external abdomen.

Dacron cuffs can serve as the nidus for an abdominal wall abscess. Generally the cuff cannot be removed independently of the tube. A replacement tube without the cuff can be inserted, if one is careful not to dissect the tube into the wall of the abscess. Extensive abscesses may require incision and drainage.

## CLOGGED FEEDING TUBES

Clogging is a problem common to all feeding tubes. Although it may only be a temporary solution, it is prudent to attempt to unclog a tube before it is replaced, especially if the tube has a complex placement or the physician is unsure of how the tube is secured internally. However, whenever feasible, clogged tubes should be replaced with a new

tube.

Large gastrostomy tubes are the least likely to clog. Gastrostomy tubes at least 28 Fr in size can tolerate home-blenderized foods and viscous feeding solutions. Isosmotic feeding solutions are tolerated by fairly narrow tubes and cost one sixth of what elemental feedings cost. Isosmotic feedings will clog needle catheters. [45] When tube lumina are 14 Fr or smaller, all pills and the contents of all capsules should be dissolved in water to prevent tube obstruction. [73]

Acid precipitation of feeding formulas is an important factor in the occlusion of gastrostomy and nasogastric feeding tubes. Sodium and calcium caseinate and soy protein molecules are most soluble at a pH of 6.3 to 6.6 and least soluble at a pH of approximately 4.7. [88] They are insoluble in nonpolar organic solvents. A study of 14 feeding solutions showed Pulmocare, Ensure Plus, and Osmolite to be the most clog-prone on exposure to acidic solutions; Citrotein had the least tendency to clog. [89]

Kinking is a frequent cause of tube blockage during the immediate post-reinsertion period. Withdrawing the tube a few centimeters usually relieves the kink and obstruction. A persistently recurring kink requires tube removal and insertion of a fresh tube.

Accumulated feeding solution or medication precipitates are very difficult to clean or remove. Milking a pliant tube backward may remove some of the cheesy precipitates. Guide wires or stylets may clear the proximal portion of a clogged tube lumen but are unsafe to use in subcutaneous (SQ) areas of the lumen because they can puncture the tube and injure the patient or create a tube leak.

Fogarty arterial embolectomy catheters can be used to unclog jejunostomy [90] and gastrostomy tubes. The soft tip of the Fogarty catheter is inserted into the feeding tube and advanced while the insertion distance is monitored to avoid penetrating farther than the length of the feeding tube. The allowable length of insertion should be premeasured. A No. 4 embolectomy catheter is suitable for a 10 or 12 Fr tube, whereas a No. 5 catheter should be used in 14 Fr feeding tubes. When the catheter meets an obstruction, the balloon can be inflated, which usually opens the obstruction sufficiently that catheter passage can continue. Once the Fogarty has been manipulated to just proximal to the internal feeding opening, it is withdrawn while the balloon is intermittently inflated and deflated gently. The catheter should not be withdrawn while inflated, because it and the feeding tube tend to move as a unit. The procedure may need to be repeated several times. Contrast injection to confirm tube position and integrity should be performed after declogging is completed. [90]

Irrigation with carbonated beverages and high-pressure irrigation with small-volume syringes have also been recommended as techniques for unclogging feeding tubes. Although irrigation seems like a straightforward and simple solution, these techniques are generally ineffective; furthermore, the possibility exists for dangerous tube ruptures with internal leakage. Broviac catheters are especially prone to tube aneurysms that can rupture under pressure. [70] Tubes unclogged by forceful irrigation or by deep luminal

probing should be radiographed after injection of contrast to check tube integrity.

Enzymatic declogging of feeding tubes may sometimes be effective. Most enzymatic preparations are insoluble in an acidic environment and require mild alkalinity for effective action. Such precipitates can add to the obstructing material. One study suggested that 2 enzyme preparations can soften clog consistency sufficiently to enhance tube clearing with insufflation. [88] A crushed chymotrypsin tablet or 2 papain tablets (effervescent Allergan) can be dissolved in 2 mL of distilled water and irrigated into the drained feeding tube. A 12.5-cm catheter may make such irrigation more effective. The feeding tubes should be closed or clamped and left for 1 to 4 hours. One study attempted tube insufflation only at 4 hours, but clog changes were noted after one-half hour. [88] Insufflation of air with a 50-mL syringe also may clear the tube.

Most clogged tubes should be replaced. Tubes that have been unclogged by using force should be radiographed after water-soluble contrast injection (see section Transabdominal Feeding Tube Replacement) to check for internal leaks. Regular tap water irrigations and selection of a feeding solution appropriate for the diameter of the feeding tube are vital to prevent tube clogging.

## CONCLUSION

Emergency physicians must commonly manage the patient who requires nasogastric tube placement or management of a dislodged or malfunctioning feeding tube. While placement of these tubes is generally straightforward in the cooperative patient, many patients requiring such tubes will be uncooperative or have an altered sensorium. Therefore, careful attention to the details recommended for these procedures is encouraged, as the complications associated with a misplaced tube can be disastrous.

# Chapter 44 - Balloon Tamponade of Gastroesophageal Varices

**Edward A. Panacek**

More than 2% of all hospital admissions in the United States and more than 5% of admissions from emergency departments (EDs) are related to acute gastrointestinal (GI) bleeding. In the vast majority of these patients, the bleeding source is in the upper GI tract. Bleeding from varices, both esophageal and gastric, is the third most common cause of upper GI bleeding, accounting for about 20% of cases. [1] Variceal hemorrhage is the most dramatic and life-threatening complication of portal hypertension. After 1 bleeding episode, the risk of a second is 70%, accounting for up to 50% of all deaths in patients with cirrhosis. [2] The risk of mortality from each bleeding episode ranges from 20 to 84% and depends on the etiology of the portal hypertension, the hepatic functional reserve of the patient, and the duration of hemorrhage prior to presentation. [3] Individuals with noncirrhotic portal hypertension and intact hepatic function generally tolerate the hemorrhage better than those patients with cirrhosis and advanced hepatic dysfunction. The greatest risk of death is in the first few days after the onset of variceal hemorrhage. [3] Therefore, prompt and effective therapy during this initial period is essential to maximize the patient's chance of survival.

## BACKGROUND

The use of balloons to control variceal hemorrhage dates back to the 1930s, although the balloons were initially filled with water rather than air. [4] In 1950, Sengstaken and Blakemore first described the technique of a double-balloon tamponade system similar to what is currently used. [5] During the subsequent 30 years, the Sengstaken-Blakemore tube underwent a number of modifications or refinements by Linton, Nachlas, Boyce, and Edlich.  These modifications generally carried the name of their originator and altered the size or shape of the respective balloons or added aspiration ports in the stomach or the esophagus to allow monitoring of ongoing bleeding.

Currently there are 2 types of gastroesophageal balloon tamponade (GEBT) tubes commonly available: the 3-lumen Sengstaken-Blakemore tube (gastric balloon, esophageal balloon, and gastric aspiration) and the 4-lumen Minnesota tube (which adds an esophageal aspiration port). [8] [9] Figures 44-1 and 44-2 show these 2 types of tubes. Institutions generally stock a single type of tube. Most hospitals also generally only stock adult sizes, although pediatric tamponade tubes do exist. [10] Although GEBT tubes are used less frequently today than previously, their use can still be temporizing or life-saving. Although these tubes are not usually placed in the ED, most emergency physicians will encounter a GEBT tube during their professional career and should be familiar with their structure, placement, function, and management. This may be particularly true in more remote settings, where an invasive gastroenterologist is not readily available.

## INDICATIONS AND CONTRAINDICATIONS

A nasogastric (NG) tube should be placed in all patients in whom GI bleeding is suspected or known, regardless of the presumed source or degree of the bleeding. There is no evidence that passage of an NG tube in a patient with esophageal varices results in variceal trauma or increases bleeding. [11] Lavage should be carried out, ideally with the patient in the left lateral decubitus position, to determine if the upper intestinal bleeding is limited in extent (i.e., gastric aspiration becomes clear with about 1 to 2 L of fluid). Lavage is generally performed to decompress the stomach and minimize the risk for further emesis. Removal of large clots also allows gastric wall contraction in those cases where the upper GI bleed has a gastric origin (see Chapter 43) . Ongoing lavage has little effect on gastric hemorrhage, and extended lavage with cold solutions may induce hypothermia.

When the gastric aspirate does not clear with lavage, more aggressive therapeutic approaches must be considered. The approach to patients with acute hemorrhage from esophageal varices is substantially different from that used with other causes of upper GI bleeding. [11] The presence of advanced hepatic disease, evidence of portal hypertension, or prior known variceal hemorrhage greatly increases the likelihood of a variceal source for the bleeding. [1] However, in 25%

to 50% of such cases, upper GI bleeding can still be due to nonvariceal sources. [12] For this reason, emergent endoscopy is indicated in such patients whenever available. [11] Endoscopic sclerotherapy and other techniques are the most effective therapy to stop active bleeding from varices and to stabilize varices that have recently bled.

The other early therapeutic option for variceal hemorrhage is IV vasopressin, octreotide, or somatostatin, potent nonselective vasoconstrictors. They can be used in conjunction with sclerotherapy or as the sole therapy when sclerotherapy is unsuccessful or unavailable. These drugs must be used with caution in patients with coronary artery or other vascular disease because of the risk of adverse ischemic effects. [15]

When sclerotherapy is unavailable or unsuccessful and vasoconstrictor therapy is not adequate, balloon tamponade is the next therapeutic option. Balloon therapy is less successful than sclerotherapy but can control bleeding acutely in up to 80% of cases. [16] [17] [18] The role of balloon tamponade in these other therapies is depicted in Figure 44-3 .

Some authors have advocated the use of esophageal balloon tamponade based upon transfusion requirements or ongoing hemorrhage exceeding a certain amount (usually 2000 mL of blood within a 24-hour period). [1] Other recommendations have focused on endoscopic findings, including active variceal bleeding that cannot be controlled with sclerotherapy or traumatic longitudinal tears of the esophagogastric junction (Mallory-Weiss tear), with active persistent bleeding. [16] However, these indications are generally more relevant for the inpatient setting. In the absence of endoscopy, the indication in the ED would be a patient with known portal hypertension or prior variceal hemorrhage who has substantial ongoing upper GI bleeding that does not clear with

gastric lavage and vasoconstrictor therapy. When endoscopy is available, the indication for a GEBT tube is substantial ongoing variceal hemorrhage that cannot be controlled with endoscopic interventions. [16]

The use of esophageal balloon tamponade tubes is associated with a number of serious and potentially lethal complications. The overall complication rate is much higher than for most other procedures that emergency physicians perform. [19] Therefore, clear indications for GEBT tube use and a complete understanding of the instructions for their placement are required. GEBT tubes are best placed by the individual most knowledgeable about their use.

GEBT tubes are meant only for temporary bleeding control. [16] Although most studies have shown that they provide initial hemostasis in up to 80% of patients with bleeding from esophageal varices, they have not measurably affected the long-term mortality of these patients. [17] Their success rate improves when used in conjunction with vasoconstrictor therapy. [20] However, these therapies often do not control hemorrhage definitively, and arrangements for more definitive endoscopic procedures should be initiated.

## EQUIPMENT

Most hospitals stock only 1 type of GEBT tube. Ideally, the tubes are stocked in the ED itself or are readily available when needed. There are multiple companies making these tubes, and each company may include some of the items listed below. The equipment required for this procedure is as follows:

1. GEBT tube
2. Traction device or setup, including weights (see below)
3. Manual manometer or sphygmomanometer
4. Y tube connector, if not already part of the tamponade balloon ports
5. Vacuum suction device
6. Connectors for the suction tubing
7. Plastic tubing to connect to suction
8. Soft restraints
9. Topical anesthetic (spray and jelly)
10. Water-soluble lubricating jelly
11. 4 tube clamps (see text)
12. Large (e.g., 50 mL) catheter tip irrigating syringe
13. Surgical scissors for emergency balloon decompression

There are multiple ways of providing a traction setup for the tube, and individual hospitals may have specific policies. [9] Tubes can be taped to the mouth guard of a football helmet, although currently it is extremely unusual to see that technique used. Even in those institutions that try to keep a helmet available, it can rarely be located when needed. More often traction is maintained with a cube of foam rubber that is generally included in the package with the tube itself, as shown in Figure 44-2 . The tube is inserted between the 2 halves of the foam, and the foam "cuff" is placed against

the nose and taped.

The more common way of providing traction, and generally the way considered most effective, is through a pulley apparatus similar to the system used for orthopedic traction on lower extremity fractures. [21] It is a bit more cumbersome, and there are concerns regarding its use in disoriented or agitated patients, but it can effectively and consistently maintain the desired 0.45 to 0.91 kg (1 to 2 lb) of traction. The usual trapeze bar apparatus is used, but this requires 2 pulleys: 1 over the patient and 1 at the end of the bed. It also requires a longer rope (about 3 m [10 feet]), as well as the suspension hook and 0.23- to 0.45-kg (0.5- to 1.0-lb) weights.

Clamps are needed for the process of inflating the balloons, checking pressures, and maintaining balloon inflation. Never use bare standard hemostats for this purpose, as the serrations on the clamp jaws can puncture the rubber tubing. Specific tube clamps are best, if available (e.g., hosecock clamps). Alternatively, large surgical clamps or large hemostats can be modified by covering the clamping surfaces with sections of plastic or rubber tubing or multiple layers of tape.

## PROCEDURE AND TECHNIQUE

Patients requiring GEBT tubes are critically ill and must be closely monitored within the ED or in an intensive care unit. In the best of circumstances, these tubes can be difficult to place. However, these patients are often uncooperative and sometimes even combative due to encephalopathy. Control of the patient is imperative. Soft restraints should be used routinely, and sedating medications considered in most patients. If the patient is not awake, alert, and fully able to protect the airway, endotracheal intubation should precede placement of the GEBT tube (see Chapter 2) . These patients are at extremely high risk for regurgitation and aspiration, and the threshold for endotracheal intubation should be lower than usual. [22]

The procedure itself is unfamiliar to most emergency physicians and requires a number of items of equipment. Each of these should be checked prior to beginning the procedure. In particular, the balloons on the tamponade tube must be checked for patency and lack of leaks. If there is any question, the balloons should be submerged beneath water for checking. During testing, inflation of the gastric balloon is done in progressive steps (generally in 100-mL increments), up to the maximum recommended volume (generally 500 mL), while the pressure is monitored with the manometer. The pressure within the gastric balloon should not increase by >15 mm Hg with each progressive administration of 100 mL of air. The operator should note the pressure at full inflation of the gastric balloon. The esophageal balloon is simply checked for patency. The balloons are then deflated and coated with water-soluble lubricating jelly, preferably with a topical anesthetic.

The patient is positioned for the procedure by having the head of the bed elevated to about 45°, if possible. If the patient is unable to tolerate that position, the left lateral decubitus position is also acceptable. The posterior pharynx and nostrils are anesthetized with a topical anesthetic. The patient should already have undergone gastric lavage with a standard NG tube. At this point the stomach is maximally

evacuated (to decrease regurgitation), and the NG tube is removed.

After suctioning all air from the gastric and esophageal balloons and ensuring that they are maximally collapsed, each of the balloon ports is clamped, or the plastic plugs (if provided with the tube) are inserted into the lumens. This maneuver maintains deflation of the balloons during placement. In awake and alert patients, passage through the nostril is an option, but passage through the mouth is preferred, especially in tracheally intubated patients. The alert patient can assist the process by taking sips of water through a straw. The tube is then passed to at least the 50-cm mark, or the maximum depth allowed by the length of the tube, in the same manner as a standard NG tube. Suction is then applied to the gastric and esophageal aspiration lumens to minimize chances of further regurgitation or aspiration. Aspiration of gastric juice or fresh blood from the gastric lumen provides further evidence for proper location of the tube. However, its position must be confirmed radiographically.

Some authors recommend initial inflation of the gastric balloon with 50 mL of air to assist with radiographic visualization to ensure that the gastric balloon is below the diaphragm. [16] However, this is not routinely necessary, and the position of the distal end of the tube is usually obvious on radiograph. Absolute confidence regarding tube location is extremely important to reduce the risk of esophageal perforation caused by inflation of a misplaced balloon. Once gastric positioning of the distal balloon is ensured, the tube clamps (and plastic plugs if used) are removed from the gastric balloon inflation ports.

The pressure monitoring outlet for the gastric balloon lumen is connected to a manometer, similar to Figures 44-2 and 44-4 . Increments (generally 100 mL) of air are then introduced through the gastric balloon inflation lumen until the recommended total volume (generally 450 to 500 mL) fills the gastric balloon. Only air, never water or any liquid, is used to inflate the balloons. As the air is introduced into the gastric balloon, the intragastric balloon pressure is monitored. If the gastric balloon pressure at any step is 15 mm Hg greater than the intragastric balloon pressure at an identical volume noted prior to intubation (i.e., during testing), the gastric balloon may be located within the esophagus, and further inflation of the balloon could result in overdistention and rupture of the esophagus. If an elevated intragastric balloon pressure is recognized, the balloon should be deflated, advanced, and reintroduced into the stomach. A repeat radiograph is then obtained to confirm proper positioning prior to restarting the inflation procedure.

When the gastric balloon, positioned correctly in the stomach, has been inflated with the recommended full volume (generally 450 to 500 mL) of air, the air inlet and pressure monitoring outlet of the gastric balloon are each clamped. The tube is then pulled back gently until the resistance of the diaphragm is firmly felt. With a small amount of tension on the tube, the proximal end is secured using a traction device. The tube kit generally includes a sponge rubber cuff, which can then be fixed at the nostril and taped, if that approach is used. If the tube has been passed orally, an external pulley traction device is preferred. Once the tube is secured in place, the gastric aspiration port is attached to high intermittent suction. A final check should be made by irrigating the tube with water under auscultation. Lavage the gastric port until clear. [21] If there is any question

regarding correct tube position, obtain a repeat radiograph before proceeding.

If blood is detected continually in the gastric aspiration port (or in the esophageal aspiration port on a 4-lumen tube) despite lavage, the esophageal balloon should be inflated to the pressure recommended in the accompanying instructions (generally 30 to 45 mm Hg). Inflation of the esophageal balloon should be monitored continuously by a manometer attached to the esophageal balloon monitoring outlet. The esophageal balloon pressure should be maintained at the lowest level that will stop bleeding from each of the aspiration suction ports. In addition, the esophageal balloon pressure should not exceed the maximum listed in the instructions (generally 45 mm Hg). Once the balloon has been inflated to the desired amount, the port for the esophageal balloon is clamped, and periodic readings are taken.

If bleeding continues from the gastric aspiration port after full inflation of the gastric and esophageal balloons, it usually originates from a gastric rather than an esophageal varix. In this case, external traction on the tube should be increased. If a foam rubber block is used, the tube should be pulled to a more taut position and refixed to the nasal cuff at the point where the tube emerges from the nose. If the tube was passed through the mouth, and a trapeze-bar pulley system was used, adding additional traction is easy. An additional 0.45 to 0.91 kg (1 to 2 lbs) of weight can be applied to the pulley system, in progressive steps (maximum of 1.1 kg [2.5 lb]). [21] The pulley system should be attached to the GEBT tube through use of a nonoccluding knot (e.g. a bowline knot) passed around the area of the tube where all the respective ports separate. Tightening the knot directly onto the tube itself can occlude the ports.

Direct pressure from the tube can cause ulceration of mucosal surfaces within a matter of a few hours. Therefore, there should be frequent examinations to ensure that the tube is not placing excessive pressure on a given mucosal surface. If one is using an external pulley traction device, the angle of the tube, as it exits the mouth, is adjusted to minimize any such pressure by altering the location of the pulley. If the tube is passed through the mouth, precautions are also needed to preclude patient biting of the tube. A rubber or plastic mouthpiece should be placed in dentulous patients. Suction of the aspiration ports is then adjusted. The gastric port should have intermittent 60- to 120-mm Hg suction, and the esophageal port (for 4-lumen tubes) should be attached to 120- to 200-mm Hg continuous suction. [21]

After bleeding has been controlled by the tamponade, the pressure in the esophageal balloon is generally reduced by 5 mm Hg every 3 hours (or as specified in product instructions), until an intraesophageal balloon pressure of 25 mm Hg (or as specified in instructions) is achieved without ongoing bleeding. Note that continual elevated balloon pressures (>30 mm Hg) on the esophagus for long periods of time can result in mucosal ischemia and may induce esophageal necrosis. [21] Therefore, it is recommended that periodic deflation of the esophageal balloon be undertaken for approximately 5 minutes every 6 hours. If bleeding can be controlled with an intraesophageal balloon pressure of 25 mm Hg, this pressure is generally maintained for the next 12 to 24 hours. [16] [21] The pressure in the esophageal balloon can transiently vary with respiration and esophageal spasm. This may result in intermittent increases in the measured pressure of 30 mm Hg above baseline, although this should only be for transient periods. If it remains high, air

must be removed until the pressures are acceptable.

If a 3-lumen GEBT tube has been used, it will not have an esophageal aspiration port. Because the amount of oropharyngeal and esophageal secretions can exceed 1500 mL/day, additional suction proximal to the esophageal balloon must be provided. [21] This can be done with a standard 14 to 16 Fr NG tube passed to a position measured or calculated to be just above the esophageal balloon. This should be placed even if the esophageal balloon is not maintained in an inflated position, because an inflated gastric balloon will also interfere with the ability to swallow or pass secretions.

Once satisfactory positioning of the GEBT tube has been confirmed, the tube is generally then not disturbed for some 24 hours, unless necessary due to complications. [21] During this time, adjunctive therapy is ongoing and additional evaluation instituted. [16] These tubes are very uncomfortable, and patients should be provided with analgesics and sedation. In addition, soft restraints are needed on the arms to prevent the patient from dislodging the tube. If the bleeding does not remain controlled, other therapeutic interventions must be considered. These include endoscopic interventions with sclerotherapy, as well as emergency surgery. If these are not available, patient transfer may be necessary.

## COMPLICATIONS

Complications associated with the use of GEBT tubes are frequent and often very serious. [19] Table 44-1 lists both major and minor complications. Major complications have been reported to occur in 8% to 16% of patients. [9] Mortality directly related to use of these tubes is generally reported to be 3%.  However, 1 study reported the GEBT tube directly caused death in 22% of the patients in which it was used. [23] This must be considered in the context that variceal hemorrhage itself carries a 20% to 80% overall mortality. [16] Therefore, use of a GEBT tube is sometimes viewed as a desperate measure for a desperate disease process. GEBT tubes can be temporizing or even life-saving, but the high associated complication rate requires an individual risk-benefit analysis for each patient in whom it is being considered.

Aspiration pneumonitis is probably the most frequent major complication. [19] This can result from aspiration of oral secretions; gastric contents; or, most commonly, blood. [9] The volume of aspiration can be substantial, and associated deaths have been reported.  The likelihood of this complication can be decreased by evacuating the stomach prior to placement of the GEBT tube and having a low threshold for tracheal intubation to protect the airway. [22]

Asphyxia due to airway obstruction has been reported to occur with dislodgment of the tube such that the esophageal balloon migrates into the oropharynx. This is more likely when the tube is passed through the nares such that the inflated esophageal balloon cannot pass through the nasopharynx, and it is one of the reasons that oral placement is preferred. Tube migration can be prevented by maintaining full inflation of the gastric balloon through periodic monitoring

| TABLE 44-1 -- Complications of Esophageal Balloon Tamponade Therapy | | |
| --- | --- | --- |
| | **Common** | **Uncommon** |
| Major complications | Aspiration pneumonia<br>Asphyxiation<br>Esophageal necrosis | Esophageal perforation<br>Duodenal rupture<br>Tracheobronchial rupture<br>Periesophageal abscess<br>Mediastinitis |
| Minor complications | Gastroesophageal ulceration<br>Regurgitation<br>Chest discomfort<br>Back pain<br>Pressure necrosis of nose or lip | Epistaxis<br>Pharyngeal erosions<br>Pressure necrosis of tongue<br>Hiccups |

of pressures and radiographic reconfirmation. Of course, airway obstruction can be completely prevented by prophylactic tracheal intubation. If the tube suddenly migrates, resulting in an airway obstruction in a nontracheally intubated patient, the balloons must be immediately deflated and the tube extracted. This can be achieved most quickly by cutting across all of the tube lumens just distal to the bifurcation points. This will immediately vent all of the balloons, and the entire tube can be extracted. For this reason, it is recommended that surgical scissors be kept available at the patient's bedside whenever a GEBT tube is in place.

The other relatively common major complication is esophageal perforation or rupture. [19] [23] [24] This occurs with overinflation of a misplaced gastric balloon and can be prevented through careful employment of the placement steps already outlined. However, this can also occur as a result of esophageal mucosal necrosis caused by excessive or prolonged pressure in the esophageal balloon. The treatment is immediate removal of the GEBT and initiation of diagnostic studies (e.g., contrast swallow) and broad-spectrum antibiotics (for potential mediastinitis). Again, risk for this complication can be decreased by periodic deflation of the balloons at 6-hour intervals and limiting the amount of pressure in the esophageal balloon to the minimum amount necessary to control bleeding. This problem is also more common when the balloons are left inflated for >24 hours. [21]

Common minor complications include pain, discomfort, and local pressure effects of

gastric or esophageal erosions or mucosal ulcers.  These latter can be minimized by frequently checking and optimizing tube position to minimize pressure on the nasal or oral mucosa, the tongue, and other structures. Although less common, other complications can occur; these are also listed in Table 44-1 .

## INTERPRETATION

GEBT tubes are used to temporarily control bleeding varices. This is assessed by monitoring the rate of blood aspirated from the gastric and esophageal ports after tube placement. It is not uncommon for the GEBT tube to fail to control the hemorrhage. When significant bleeding continues, correctable causes should be considered which include malpositioned balloons, inadequate balloon pressures, and misdiagnosis of the site of bleeding (e.g., a duodenal ulcer instead of variceal source). [21] [24] When these have been addressed but bleeding continues, other therapeutic options must be considered, including sclerotherapy, angiographic embolization, and surgery (see Fig. 44-3) .

## CONCLUSION

Gastroesophageal balloon tamponade is an uncommon procedure in general, and particularly for emergency physicians. Some emergency physicians may not have performed this procedure previously. However, the procedure can temporarily control an exsanguinating hemorrhage from gastric or esophageal varices in about 80% of patients when other options are unsuccessful or unavailable. As such, the emergency physician may periodically be called upon to place a balloon tamponade tube. Because of the high incidence of associated serious complications, the procedure should be used in carefully selected patients in whom the potential benefit is favorable, given the risk of exsanguination.

Each hospital is unlikely to stock more than 1 tube type, and this may not be the type most familiar to the physician. However, currently most balloon tamponade tubes are fairly similar and are packaged with a complete set of instructions. These instructions must be carefully reviewed prior to tube placement. There can be great difficulty locating these tubes within the hospital when they are suddenly needed, so advance planning is recommended, when possible.

The most serious common complications are those of aspiration and airway occlusion. [19] A low threshold for prophylactic tracheal intubation is recommended. The most serious iatrogenic complication is due to balloon inflation of a misplaced tube, with resultant esophageal rupture. This is avoidable by carefully following the instructions and insisting on radiographic confirmation of tube position before fully inflating the balloons.

# Chapter 45 - Decontamination of the Poisoned Patient

**Patrick E. McKinney**

At least 2 million cases of accidental and intentional poisoning occur each year in the United States. [1] In 1 report, approximately 1% of all patients seen in an emergency department were suffering from acute drug overdose. [2] The diagnosis and management of acute poisoning in children and adults are common problems and require that physicians caring for these patients be expert in the procedures used in their management.

After initial stabilization of the acutely poisoned patient, an attempt is usually made to prevent further absorption of any toxin. If the patient has a dermal exposure, skin decontamination may be indicated.  When the toxin is ingested, attempts may be made to decrease further absorption from the gastrointestinal (GI) tract. [3] Methods for accomplishing this vary and have evolved over time. Techniques include ipecac-induced emesis; gastric lavage; administration of 1 or more doses of activated charcoal; administration of cathartics; whole-bowel irrigation; and, rarely, gastrotomy or endoscopy. This chapter focuses on decontamination of the poisoned patient and discusses its indications and contraindications, as well as technical aspects of specific procedures and their complications.

## BACKGROUND

The historical use of a hollow tube to evacuate poison from a patient's stomach dates from the early 1800s and has been thoroughly reviewed by Major. [5] Kussmaul, who is commonly credited with inventing gastric lavage for the treatment of poisoning, did much to popularize its use after his 1869 publication. [6] During the next 75 years, gastric lavage was widely held to be the most effective procedure for emptying the stomach of an acutely poisoned patient.

Although the benefit of stomach emptying for the routine treatment of poisonings appears obvious, the safety and efficacy of gastric lavage was first questioned by Harstad and coworkers, who found that in only 5 of 80 patients suffering from severe sedative poisoning could >500 mg of drug be recovered in the gastric washings. [7] In addition, they reported that particles of previously administered activated charcoal could be found in the respiratory tract of some of the patients who died, suggesting that aspiration of gastric contents had occurred. They concluded that gastric lavage was relatively ineffective and potentially unsafe, but a number of methodologic problems exist with this study. The size of the stomach tube was not specified, the drug assay method used (crystallization) was crude, and the positioning of patients may not have been optimal. In addition, patients' airways were often unprotected during the procedure. As a result of this study, gastric lavage fell into some disrepute and was thereafter performed less often at many medical centers. [8] This practice change was accompanied by a growing interest in the use of induced emesis as a means of evacuating the stomach in poisoned patients.

The 1950s saw the beginning of a controversy regarding the relative efficacy of gastric lavage vs. ipecac-induced emesis that persists to this day. Boxer and colleagues compared ipecac vs. lavage for gastric emptying in children who had ingested unknown quantities of aspirin. [11] Their 17 patients were randomized to be treated with ipecac-induced emesis followed by gastric lavage or to undergo gastric lavage followed by ipecac-induced emesis. The relative quantities of drug retrieved by each method were then compared for each patient, and a ratio was established. More drug was apparently removed by induced emesis than by lavage, but the description of the lavage technique used in this study was incomplete. Particularly important omissions from the report included specifications of the gastric tube diameter, the patient's position, the lavage solution volume, and the time delay before instituting treatment. Finally, only negligible amounts of aspirin were removed by either method.

In a series of 259 severely poisoned patients, Matthew and colleagues showed that carefully performed gastric lavage could remove clinically important amounts of ingested drug. [12] However, because the actual ingested dose was unknown, the true efficacy of gastric lavage could not be determined. Burke lavaged 10 adult volunteers undergoing general anesthesia for elective bronchoscopy and demonstrated that water-soluble radiopaque dye can be removed from the stomach if a large gastric tube is used and careful attention is paid to lavage technique and patient position. [13]

Tandberg and associates compared lavage to emesis using cyanocobalamin tablets as a tracer in 18 adult volunteers on 2 separate days. [14] Ipecac-induced emesis was initiated 10 minutes after ingestion of the tracer. Gastric lavage was carried out on another day, also beginning 10 minutes after tracer ingestion. A mean of only 28% (range, 6% to 70%) of the administered cobalt tracer was recovered by ipecac-induced emesis, whereas 45% (range, 19% to 68%) was recovered with gastric lavage. These recovery rates are disappointing, especially in view of the short time to the initiation of gastric emptying, the absence of other materials in the stomach, and the optimal circumstances of the procedures.

Young and Bivens also examined the effectiveness of lavage compared to emesis using technetium 99m capsules in volunteers. [15] In their study, lavage was delayed until the point at which emesis occurred during the preceding ipecac treatment day. They found a slight advantage to emesis, with a mean of 54% of marker returned when ipecac was administered within 5 minutes of marker ingestion. Volunteer studies have been unable to detect a difference in drug recovery when 1 hour was allowed to elapse between drug administration and commencement of ipecac-induced emesis or gastric lavage.

Prospective studies of actual overdose patients have been unable to demonstrate a clinical advantage to gastric emptying (by either emesis or lavage) over simple administration of activated charcoal. However, Kulig and colleagues found evidence for benefit if obtunded patients were lavaged within 1 hour of ingestion. [18] Merigian and colleagues found no benefit to lavage in a similar study, which also excluded patients who had ingested methanol, ethylene glycol, lithium, monamine oxidase inhibitors, heavy metals, formaldehyde, mushrooms, digitalis, and sustained-release products. [19] The number of seriously poisoned patients was relatively small in both of these studies.

However, these studies do support the use of activated charcoal as the sole method of GI decontamination in mildly poisoned patients.

Activated charcoal use has been extensively reviewed by Cooney. [20] Charcoal has been used in medicine since the time of ancient Egypt, but its use in the treatment of poisoning was first documented in France in the 1800s. A French chemist, M. Bertrand, swallowed 5 g of arsenic trioxide mixed with charcoal in a public demonstration and survived. [21] A similar demonstration using strychnine was performed by the pharmacist P. F. Touery in 1831. Despite in vitro and in vivo evidence in animals and humans, activated charcoal use for treatment of poisoning remained sporadic until the 1960s, when it was popularized by Holt and Holz. [22]

One of the newest methods of GI decontamination is whole-bowel irrigation (WBI). WBI appears to be most useful in specific situations where substances are not well adsorbed to activated charcoal or require "flushing" through the GI tract. Case reports document the use of WBI for ingestions of extended-release verapamil, extended-release theophylline, iron, lead glaze, disc batteries, zinc sulfate, diquat, and paraquat and in "body packers" and "stuffers." Controlled volunteer studies have shown beneficial effects from WBI after ingestion of extended-release lithium and enteric-coated aspirin.

In summary, the data on gastric emptying are conflicting. In most circumstances it is probably impossible to predict which procedure will most effectively accomplish gastric decontamination and to determine how much drug should be removed to provide clinical benefit. Currently available human studies suggest that activated charcoal alone may be adequate decontamination therapy for most asymptomatic or mildly symptomatic patients or for those symptomatic patients who present for treatment >1 to 2 hours post ingestion. In the setting of potential delayed drug absorption (e.g., sustained-release medications or medicines producing delayed gastric emptying), this time interval may be extended. One of the strongest arguments supporting the use of lavage over emesis in the emergency department is that the procedure can be done immediately on presentation (compared with the 15- to 20-minute delay for ipecac to produce emesis), and charcoal can be immediately instilled to limit further absorption. This immediacy of emptying may provide a benefit to patients who have taken an otherwise lethal overdose.

## GENERAL CONSIDERATIONS

Routine gastric emptying procedures are no longer the standard of care for *all* suspected drug overdoses. Most clinicians agree that gastric emptying (whether by ipecac or gastric lavage) should be avoided in patients with a clear history of ingestion of a nontoxic substance or ingestion of an inconsequential amount of toxic substance. [33] Ingestion of a substance with a low order of toxicity that is well adsorbed to activated charcoal does not require gastric emptying (e.g., benzodiazepines). In addition, gastric emptying should not be performed if a significant time after ingestion has passed and there is no reasonable suspicion that the substance is still in the stomach (e.g., 4 hours after ethanol ingestion). Finally, gastric emptying is rarely indicated if the patient has vomited repeatedly prior to arrival.

The decision to pursue gastric emptying with ipecac-induced emesis or lavage should be based on 4 major factors: the time since ingestion, the amount of medication ingested, the relative toxicity of the substance, and the clinical condition of the patient. The first factor, the time delay between ingestion of the poison and initiation of gastric emptying, is an important consideration. For rapidly absorbed drugs, such as the short-acting barbiturates, older evidence suggests that attempts at gastric emptying >4 hours from the time of ingestion are not likely to be of clinical value. [12] The prospective randomized study of clinical outcome in poisoned patients by Kulig and colleagues found fewer cases of clinical deterioration with gastric lavage (compared with those from activated charcoal alone) *only in that subset of patients who were both obtunded and seen within 1 hour of their ingestion.*[18]

However, many conditions could theoretically result in delayed gastric emptying and the potential for retrieval of clinically important amounts of drug >1 hour after ingestion. Physiologic gastric emptying is especially likely to be delayed in patients with diminished or absent bowel sounds; in those who have ingested opiates or drugs with anticholinergic properties (e.g., cyclic antidepressants, antihistamines, benztropine, and other strong anticholinergics); or in patients who have ingested large amounts of relatively insoluble drug, such as aspirin, ferrous salts, or sustained-release preparations. Other conditions that may delay physiologic gastric emptying include the presence of food in the stomach, a high proportion of solid material in the stomach, [34] high nutritive density of the last meal, [35] high viscosity of stomach

contents, [36] and positioning in the left lateral decubitus position. [37] Finally, the history of time of ingestion may be inaccurate, a fact that should be kept in mind when considering timing as a guide to treatment choice.

The second and third factors in assessing the need for gastric emptying are the toxicity and amount of the ingested substance. Minimally toxic agents clearly do not require gastric emptying. Likewise, most authorities agree that *recent ingestion of significantly toxic agents* (e.g., cyclic antidepressants, beta-blockers, theophylline, cyanide) should be considered for gastric emptying. [33] However, there is a considerable gray area involving substances of intermediate toxicity (e.g., sedative-hypnotics, anticonvulsants, antihistamines). In these cases, activated charcoal and supportive care may be sufficient. Many clinicians forego gastric emptying in these cases for activated charcoal, but patients who have ingested large amounts and who present early to the emergency department (even if asymptomatic) may benefit from gastric emptying. Finally, given the availability of potent antidotes (naloxone, flumazenil, Digibind, *N*-acetylcysteine), the need for gastric emptying in specific poisonings may be diminished.

The final factor in determining the need for gastric emptying is the clinical condition of the patient. As noted above, Kulig and associates found a clinical benefit to lavage only in patients who were obtunded and presented within 1 hour of ingestion. [18] Although no benefit was detected when obtunded patients were lavaged >1 hour after ingestion, there were few patients in this group. It seems reasonable to lavage all obtunded, intubated patients, provided there are no contraindications.

If the decision is made to empty the patient's stomach based on the criteria above, then the patient's level of consciousness is the most important factor to consider. Neither ipecac-induced emesis nor gastric lavage *without* airway protection should be performed in patients likely to have or to develop diminished airway protective reflexes during the procedure. This includes patients with a diminished sensorium, seizures, or the potential to develop these clinical findings. Gastric lavage with a cuffed endotracheal tube in place should be carried out instead. The use of depolarizing or nondepolarizing muscle relaxants may be required to intubate the combative, confused, or obtunded patient with diminished airway protective reflexes.

# IPECAC-INDUCED EMESIS

### Indications and Contraindications

Ipecac use in the emergency department is currently limited to a few specific indications. It may be used in pediatric patients who present early after ingestion, in adults who present immediately after large ingestions of agents with delayed toxicity that may be poorly adsorbed to activated charcoal (e.g., iron, lithium, extended-release preparations), and after plant or mushroom ingestion.

Ipecac should not be given if central nervous system depression or seizures could potentially occur within the expected time frame of emesis (up to 2 hours after ipecac administration). Ipecac is also contraindicated in patients who are already vomiting or in patients who have ingested acids, alkalis, or hydrocarbons, as emesis might cause further esophageal injury or aspiration. Most clinicians feel that ipecac use in the emergency department is contraindicated after acetaminophen ingestion. [39] Persistent vomiting could preclude the timely administration of *N*-acetylcysteine.

### Technique

Syrup of ipecac is packaged in 15- and 30-mL containers. Standard dosages of ipecac and accompanying clear fluids based on patient age are as follows [3] :

> *6 to 12 months:* 5 to 10 mL ipecac plus 15 mL of clear fluids per kilogram body weight

> *12 months to 12 years:* 15 to 30 mL ipecac plus 240 mL of clear fluids

> *>12 years:* 30 mL plus 240 to 480 mL of clear fluids (repeat once in 20 to 30 minutes as needed)

Some clinicians recommend that the child be jiggled or the stomach massaged beginning 10 to 15 minutes after ingestion of the ipecac and fluids if no spontaneous emesis has occurred.

A single dose of 10 mL has been recommended by some investigators [40] for infants 6 to 12 months old, although there is some concern as to whether the gag reflex is sufficiently developed in these infants.

## Complications

The major advantage of ipecac use is its ease of administration and its potential for home use or administration by emergency medical service personnel. The main disadvantages of ipecac administration are the delay after administration to onset of emesis and the duration of emesis. The delay to emesis averages 20 minutes, but some patients may not vomit after a single dose and may require a second dose. [41] Patients usually experience 2 or 3 episodes of emesis over 20 minutes to 1 hour. [42] Drug absorption and clinical deterioration with compromise of airway protective reflexes may occur while waiting for emesis to begin or resolve. Persistent emesis may also delay administration of activated charcoal or oral antidotes such as *N*-acetylcysteine. Pediatric patients receiving ipecac in the emergency department had an additional delay of 1.7 hours to receive activated charcoal and were more likely to vomit afterward. [43]

Complications from syrup of ipecac use are uncommon. Perhaps the most significant complication from syrup of ipecac-induced emesis is pulmonary aspiration in a patient who has lost airway protective reflexes. Patients may become drowsy, but significant sedation has not been reported from ipecac alone. Other rare reported complications include Mallory-Weiss tear, [44] gastric herniation through a diaphragm defect, [45] gastric rupture, [46] cerebral hemorrhage, [47] pneumomediastinum, [48] and vagally mediated bradycardia.

# GASTRIC LAVAGE

### Indications and Contraindications

The advantages of gastric lavage include the fact that it can be performed immediately; it can be performed on patients with a decreased level of consciousness once the airway is protected; and finally, drug that is removed by lavage is no longer available for absorption (there is the possibility of desorption of drug from the activated charcoal remaining in

the GI tract). The main disadvantages of gastric lavage are the significant time commitment of health care personnel for the procedure and the risk to the patient. Watson and colleagues found that mean time required by experienced emergency department nurses to perform lavage was 1.3 ± 0.6 hours while lavaging an average volume of 12.8 L. [49]

Lavage should be considered in patients who present early (within approximately 1 hour) after ingestion of a potentially significant toxin, especially when large numbers of pills or gram amounts of toxin have been ingested. It may also be considered in patients with highly toxic ingestions in the setting of anticipated delayed physiologic gastric

emptying. Finally, gastric lavage should be performed when patients with suspected toxic ingestion are already intubated, provided there are no contraindications present.

A common dilemma involves the decision of whether to lavage the combative patient. If the patient requires intubation for airway protection, lavage can be accomplished after sedation and paralysis for intubation. If the patient does not require intubation for airway control, a careful assessment of the potential lethality of the ingestion should be made. If the ingestion is thought to be significantly life-threatening, lavage following rapid-sequence induction and intubation may be indicated (see Chapter 3) . However, in many combative patients, alternatives to lavage, such as activated charcoal, should be considered. Evacuation of gastric contents by nasogastric tube can occasionally remove significant quantities of ethanol, although patients with a significant gastric ethanol load may not be easily identified. [50] Repeated attempts at lavage risk injury to both the patient and staff.

Contraindications to gastric lavage include (1) an unprotected airway, (2) possible ingestion of strong alkalis, (3) known esophageal strictures, and (4) ingestion of hydrocarbons (unless containing highly toxic substances such as pesticides, heavy metals, halogenated or aromatic compounds, or camphor). The regional poison center can be of great help in determining whether gastric emptying is indicated, especially when unusual hydrocarbon products are involved.

The ingestion of strong acids rarely produces severe esophageal injury but may cause deep burns of the stomach and the duodenum. Continuing injury for as long as 90 minutes has been demonstrated in experimental animals [51] and suggests that rapid removal of the ingested acid could be beneficial. Gentle passage of a small-bore flexible rubber nasogastric tube and aspiration of gastric contents after acid ingestion would be reasonable; however, this approach remains controversial.

**Equipment and Preparation**

If the decision is made to perform gastric lavage, careful attention to the details of the procedure results in increased safety for the patient and more effective removal of the ingested poison. Prior to lavage, the patient should have IV access secured and should be placed on a cardiac monitor and pulse oximeter. Suction with a large, rigid suction tip should be immediately available.

Before initiation of gastric lavage, the airway should be protected with a cuffed endotracheal tube if the level of consciousness is significantly depressed or the patient's airway-protective reflexes are diminished. The traditional way to test for this is to stimulate the posterior pharynx with a tongue blade or a cotton-tipped applicator. Alternatively, the lack of a grimace or blink reflex after touching the eyelashes is strong evidence for an unprotected airway and the need to intubate the trachea before gastric lavage. [38] Cautious direct laryngoscopy with prompt endotracheal intubation in the patient who tolerates laryngoscopy may be used in questionable cases; the patient who tolerates the procedure probably needs it. If patients are fully alert and awake, lavage may be done without tracheal intubation. Attention to patient positioning, prompt suctioning, and consideration of immediate gastric tube removal should be made in

nonintubated gastric lavage to optimize protection of the airway.

The position of the patient during gastric lavage is important. All patients should be placed in the left lateral decubitus position with the head down (approximately 10° to 15°). This position diminishes the passage of gastric contents into the duodenum during lavage, a fact that has been well documented by fluoroscopy during the procedure (Fig. 45-1) . [13] In addition, the head-down position probably decreases the risk of pulmonary aspiration of gastric contents should vomiting or retching occur. The uncooperative patient's hands should be restrained to prevent removal of the gastric or endotracheal tube.

Large-diameter gastric hoses with extra holes cut near the tip are recommended for gastric lavage (Fig. 45-2) . There are no convincing data on humans to refute or support this recommendation, and 1 study of a small number of dogs failed to show any difference in efficacy with lavage through a 32 Fr tube compared with a 16 Fr lavage tube. [52] It is generally held that large-diameter nasogastric or orogastric tubes (>1 cm) are more likely to retrieve particulate matter successfully. Also, smaller, more flexible tubes may kink and are significantly more difficult to pass. [53] A 32 to 50 Fr tube is usually recommended for adults. A 28 Fr tube is the size of a pediatric endoscope and may be passed in an infant; proportionately larger tubes should be used for larger children.

Before passage, the length of the tube required to enter the stomach should be estimated by approximating the distance from the nose to the mid-epigastrium (Fig. 45-3) ; premeasurement avoids the curling and kinking of excess hose in the stomach. In addition, passage of an excessive length of hose may cause gastric distention, bruising, and perforation. Passage of an insufficient length of hose may result in lavage of the esophagus and the increased risk for emesis and aspiration. One study of radiographs done to document proper placement of the lavage tube in children found that 7 of 14 patients had improper tube placement (too high or too low), despite positive gastric auscultation in all cases. [54]

Commercial lavage systems are available and often use either a gravity fill-and-empty system with a Y connector (e.g., Travenol or Ethox) or a closed irrigation syringe system. Alternatively, an irrigation syringe can be used for intermittent lavage fluid input and withdrawal. Closed systems minimize the potential for creating a mess and allow 1-person operation, but may permit excessive gastric filling if the operator is not attentive.

### Technique

If gastric lavage is considered essential in the highly anxious or agitated patient, rapid-sequence induction and intubation should be considered. Alternatively, small doses of a benzodiazepine agent (e.g., 1 to 2 mg midazolam IV) may be considered. The procedure should proceed deliberately without significant patient resistance. *The procedure is intended to be therapeutic, not punitive.*

The gastric tube should be passed gently to avoid damage to the nose or the posterior

pharynx. It may be passed through either the nose or the mouth, although tubes of 36 Fr or larger should be passed orally to avoid nasal mucosal or turbinate injury. Passage through the mouth is generally more comfortable for the patient, but the inserter is in danger of being bitten when this technique is used. In addition, orogastric tubes tend to be chewed and occluded by stuporous or combative patients. These problems may be minimized by the concomitant use of a bite block or an oral airway. Elliptically shaped endoscopy bite blocks are recommended.

Nasogastric intubation with larger diameter tubes can be carried out more easily if lubricating or local anesthetic jelly is used; shrinkage of the nasal mucosa with phenylephrine spray (Neo-Synephrine) is advised. Passage of the tube into the esophagus once the pharynx has been entered can be facilitated by putting the patient's chin on the chest. Cough, stridor, or cyanosis indicates that the tube has entered the trachea; the tube should be withdrawn immediately and passage reattempted. Once the tube is passed, its intragastric location should be confirmed by auscultation of the stomach during injection of air with a 50-mL syringe and aspiration of gastric contents. If this step is omitted, the physician may occasionally irrigate the esophagus with a tube that has doubled back on itself during passage or, worse, lavage the patient's lungs.

Before gastric irrigation, a large fraction of the gastric contents can be removed by careful gastric aspiration with repeated repositioning of the tube tip. Only after the stomach has been thoroughly "vacuumed" should gastric lavage be carried out. Indeed, some believe that aspiration of gastric contents may be the most effective part of the procedure. After gastric aspiration, the tube should be taped in place.

With the Y connector closed system (Fig. 45-4) , lavage is performed by clamping the drainage arm of the Y adapter and infusing aliquots of fluid into the stomach from a reservoir. The reservoir arm of the Y is then clamped, and the drainage arm is opened to permit gravity drainage of the stomach contents. The procedure is then repeated. Some resistance is produced by the Y connector and tubing. Suction can be applied intermittently to the drainage tubing to enhance stomach emptying. Rudolph has described a device that performs this task automatically. [55]

Generally lavage can be performed adequately with tap water. However, since severe dilutional hyponatremia has occurred in children lavaged with tap water, physiologic saline is generally recommended for children. [56] Ideally the solution should be prewarmed (45 °C) to minimize patient cooling. Warmed lavage fluid also increases the solubility of most substances, delays gastric emptying, and theoretically should increase the effectiveness of the procedure. Small aliquots of lavage solution should be repeatedly introduced into the stomach and removed. Empiric recommendations for the volume of each aliquot range from 150 to 300 mL in adults and 10 to 15 mL/kg, or 50 to 100 mL, in children.Larger amounts may increase the risk that the gastric contents will be washed into the duodenum, and much smaller amounts are not clinically practical because of the dead space in the tubing (approximately 50 mL in the 36 Fr hose) and the increase in time that is required. The amount of fluid that is returned should approximate the amount that is introduced.

The fluid should flow in freely and drain easily by gravity. If this does not occur, the tube

is usually malpositioned or kinked in the stomach and should be withdrawn or advanced a few centimeters. Manual agitation of the patient's stomach before removal of each aliquot may increase recovery and is recommended. [58] This is done by gently "kneading" the stomach with a hand placed on the abdominal wall. The optimal total volume of lavage solution is unknown. A common recommendation is a minimum volume of 1 to 2 L additional fluid *after* the return becomes grossly clear.

Rarely, special lavage solutions may be used, but the clinical efficacy of these lavage solutions is generally unproven. Soluble starch such as cornstarch or milk may be used after iodine ingestion. The starch converts iodine to less toxic iodide. Calcium salts, milk, or magnesium-containing antacids may be used after fluoride or oxalic acid ingestion. These salts form an insoluble precipitant with the ingested agent. However, in the vast majority of cases where lavage is indicated, the procedure should be rapidly performed with normal saline or tap water rather than delaying gastric lavage while awaiting specialized lavage solutions that have not been clinically proven. The use of a "neutralizing" solution in strong acid or base exposures remains controversial, but the heat of neutralization in vivo appears minimal. [63]

After gastric aspiration and lavage have been completed, a slurry of activated charcoal should be administered through the gastric tube (Fig. 45-5) . When no longer needed, the gastric tube should be pinched or clamped during its removal to avoid "dribbling" fluid into the airway. With the increasing use of repetitive doses of activated charcoal, the gastric tube is often left in place after the lavage procedure is completed. However, because this large tube is irritating and may predispose the patient to gagging, drooling, or aspiration, it should be removed. The alert patient should take subsequent doses orally (see Activated Charcoal below). The patient who remains obtunded may receive additional doses via a standard nasogastric tube, although the high viscosity of the charcoal makes this route challenging. If endotracheal intubation was required prior to lavage tube placement, the endotracheal tube should *not* be removed until the patient is clearly awake and able to control his or her airway, since emesis is common after the procedure.

## Complications

The complications associated with gastric lavage can be subdivided broadly into those associated with the placement of the tube and those resulting from the lavage fluid itself.

Because gastric intubation is a blind procedure that may be required in uncooperative or obtunded patients, some complications are inevitable, but acceptable where clinical benefit is anticipated. If the nasal route is selected, care must be exercised not to damage the delicate nasal turbinates. During tube advancement, injury to the pharynx, esophagus, or stomach rarely may occur. This risk is of most concern in cases in which substantial damage has already been done to these tissues as with caustic ingestions. Preexisting esophageal stricture or previous gastric bypass surgery also makes tube passage more hazardous. [69] Once the tube has been placed, it is important to make sure that it is in the stomach and not in the lungs, as inadvertent placement of the tube in the lungs can be fatal. [70]

Gastric lavage has also been associated with changes in cardiorespiratory function. The patient's pulse rate may rise and oxygen saturation may fall. Thompson and colleagues found that 41% of overdose patients had electrocardiographic changes, and 29% had a fall in oxygen tension to 60 torr or less during lavage. [71] Electrocardiographic changes consisted of atrial or ventricular ectopy in 36% of patients and transient ST segment elevation in 4.8% of patients. [71] Patients at greatest risk for these findings were the elderly, smokers, and those with underlying lung disease. These changes may be more marked in patients ingesting cyclic antidepressants. [72]

The lavage fluid itself is a potential but generally inconsequential source of problems. The large amount of fluid used during a lavage procedure has the potential to produce fluid and electrolyte disturbances in the patient; these imbalances have been reported with both hypertonic and hypotonic [56] lavage fluids. These problems appear to be encountered most commonly in children; adults seem to be more resistant to lavage-induced electrolyte disturbances. [56] Rudolph, however, was unable to document electrolyte changes in 60 patients, age 2 to 94 years, lavaged with tap water. [55] Hypothermia is another possible complication of gastric lavage, leading many pediatricians to warm the lavage fluid after the first liter.

The use of large aliquots of lavage fluid (>300 mL per wash in adults or 10 mL/kg in children) has the potential to force the gastric contents through the pylorus and into the upper small intestine, where more rapid absorption may take place.

Pulmonary aspiration of gastric contents or lavage fluid is the primary potential risk during lavage, although if small aliquots are used and the patient is positioned properly, this risk should be low. One group reported a 10% incidence of aspiration pneumonia in lavaged patients who underwent careful follow-up. [19] Most of the patients with aspiration pneumonia had been intubated prior to gastric lavage to protect the airway. It is generally believed that both emesis and gastric lavage increase the incidence of pulmonary radiographic changes in patients who have ingested petroleum distillates or turpentine. [75] One case of legionnaires' disease has been attributed to gastric lavage with contaminated tap water. [76]

Occasionally it may be difficult to remove a lavage tube once the decontamination procedure is finished. If the tube is not easily withdrawn, it is unwise to use excessive force, because significant gastric or esophageal injury may occur. Kinking or knotting of the tube can occur, but occasionally a tube may be stuck because of lower esophageal spasm. If fluoroscopy or a contrast study fails to demonstrate tube deformation as the cause of impaction, one can administer glucagon (1 to 2 mg IV) in an attempt to relieve spasm of the lower esophageal sphincter. [77] If a knot or kink is demonstrated, surgical removal is often required to avoid esophageal or gastric rupture due to forceful withdrawal of the tube.

## ACTIVATED CHARCOAL

## Background

Charcoal is a pyrolyzed, powdered carbon product. The term *activated* refers to oxidation, which greatly increases the surface area of the charcoal and converts molecules on the surface to chemical moieties that have the capacity to adsorb a wide variety of substances. Currently available products have surface areas ranging from 850 to 2000 m [2] /g. [20] Gram for gram, preparations with a high surface area (e.g., Charcoaid, Requa) are theoretically superior becaue they adsorb more toxin than similar amounts of lower-surface-area products. [77A] The use of activated charcoal in the emergency department has consistently increased since the 1980s; in 1995, 29.4% of poisoned patients treated at health care facilities received activated charcoal. [1]

Activated charcoal may be beneficial in 2 ways. First, it may bind drug or toxin present in the GI tract and make it unavailable for absorption by the body. Unlike ipecac and gastric lavage, activated charcoal may act on drug that has passed the pylorus by "catching up" to drug further along in the GI tract. Second, activated charcoal may increase clearance of drug already absorbed into systemic circulation. For some drugs such as digitoxin, this increase in serum clearance occurs when the drug is secreted in the bile and thus comes into contact with activated charcoal in the bowel prior to reabsorption, interrupting enterohepatic circulation. [78] For most drugs, the increase in clearance is thought to be a result of passive diffusion along a concentration gradient from the circulation into the gut, where it is bound to activated charcoal. Because of the mechanism of diffusion and the large surface area of the small bowel, this mechanism is known as *gut dialysis.*

## Indications

The advantages of activated charcoal are that it is easy to administer, it is effective, and significant complications are rare. Disadvantages include problems with palatability, constipation, nausea, and emesis. Emesis with resultant pulmonary aspiration of gastric contents is a potentially significant complication.

Activated charcoal is indicated if the clinician estimates that a clinically significant fraction of the ingested substance remains in the GI tract and further absorption may result in clinical deterioration. It is also indicated if there is a reasonable expectation that it will result in increased clearance of an already absorbed drug and thereby be of clinical benefit. Studies have shown the ability of activated charcoal to decrease drug absorption and/or increase clearance in volunteers.  There are limited data documenting significant clinical benefit from charcoal administration, but in view of the minimal risk, low cost, ease of administration, and potential benefit, activated charcoal should probably be given to most poisoned patients who present to health care facilities for evaluation and treatment.

Activated charcoal is *not* indicated when it is unlikely to adsorb the substance ingested. Metals such as iron and lithium are not well adsorbed to activated charcoal. For many metals, definitive adsorption data do not exist. However, some metallic salts such as mercuric chloride are well adsorbed by activated charcoal. If data regarding adsorption

are inconclusive or if there is a suspicion of coingestion, activated charcoal should be given, provided there are no contraindications.

Acids and bases are not well adsorbed by activated charcoal. In addition, charcoal may precipitate vomiting, as well as obscure the endoscopist's view, and therefore it should not be given in these cases. Hydrocarbons are not

well adsorbed by activated charcoal, and it should not be used in cases of a pure aliphatic petroleum distillate ingestion. Many hydrocarbons are potential systemic toxins (e.g., carbon tetrachloride, benzene) or are mixed with other potentially significant toxins such as pesticides. In these cases, data are lacking, and charcoal administration is probably appropriate. In some cases, charcoal affinity for a toxic compound may be relatively poor, as with cyanide. However, animal data demonstrate the utility of activated charcoal in cyanide ingestion, even though the in vitro affinity is relatively poor. [81]

The use of activated charcoal in the treatment of acetaminophen ingestion presents a special problem since the antidote, *N*-acetylcysteine, is administered orally in the United States. Although activated charcoal could potentially prevent acetaminophen from reaching toxic concentrations in the blood, there are concerns that charcoal may also adsorb significant amounts of the antidote as well. Pharmacokinetic studies evaluating the effect of activated charcoal on *N*-acetylcysteine absorption have produced conflicting results.  However, based on these data, some authors recommend increasing the *N*-acetylcysteine dose or considering lavaging charcoal from the stomach if *N*-acetylcysteine is to be given within 1 hour of activated charcoal administration. Other authors speculate that the standard *N*-acetylcysteine dose currently in use is much larger than needed to treat the vast majority of acetaminophen overdoses, and therefore no adjustment is required in this scenario. [39] Each of these opinions is based on the same data, and pending more conclusive studies, more definitive recommendations cannot be made. [87]

Multiple doses of activated charcoal (MDAC) may be indicated to increase systemic clearance of a drug that has already been absorbed or to maximize binding of a substance present in large amounts. MDAC may also be indicated when the physical form of the toxic substance might preclude maximal or prolonged contact with a single dose of activated charcoal (e.g., drug packets, plant or mushroom ingestion, extended-release preparations). Table 45-1 (Table Not Available) is a list of some drugs for which MDAC may be of benefit. For some compounds, such as theophylline, MDAC may significantly increase clearance, decrease drug half-life, and potentially avoid the need for other extracorporeal drug removal techniques such as hemodialysis and hemoperfusion.Despite volunteer and animal data showing increased drug clearance during MDAC therapy, no controlled clinical studies demonstrating a beneficial impact on clinical outcome from MDAC have been published.

MDAC is contraindicated if there is evidence of bowel obstruction or ileus. In addition, vomiting may expose the patient to an increased risk of pulmonary aspiration if the stomach is distended with activated charcoal. Another risk of MDAC therapy is the potential for exposure to multiple doses of cathartics. Repeated doses of activated charcoal with sorbitol have been associated with hypernatremia and dehydration.

Repeated doses of magnesium cathartics have been associated with hypermagnesemia, neuromuscular weakness, and coma. When MDAC therapy is being considered, the initial dose may contain a cathartic, but subsequent doses should be the aqueous formulation. Some clinicians administer activated charcoal with cathartic until the first charcoal stool, then switch to aqueous activated charcoal. Either approach is satisfactory.

## Technique

Activated charcoal may be given orally if the patient is awake and cooperative or by nasogastric tube if the patient is uncooperative or unconscious. It may also be given through the lavage tube after gastric lavage. In many formulations the contents settle with time, and vigorous shaking prior to administration is recommended. [95] Rinsing the container with a small amount of tap water and giving this slurry to the patient will allow administration of the full dose to the patient. Aqueous activated charcoal has no taste but does have a gritty texture that most patients find unpleasant. Formulations premixed with sorbitol have a sweet taste and smoother texture. Many attempts have been made to improve the taste and texture of charcoal. Mixing activated charcoal with melted chocolate, chocolate syrup, or ice cream has been shown to increase palatability in children. However, mixing with these additives decreases the adsorptive capacity of activated charcoal to some extent. [97]

Other methods of administering activated charcoal to reluctant patients include using a cup with a lid and a straw or simply clipping the tip of the spout on the lid off and placing a straw in the opening. Manufacturers continue to work with flavorings and texturizers to improve patient acceptance. Calvert and coworkers described 50 children presenting to an emergency department after ingestion who were given slurries of activated charcoal in paper cups. [98] Children were asked in a "firm but kindly manner" to drink the charcoal and were told that it would make them feel better and not sick and that it would not taste bad. Most (86%) readily drank the slurry, and the majority of these drank the entire dose.

If the patient refuses to drink activated charcoal, another option is administration of the dose by nasogastric tube after confirmation of tube placement. Remember: Any gastric decontamination procedure loses efficacy with time, so if the decision is made to give activated charcoal, the patient should be given a brief (5- to 10-minute) period of time to drink the dose. If the dose is not consumed by that time, the clinician should consider giving the dose by nasogastric tube.

## Dose and Concurrent Cathartic Use

The older literature suggests that a charcoal-to-toxin ratio of at least 10:1 is desirable. However, this ratio has not been systematically evaluated for many compounds, and the amount of toxin ingested is often unknown. However, the optimal dose of charcoal is the maximum amount that can be safely given based on estimated stomach volume. Most

authors recommend 50 to 100 g in adults and 1 g/kg in children under 5 years. Palatnick suggests that dosing charcoal in children on a "per-kilogram" basis may lead to

inadequate dosing and recommends a total dose of 25 to 50 g in children under 5 years. [101] Since activated charcoal is usually packaged in containers containing 25, 30, or 50 g, doses in multiples of these units are most practical.

Coadministration of a cathartic with activated charcoal remains a controversial but common practice. [102] Cathartics are given with the intention of preventing activated charcoal-induced constipation and decreasing GI transit time of the activated charcoal-drug complex. Theoretically, this will minimize the chance of continued drug absorption in the gut, as well as the possibility of desorption of drug from activated charcoal. However, the majority of data suggest minimal or nondetectable clinical benefits on drug absorption from cathartic use. There is little evidence that a single dose of aqueous activated charcoal is significantly constipating; however, cathartics are often given for this potential problem. The most commonly available cathartics are sorbitol, sodium sulfate, magnesium citrate, and magnesium sulfate. Sorbitol is most effective in decreasing GI transit time [40] but is also associated with nausea, GI cramping, and abdominal pain. Because cathartics are of unproven benefit and have possible adverse effects, some clinicians avoid their use.

The optimal dose of sorbitol remains to be determined. Dosing studies in healthy volunteers indicate that an initial dose of 60 g of sorbitol with charcoal would best produce reliable catharsis while minimizing adverse effects. [105] Many charcoal formulations come premixed with sorbitol, but there is considerable variation in sorbitol content. Liqui-Char with Sorbitol contains 50 g of activated charcoal in 54 g of sorbitol. Actidose with Sorbitol contains 50 g of activated charcoal in 96 g of sorbitol. Activated charcoal USP with sorbitol contains 25 g of activated charcoal in 27 g of sorbitol. Charcoaid contains 30 g of activated charcoal in 110 g of sorbitol. [20] Thus, there is an almost three-fold variation in sorbitol content between the various formulations. Attention should be paid to the brand of charcoal and the sorbitol content to avoid excessive sorbitol administration.

If aqueous activated charcoal is used and a cathartic is desired as well, a single 50- to 100-mL dose of sorbitol 35% to 70% solution in adults or 2 mL/kg in older (i.e., > 5 years) children can be used. Commonly used doses of the saline cathartics are as follows:

  Magnesium citrate as a 6% solution: 300 mL in adults and 4 mL/kg in children

  Magnesium sulfate as a 10% solution: 15 to 20 g in adults and 250 mg/kg in children

  Sodium sulfate as a 10% solution: 15 to 20 g in adults and 250 mg/kg in children [106]

Multiple doses of magnesium-containing cathartics have been associated with severe hypermagnesemia. Multiple doses of sorbitol have been associated with volume depletion. [92] Children are particularly susceptible to the adverse affects of cathartics, and therefore cathartics should be used with caution, or totally avoided, in this group.

**Multiple Doses of Activated Charcoal**

MDAC may be useful in select cases. It may be used to prevent continued absorption if there is a large amount of drug present, if drug is dispersed throughout the GI tract, or if the drug is in the form of extended-release or enteric-coated preparations. MDAC maximizes the possibility that the majority of drug remains in contact with charcoal during transit through the gut. MDAC may also increase clearance of drug that has already been absorbed by interrupting either enterohepatic circulation or the continuous diffusion and reabsorption of drug from the circulation to the gut (so-called *entero-entero circulation*). Table 45-1 (Table Not Available) is a list of drugs for which MDAC is thought to be of benefit. For most of these drugs, data are sparse, and clinical benefit remains to be proven. For some drugs such as theophylline and phenobarbital, clearance is well documented to be increased by MDAC. Despite increases in drug clearance, clinical benefits of MDAC have not been demonstrated. For example, Pond and colleagues described 10 patients comatose from phenobarbital overdose who were randomized to receive either single activated charcoal or MDAC therapy. Although the serum half-life of phenobarbital was significantly shorter in MDAC patients, there was no difference between groups with regard to duration of intubation or time in the hospital.

When using MDAC therapy, the first dose is 50 to 100 g of charcoal, usually with cathartic. Subsequent dosing is not standardized, and doses range from 12.5 to 50 g without cathartic every 2 to 6 hours. Charcoal therapy should continue until there is clinical improvement and plasma drug levels have fallen to acceptable values.

Emesis with activated charcoal therapy may be a problem, particularly when using MDAC therapy for poisonings by drugs that cause nausea and vomiting (e.g., theophylline). Some clinicians have reported fewer problems with vomiting if a continuous nasogastric infusion of activated charcoal is used. [109] Standard antiemetic therapy such as prochlorperazine or promethazine IV may be tried. [110] Some authors have reported success in controlling severe drug-induced vomiting with ondansetron. If there is evidence of ileus or obstruction, charcoal should be stopped and the nasogastric tube placed on low intermittent suction.

**Complications**

Considering the frequency of its use, the number of complications from activated charcoal is relatively small. The most significant complication of activated charcoal use is pulmonary aspiration. Since the overdose population as a whole is at risk for sedation and loss of airway protective reflexes, the instillation of 8 to 16 oz of liquid activated charcoal into the stomach may put these patients at risk for aspiration. Charcoal is inert, but mixture of charcoal with acidic gastric contents may cause aspiration pneumonitis. [113]

The charcoal slurry is viscous, and its aspiration has been associated with tracheobronchial obstruction. [114] Activated charcoal has also been directly instilled into the lung inadvertently through a nasogastric tube. [115] Patients who have been traumatically lavaged and have sustained esophageal or gastric perforation have been

noted to have charcoal hemothorax and charcoal peritoneum, respectively.

Other residual effects after activated charcoal aspiration include bronchiolitis obliterans and charcoal empyema.  One immunocompromised patient who received MDAC therapy vomited, aspirated the vomitus, and developed pneumonia with *Aspergillus niger*, *Paecilomyces variotii,* and

*Penicillium* spp; interestingly, *Aspergillus* and *Paecilomyces* were grown from activated charcoal in the hospital pharmacy. [120]

Activated charcoal is also reported to cause constipation. [121] The frequency of this problem in the overdose population receiving a single dose of activated charcoal is unknown. However, GI obstruction and perforation have been reported in patients receiving MDAC therapy, particularly in conjunction with ingestion of drugs with anticholinergic properties. [122] As charcoal passes through the gut and water is resorbed, charcoal may harden to form "briquettes." An activated charcoal stercolith with bowel perforation and a rectal ulcer have been reported.

Finally, corneal abrasions have been noted when charcoal has inadvertently come in contact with the eye in comatose or combative patients.

## WHOLE-BOWEL IRRIGATION

### Background

WBI is the newest method of GI decontamination. It involves the oral administration of polyethylene glycol (PEG)-balanced electrolyte lavage solutions (i.e., GoLYTELY or Colyte) in a sufficient amount and at a sufficient rate to physically wash ingested substances through the GI tract. These lavage solutions are traditionally used to prepare the bowel for surgical, radiologic, or endoscopic procedures and have been specifically formulated to minimize fluid or electrolyte shifts across the gut wall. [126] Other lavage solutions, such as normal saline and lactated Ringer's solution, are not recommended. WBI may be performed in children and has been reported after iron ingestion in an 11-month-old. [27] WBI has also been used without adverse effects after iron ingestion during pregnancy. [127]

### Indications and Contraindications

Tenenbein has suggested that WBI be considered for 4 indications: ingestion of a large amount of a toxic substance, late presentation after ingestion of a toxin, ingestion of delayed-release preparations, and overdoses of iron and other substances not adsorbed by activated charcoal. [128] Current widely accepted indications for WBI include ingestion of sustained-release products and iron and lithium ingestion, as well as in body packers and stuffers. The value of WBI for large ingestions or delayed presentations is unknown.

Contraindications to WBI are few and include GI ileus, obstruction, or perforation.

Significant GI bleeding has also been suggested as a contraindication. Adverse effects are usually limited to nausea, vomiting, bloating, abdominal discomfort, and anal itching. However, 1 study found that most volunteers preferred WBI to activated charcoal with sorbitol because of the sorbitol-induced cramps and diarrhea. [32] Proposed therapies for ingestion of several drugs, including extended-release theophylline, aspirin, and cocaine packets, include both WBI and MDAC therapy, since in vitro data suggest that PEG-balanced electrolyte lavage solution can cause desorption of these drugs from activated charcoal,  but the clinical significance of this finding is unknown.

A special consideration after overdose is the possibility that semisolid masses of drug (pharmacobezoars) can form in the stomach and remain there for long periods. Table 45-2 lists drugs that have been associated with bezoar or concretion formation. Drug bezoars or concretions should be suspected when plasma drug concentrations continue to rise or if clinical deterioration occurs, despite customary GI decontamination procedures, especially in cases involving ingestion of medications known to cause drug bezoars. The best approach to the patient with a suspected pharmacobezoar remains to be determined. MDAC therapy, gastric lavage with gastric massage, and WBI are all reasonable initial managements.  In cases where the initial management strategy is failing or the diagnosis remains in doubt, endoscopy can be performed. The advantage of endoscopy is that the stomach contents can be directly visualized and an attempt can be made to break up the drug mass with the endoscope. In rare cases involving iron, gastrotomy has been used to remove drug bezoars. [135]

**Technique**

Once the decision has been made to use WBI, the solution is prepared by mixing the PEG electrolyte powder with water to a volume of 4 L. It is then administered to the patient at a rate of 1 to 2 L/hour to adults and adolescents. Children may receive WBI solution at a rate of up to 40 mL/kg/hour. [136]

Cooperative patients with intact airway protective reflexes may drink this quantity, although taste and volume may be limiting factors. Patients who are unable or unwilling to drink at this rate may receive the solution through a small-bore nasogastric tube after tube placement is confirmed. Unconscious patients with protected airways may receive WBI. With more rapid rates of infusion, vomiting may become a problem. Emesis during WBI usually responds to a temporary decrease in rate of infusion. In these cases, after an arbitrary time of 15 to 30 minutes without emesis, the rate should be slowly increased to a goal of 2 L/hour in adults. Metoclopramide has been suggested as an antiemetic in this circumstance because of its additional prokinetic effects on the GI tract; however, controlled studies have failed to show a benefit in decreasing transit time of a marker compared to WBI alone. [137]

The temperature of the fluid should probably be between ambient and body temperature. One study using chilled PEG electrolyte solution noted that subjects were shivering and uncomfortable. [138] Pediatric patients might be at risk for hypothermia in these conditions. On the other hand, there is the potential for increased drug solubility and thus increased absorption in a warmed solvent. Thus, a compromise would be to

use a solution at a temperature tolerated by the patient but not above body temperature.

| TABLE 45-2 -- Examples of Drugs Associated with Pharmacobezoar Formation | |
| --- | --- |
| Barbiturates | Extended-release lithium |
| Bromides | Extended-release verapamil |
| Ethchlorvynol | Enteric-coated aspirin |
| Carbamazepine | Iron |
| Glutethimide | Meprobamate |
| Extended-release theophylline | |

Once WBI is begun, the awake patient may be seated on a commode if feasible. Comatose patients may have a rectal tube inserted as stool becomes liquid to accommodate the large volume of rectal effluent.

The end point of WBI is controversial. When the ingested substance is radiopaque, as with iron, radiographs may be obtained to follow progress and document decontamination. Most ingested substances are not radiopaque, however, and end points are more arbitrary. Suggested end points include the appearance of clear rectal effluent or total time of WBI, usually 4 to 6 hours. However, case reports have documented passage of tablets, drug packets, or plant parts after clear rectal effluent. Hence, existing data do not provide a clear end point for WBI. Clear rectal effluent appears to be a minimum end point, and one may argue for an additional arbitrary amount after clear rectal effluent. [137] If the clinical or laboratory evidence points to continued drug absorption, WBI should be continued until the patient has stabilized.

Patients who ingest packets of drugs, usually cocaine or heroin, especially wrapped for smuggling are called *body packers*. In contrast, *body stuffers* may hastily ingest drugs that may be poorly wrapped in an attempt to avoid arrest. Both types of patients should

be placed on a cardiac monitor, and an IV line should be established. Fifty grams of activated charcoal should be given. If the patient is asymptomatic from the ingestion, WBI should be started (Fig. 45-6 *A* and *B*). Body packers usually know the exact number of packets ingested, and these may be counted in the commode. Up to 20 L of PEG electrolyte solution have been used in the decontamination of body packers. [30] After WBI is finished, efficacy of evacuation may be confirmed by a contrast radiologic study or a plain radiograph if the packets are radiopaque. Because of the potentially fatal amount of drug contained in each packet, symptomatic patients should be considered for emergent surgical removal of packets. Body stuffers usually ingest smaller quantities of drug, but it may be unwrapped or poorly wrapped, and there is a greater likelihood of absorption. Management of these patients should consist of activated charcoal and WBI. If the ingested substance can realistically be detected by contrast radiologic study (crack vials), these studies should be performed. Since the ingested material is often of a smaller quantity and dispersed through the GI tract, surgical intervention is unlikely to be indicated, although the amount, form, and type of drug ingested should be considered in each case.

### Complications

There have been few reported complications from WBI therapy. The procedure may cause bloating, nausea, vomiting and abdominal discomfort, and anal itching. [39] [138] Vomiting may respond to a decrease in the rate of administration or to antiemetics. [128] As with all other methods of GI decontamination, attention should be directed to the airway and the potential for aspiration. Administration of a large amount of chilled or room temperature WBI fluid to pediatric patients could potentially cause hypothermia, and therefore warmed fluid should be considered in these patients. Mild asymptomatic hypoglycemia (61 mg/dL) occurred after 5 hours of WBI in a 11/2-year-old child. [136] It may be prudent to check the serum glucose level in children or other individuals at risk for hypoglycemia if prolonged WBI is required.

## DERMAL DECONTAMINATION

### Indications and Contraindications

Decontamination of the skin is indicated after a cutaneous exposure (skin, eyes, mucosa, open wounds) to potentially hazardous materials. A dermally contaminated patient is managed like any other patient, except health care personnel must also protect themselves and others from the danger of secondary contamination. Dermal decontamination of most hazardous materials has not been systematically evaluated. In addition, the hazardous material may not be identified or confirmed prior to patient arrival.

Decontamination is contraindicated if hospital personnel cannot adequately protect themselves from exposure and health risk. Every emergency department should have a disaster plan with contingencies for hazardous materials incidents. A variety of forms of chemical protective clothing should be available. Life-threatening issues should be promptly addressed before decontamination takes place. If the patient arrives at the emergency department after treatment and decontamination by out-of-hospital

personnel, further decontamination may not be needed. In these cases, the patient should be evaluated by the triage officer on arrival to the health care facility for assessment of clinical stability and adequacy of decontamination. Some substances, such as radioactive materials, pose a significant risk of contaminating the health care facility and hospital personnel. In these cases, provisions should be made for containment of the decontamination area.

**Technique**

Cutaneous exposures to hazardous materials pose several problems that must be managed simultaneously by the emergency physician. Continued exposure to the hazardous material must be prevented, and dermal and systemic manifestations of the specific toxic exposure must be anticipated and treated. In addition, the physician must also prevent contamination of health care workers and of the emergency department and the hospital. Guidelines for managing hazardous materials incidents are available from the Emergency Response and Consultation Branch (E57), Division of Health Assessment and Consultation, Agency for Toxic Substances and Disease Registry, 1600 Clifton Road, N.E., Atlanta, GA 30333. [4]

Emergency departments should have preexisting hazardous materials incident protocols that designate the decontamination area and the triage and decontamination team. The decontamination area must meet several qualifications. First, it should be secured to prevent spread to other areas of the hospital. Second, the ventilation system should be separate from the rest of the hospital or it should be shut off to prevent airborne spread of contaminants. Third, provisions must be made to collect the rinsate from contaminated patients to prevent contamination of the facility and water supply. Some hospitals may have designated decontamination rooms. In most facilities, the best place to begin initial treatment and evaluation is outside, weather permitting. Portable decontamination facilities are available, but their cost may be prohibitive for many institutions. A practical alternative is to have a warm shower nozzle, soap, and a wading pool available outside the entrance to the emergency department. A tent or screen can provide privacy. Stable patients may be able to decontaminate themselves by disrobing and discarding clothing and jewelry (including watches) and using soap and water as directed by hospital personnel.

Health care workers can protect themselves in most circumstances with hospital gowns, shoe covers, masks, eye protection, and gloves. Intermediate levels of chemical protective clothing can be purchased and stored for use as needed. If it is anticipated that the facility will receive heavily contaminated patients, specialized personal protective equipment may be needed. This level of protective equipment carries some expense and requires training prior to use.

Care should be taken to prevent unnecessary contamination outside the decontamination area. The floor should be covered with plastic or paper that is taped in place. Doorknobs, light switches, and cabinet handles should be covered. As patients or health care personnel leave the decontamination area, protective clothing and contaminated articles should be left behind for appropriate disposal.

Actual skin decontamination should be started as soon as possible. Decontamination with soap and water should not be delayed while awaiting specialized decontamination fluids. Starting from the head and working down, the patient should be washed with warm tap water, with special attention paid to skin folds, which may retain the contaminant despite thorough rinsing. A mild soap, such as dish soap, should be used. Since mucosal surfaces and open wounds may potentially absorb toxic materials faster than intact skin, these areas should be cleaned first. Once wounds are decontaminated, they should be covered with a waterproof occlusive dressing to avoid recontamination. Contaminated nares or ears should be gently irrigated. Anything that abrades the skin or causes vasodilation, such as stiff scrub brushes, hot water, or vigorous scrubbing, should be avoided, as this may potentially increase toxin absorption. A commonly recommended minimum time for decontamination is 15 minutes, although this appears to have no scientific basis. Exposure to caustics such as strong acids or alkalis may require irrigation over extended periods of time. All runoff fluid should be collected for disposal. Decontamination of the eye is discussed in Chapter 67 .

## CONCLUSION

Gastric emptying techniques such as gastric lavage and ipecac-induced emesis are being used less frequently and for a more narrowly defined patient population. Concurrently, activated charcoal as the sole means of gastric decontamination is increasing in popularity. The evaluation and treatment of asymptomatic or minimally symptomatic patients who have not ingested significantly toxic substances continue to evolve, and it has been suggested that these patients will do well regardless of therapy. The major problem currently facing the clinician is the choice of GI decontamination in the significantly poisoned patient. Studies evaluating this subpopulation are few and usually involve small numbers of patients. Thus, the choice of decontamination method for these patients must be individualized using clinical acumen and common sense. Although the risks associated with properly conducted GI decontamination appear slight, they are

measurable, and no patient should undergo any of the available procedures unless it is anticipated that decontamination will provide clinical benefit.

# Chapter 46 - Peritoneal Procedures

**John A. Marx M.D.**

Paracentesis and diagnostic peritoneal lavage constitute the 2 primary intraperitoneal procedures. They are fundamentally similar in purpose and design. However, the former is generally reserved for medical concerns and the latter for traumatic pathology.

## DIAGNOSTIC PERITONEAL LAVAGE

Root and colleagues introduced diagnostic peritoneal lavage in 1964. [1] It has withstood the passage of more than 3 decades and remains a mainstay in the management of penetrating torso trauma. Following a blunt mechanism of injury, its greatest utility is as a triage tool in the hemodynamically unstable multiply injured patient. Otherwise, it serves with computed tomography (CT) and ultrasound (US) in the diagnostic armamentarium of blunt trauma.

While commonly referred to as *diagnostic peritoneal lavage* (DPL), this procedure comprises 2 distinct components: peritoneal aspiration and peritoneal lavage. In the lavage portion, normal saline is introduced by catheter into the peritoneal cavity, recovered by gravity, and analyzed. Peritoneal aspiration, in which an attempt is made to retrieve free intraperitoneal blood, precedes lavage. A finding of intraperitoneal blood presages intraperitoneal organ injury and precludes the need for subsequent lavage.

Peritoneal lavage can be used as a therapeutic tool in hypothermia and as a means of removing toxins. [2] It has also been used as a diagnostic instrument for suspected intra-abdominal infection and nontraumatic sources of hemorrhage. However, its primary use is as a determinant for the need for laparotomy following trauma, and this chapter focuses on that use.

### Indications

#### Blunt Trauma

Prior to the advent of CT and US, DPL was the sole diagnostic option to physical examination for predicting the need for operative intervention. It was integral both to the reduction of unnecessary laparotomies and to the discovery of unsuspected and life-threatening intra-abdominal hemorrhage in patients with significant closed head injury.

In a number of respected centers in the United States, DPL continues to be the focal diagnostic instrument. It serves 2 primary functions. First, it can rapidly determine or exclude the presence of intraperitoneal hemorrhage (Table 46-1) . Thus, the patient with a critical closed head injury, the unstable motor vehicle crash victim with multiple potential sources of blood loss, or the patient with pelvic fracture and retroperitoneal hemorrhage can be appropriately routed to life-saving laparotomy.  Furthermore, given

its exquisite sensitivity, a negative peritoneal aspiration allows the clinician to proceed to alternative management steps and the patient to forego unnecessary laparotomy. Second, DPL can

| TABLE 46-1 -- Indications for DPL Following Blunt Mechanism | | |
|---|---|---|
| **Purpose** | **Circumstance** | **Alternate or Complementary Diagnostic** |
| Rapidly determine presence of IPH | Hemodynamically unstable multiple blunt trauma | US |
| Determine presence of organ injury | Suspected or known blunt trauma with unreliable examination: | CT |
| |   Head injury with altered mental status | |
| |   Alcohol intoxication | |
| |   Drug intoxication | |
| |   Spinal cord injury | |
| Determine presence of IPH or injury | Multiple trauma patients who require general anesthesia for other injuries | CT, US |

IPH, intraperitoneal hemorrhage; US, ultrasound; CT, computed tomography.

be employed in less exigent circumstances as a means of predicting solid or hollow visceral injury requiring laparotomy.  In this venue, its sensitivity to the presence of hemorrhage may prompt unnecessary laparotomy in a small percentage of patients with self-limited lacerations of the liver or spleen.  CT scan specifically evaluates all intraperitoneal structures as well as the retroperitoneum, a region inaccessible to DPL. Because resolution and the speed with which it can be undertaken have vastly improved, CT has become an invaluable adjunct in the management of blunt trauma. [15]
 It is most useful in the identification of injury to solid organs with accompanying intraperitoneal hemorrhage and greatly assists nonoperative management of those injuries. However, its ability to discern hollow viscus and pancreatic pathology remains inconsistent.  It is when serial clinical evaluations cannot be performed that gut perforation leads to preventable mortality. Therefore, certain authorities recommend the performance of DPL as a complement to CT for this express scenario.

Experience with US in North America is meager in comparison with that in Western Europe (notably Germany) and Asia (notably Japan). In the past, US in the United States had been used exclusively for the detection and serial examination of traumatic pancreatic pseudocysts. There are 2 paradigms that have brought US to the forefront. First, this modality has been considered for use as a triage instrument, similar to DPL, for the detection of intraperitoneal hemorrhage on the basis of identifying which pouches and gutters are fluid filled. Clinical success in this role has been mixed with reported sensitivities for intraperitoneal hemorrhage of 65 to 95%. Additionally, to be useful in this role, a competent technician, interpreter, and equipment must be present in real-time. It has been demonstrated that emergency physicians and surgeons can be trained in this technique to a level of competence sufficient for this need. [19]

Second, US can determine injury to solid viscera such as the liver, spleen, kidneys, and pancreas. This requires considerably greater expertise, and in most centers US has not supplanted CT for this purpose.

DPL is a readily available procedure that can be conducted rapidly in the safe confines of the emergency department. The ability to undertake CT or US in a similar manner requires careful consideration of clinical circumstances, equipment location, and the capabilities of available personnel.

**Penetrating Trauma**

The advent of DPL was seminal in the promotion of selective management for penetrating abdominal injury. Here its role is more dominant than that of either CT or US due to the far greater likelihood of occult injury to hollow viscera and the diaphragm following a penetrating mechanism.

Instruments and missiles may penetrate the abdominal cavity via the anterior abdominal wall, flank, back, or low chest. The intraperitoneal space is vulnerable if penetration occurs as high as the fourth intercostal space anteriorly and the sixth or seventh laterally and posteriorly, as the diaphragm may rise to these levels in the expiratory phase. [23] Indeed, coincident thoracic penetration has occurred in up to 46% of abdominal injuries. The likelihood of retroperitoneal injury increases when the entry site is over the flank or back, but the prospect of intraperitoneal pathology remains considerable with cited incidences of 21 to 44% for the flank and 7 to 14% for the back (Table 46-2) (Table Not Available) .

**Stab wounds.**

Because only one-fourth to one-third of patients who sustain stab wounds to the anterior abdomen require laparotomy, diagnostic algorithms are used to decrease the rate of unnecessary operation. An optimal approach would not sacrifice sensitivity for morbid intraperitoneal injury. A pathway using a combination of clinical mandates, local wound exploration, and DPL is well established (Fig. 46-1) (Figure Not Available) . [30] These clinical mandates are reasonably accurate predictors of significant intraperitoneal injury (Table 46-3) (Table Not Available) . Thus, the presence of one or more mandates suggests the need for urgent laparotomy and precludes the undertaking of other diagnostic studies.

DPL fills 3 roles in the evaluation of patients with abdominal stab wounds (Table 46-4) : (1) rapid determination of the presence of hemoperitoneum, (2) discovery of intraperitoneal injury requiring operation in stable patients, and (3) the establishment of diaphragmatic violation. As is the case in blunt trauma patients, DPL can be invaluable as a rapid triage tool when the source of hemodynamic instability is not known. Pericardial tamponade, intrathoracic hemorrhage, and intraperitoneal hemorrhage may be contributory to hemodynamic instability or wholly causal. Again, as for blunt trauma evaluation, US is the only diagnostic modality for intraperitoneal hemorrhage that is competitive for this role. In the determination of injury following stab wounds, DPL carries 90% accuracy.Serial examinations, CT, and laparoscopy are alternative modalities in specific circumstances and centers. Diaphragmatic rents created by stab wounds are generally small; thus, at the outset, they do not create apparent clinical or radiologic abnormalities.However, morbidity due to delayed herniation of bowel is common and substantive. [40] DPL is currently the most sensitive means of discerning this injury in the immediate post-trauma phase. [31] Physical examination and CT are notoriously insensitive. Laparoscopy has demonstrated promise in experienced hands.

**Gunshot wounds.**

Multiple organ injury is the rule following gunshot wounds, and mortality is significantly greater when compared with that for stab wounds. [41] The diagnostic approach is more conservative for gunshot wounds because the likelihood of intraperitoneal injury requiring operative intervention exceeds 95% when the projectile has entered the intraperitoneal cavity (Fig. 46-2) (Figure Not Available) . If clinical mandates are met (see Table 46-3) (Table Not Available) or if peritoneal violation has occurred, most

centers proceed to laparotomy. [30] DPL is reserved for 2 circumstances: (1) the wound tract is neither obviously superficial nor intraperitoneal, and (2) penetration is to the low chest, where diaphragmatic injury is more likely, yet the possibility of intraperitoneal injury exists.

## Contraindications

Diagnostic peritoneal lavage can be undertaken in virtually any patient irrespective of age, pregnant state, or comorbid illness. Adjustment of the technique and site of performance allows relative contraindications to be overcome. Relative contraindications include prior abdominal surgery or infections, obesity, coagulopathy, and second- or third-trimester pregnancy. The sole absolute contraindication is when clinical mandates for urgent laparotomy already exist.

## Technique

### Preliminary Steps

The stomach and bladder should be decompressed to prevent inadvertent injury. This is most relevant when the semi-open

technique is used and a trocar is passed through the peritoneum. DPL should be performed according to compliance with standards for body fluid precautions (see Chapter 75) . Prior to making the skin incisions described below, the site of placement should be prepped with standard skin antiseptics (e.g., povidone-iodine) and appropriately draped. The operator should observe sterile precautions throughout the procedure. Prophylactic antibiotics are not indicated for routine DPL because local and systemic infections are rare. [32] [45]

Local anesthesia (1% lidocaine *with* epinephrine) should be infiltrated liberally into the area for incision and dissection (Fig. 46-3) . It is best to delay the incision for >30 seconds following local anesthetic infiltration to permit local vasospasm, which minimizes wound bleeding during the procedure. Standard equipment for an open peritoneal lavage catheter placement is shown in Figure 46-4 .

**Catheter Placement**

DPL is performed via 2 basic methods: open and closed. The 2 open techniques are *semi-open* and *fully open,* and they typically require an assistant. DPL is clearly within the diagnostic armamentarium of the emergency physician and surgeon. It may be undertaken by either or both in keeping with clinical policies established at the particular trauma center.

**Open technique.**

In the semi-open method, sharp then blunt dissection using a No. 11 scalpel and Army-Navy retractors, respectively, proceeds to the rectus fascia (Fig. 46-5 *A* and *B*). The skin incision should be 4 to 6 cm in length. When the selected site is infraumbilical in the midline, the operator should reach the linea alba; its crossing bands of crural fibers may be apparent. [46] A small 2- to 3-mm opening is then made in the linea alba, preferably with a No. 15 scalpel blade ( Fig. 46-5C ). (The operator will notice a tough, gritty sensation when cutting the linea alba with the scalpel.) Towel clips can be placed through this opening to grasp each side of the rectus fascia (Fig. 46-5 *D*). These 2 towel clips are then lifted to allow safe percutaneous advancement of the catheter via trocar in a 45 to 60° caudad orientation through the peritoneum and into the peritoneal cavity (Fig. 46-5 *E* and *F*).

To decrease the likelihood of penetrating underlying viscera, some operators advocate holding the fingers low on the catheter-trocar instrument such that on entering the abdominal peritoneum, the fingers will prevent deep penetration. Excessive pressure during trocar penetration is a common error. Steady "one-finger pressure" applied to the handle is sufficient to "pop" through the fascia and peritoneum. After controlled peritoneal penetration of 0.5 to 1.0 cm in the midline, the trocar is retracted 1.0 to 2.0 cm within the catheter, and the catheter is carefully advanced toward the pelvis. Some operators prefer to advance the catheter toward the right or left side of the pelvis. Use of a slight twisting motion during advancement may minimize visceral or omental injury.

The *fully open* technique extends the semi-open technique by one step. The opening in the linea alba is lengthened, and the peritoneum is opened to allow direct visualization during catheter placement into the peritoneal cavity.

The 2 open techniques can be accomplished with a single technician, but an additional pair of hands can be helpful for retraction and handling of instruments. The fully open method is the more technically demanding and time consuming. It is reserved for clinical circumstances in which closed or even semi-open technique is not deemed safe or has been attempted and failed. These include pelvic fracture, pregnancy, prior abdominal surgery or infections, and obesity.

**Closed technique.**

With closed techniques, the catheter is introduced into the peritoneal space in a blind percutaneous fashion. [49] Formerly, this was accomplished via trocar. This has been abandoned in favor of the much safer but equally simple Seldinger (guide wire) method, in which a small-gauge guide needle is inserted into the peritoneal cavity in the infraumbilical midline (Fig. 46-6 *A*). A flexible wire is then passed through the needle (Fig. 46-6 *B*), and the needle is removed, allowing the over-the-wire placement of a soft catheter into the peritoneal cavity. A stab with a No. 11 scalpel at the entry site of the wire allows easier passage of the catheter through the abdominal wall (Fig. 46-6 *C* and *D*). Rotating the catheter while pushing it over the guide wire is recommended to facilitate entry into the peritoneal cavity. The catheter is placed as above, into the right or left pelvic gutter.

The wire is then withdrawn, and aspiration conducted, followed by lavage when necessary. The guide wire should always be controlled to avert intra-abdominal migration of the wire. Proponents of the guide wire technique promote its ease and rapidity. Those who prefer the semi-open method argue that the time to peritoneal aspiration, the more critical interval, is minimally different, and that this method may have fewer complications and thus be more accurate than the guide wire technique. Note that time to aspiration for semi-open or closed approaches should entail no more than 2 to 5 minutes.

**Site**

The optimum location for DPL is at the infraumbilical ring, at the inferior border of the umbilicus (Table 46-5) . Here, between the rectus abdominis muscles, there is adherence of the peritoneum and relative lack of vascularity and preperitoneal fat. [46] Closed DPL should always be conducted here. In the event of second- or third-trimester pregnancy, a suprauterine approach is used. If there is midline scarring, a fully open technique at the lateral border of the rectus abdominis in the left lower quadrant may be necessary. The left is preferred to avoid later confusion about whether an appendectomy has been performed. It is interesting to note that Moore and colleagues found no increase in complications or misclassified lavages when the closed technique was used in a small series of patients with prior abdominal surgery. [59] In the presence of a pelvic fracture, a fully open supraumbilical approach is recommended. This greatly decreases the likelihood of passing the catheter through retroperitoneal hematoma that has dissected from the fracture anteriorly and across the abdominal wall. [60] In penetrating trauma, DPL should not be conducted through the stab or missile entry site. Such an approach may contaminate the intraperitoneal cavity and potentially exacerbate abdominal wall bleeding, which could in turn lead to a false-positive result.

**Aspiration and Lavage**

Once the catheter has been placed successfully into the peritoneal cavity and the right-angle adapter, extension tubing, and a non-Luer-Lok syringe have been attached, aspiration is attempted (Fig. 46-7) . The recovery of 10 mL of blood is considered positive, and the procedure terminated. In penetrating trauma, the acquisition of lesser amounts may be meaningful because of the tendency for the diaphragm and bowel to hemorrhage minimally when injured. However, there are no established rules in this regard.

If little to no blood is aspirated, the peritoneal cavity is lavaged with either normal saline or lactated Ringer's solution (Fig. 46-8) . A blood pressure cuff or blood infusion pump can be applied to the plastic intravenous (IV) bag to speed the influx (i.e., decrease lavage time), but is generally not needed. Large-bore infusion tubing (e.g., urologic irrigation tubing sets; Abbott No. 6544 cystoscopy/irrigation set) also shortens fluid influx time. The normal amount is 1 L in adults or 15 mL/kg in children. When possible, the patient is rolled or shifted from side to side after infusion to increase mixing. The IV bag or bottle is placed on the floor (or below abdominal level), and the fluid is allowed to return by gravity.

The fluid may not continue to return because of several factors. Some IV tubing contains a one-way valve; if tubing with a valve was used in error, valveless tubing must be reinserted into the IV bag. Another reason for poor return is inadequate suction. This problem can be corrected by insertion of a needle into the second opening at the bottom of the IV bag or into the head of the IV bottle for aspiration of 10 mL of air. Alternatively, the catheter may be adherent to peritoneum. If so, relieving some of the pressure in the IV bottle or gently wiggling and twisting the catheter as well as applying abdominal pressure may aid flow return.

It is generally accepted that the return of 700 mL in the adult is adequate for

interpretation of findings. However, as little as 10 to 20% of the infusate may give a representative sample for both gross and microscopic determinations. Only 10 mL of fluid from the return need be sent to the laboratory for cell count analysis; another 10 mL can be sent for enzyme analysis (see interpretation below). Some operators prefer to leave the dialysis catheter in place until the returned fluid is analyzed. The physician may wish to re-lavage when the initial results are borderline or an occult bowel perforation is suspected.

* The SW or GSW site should be avoided.

## Complications

### Local and Systemic

Local wound complications, including infection, hematoma, and dehiscence, have occurred in only 0.3% of patients in 2 large series. Systemic infection has been described rarely.

### Intraperitoneal

Iatrogenic intraperitoneal injury can be inflicted by the trocar or wire and, rarely, the catheter. Virtually any structure in the peritoneal cavity has been breached, including the small and large bowel, the bladder, and major vessels. Typically, if the needle is the culprit, and even if the trocar is responsible, injury to these structures is minimal and self-limiting, and observation of the patient is sufficient.

### Technical Failure

Inability to recover peritoneal aspirate or lavage fluid can result in a false-negative interpretation. This can occur in several circumstances. It follows unwitting placement of the catheter into the preperitoneal space, which is less likely to occur with either open technique. Compartmentalization of fluid by adhesions or obstructing omentum can impede egress of fluid. Finally, large diaphragmatic tears typical of blunt pathophysiology allow flow of lavage fluid from the intraperitoneal to the thoracic cavity.

False-positive findings can occur in 2 ways. First, iatrogenic misadventure can be responsible. Second, in penetrating trauma, particularly stab wounds, bleeding from the abdominal wall injury site into the peritoneal cavity can lead to positive findings when no injury to intraperitoneal structures has occurred. [32]

## Interpretation

### Gross Blood

The recovery of 10 mL blood via aspiration is considered a positive finding. Lesser-volume aspirates are generally discarded and are not factored into lavage analysis. Grossly bloody aspirates are typically indicative of solid visceral or vascular injury, with a positive predictive value >90%. Aspiration of blood is responsible for approximately 80% of true-positive DPL findings in blunt trauma and for 50% of those following stab wounds.

A positive aspiration in the blunt trauma patient who is hemodynamically stable or has been resuscitated to apparent stability need not mandate urgent operation. Unnecessary laparotomy will occur if there has been minimal and self-limited damage to the liver, spleen, bowel serosa, or mesentery. [15] In this situation, CT and clinical indicators may be used in concert with the DPL findings.

**Red Blood Cell (RBC) Count**

The recommended RBC threshold varies according to mechanism and, in the case of stab wounds, the external site of injury (Table 46-6) . The optimum criterion will deliver excellent sensitivity, a high positive-predictive value, and, therefore, a minimum incidence of unnecessary laparotomy. Negative laparotomy incurs a prolongation of hospitalization and increases the cost of care, in addition to creating the potential for procedural complications.  RBC counts >10$_5$ /mm$_3$ (i.e., >10$_5$ /muL) are generally considered positive with a blunt mechanism or following stab wounds to the anterior abdomen, flank, or back. Counts of 20,000 to 100,000/mm$_3$ should be considered indeterminate.  For stab wounds to the low chest, where the diaphragm is at increased risk of injury, the red blood cell criterion should be lowered to 5000/mm$_3$ to maximize sensitivity for isolated injury to this structure. With gunshot wounds to the abdomen or low chest, the same criterion is applied. This is intended to increase the sensitivity of the test, because intraperitoneal entry by a missile carries a likelihood of intraperitoneal injury of 95%.  An uncomplicated DPL should not create more than several hundred to several thousand RBCs in the peritoneal lavage fluid.

The incidence of false-positive RBC interpretation in the setting of pelvic fracture is considerable. However, aspiration of free blood in the critical pelvic fracture patient predicts active intraperitoneal hemorrhage in >80% of cases. [69] A positive RBC count should generally prompt corroboration or refutation of intraperitoneal injury by CT. In this fashion, needed pelvic angiography and embolization will not be delayed unnecessarily.

**White Blood Cell (WBC) Count**

An inflammatory peritoneal response occurs to a multitude of stimuli, including stool, blood, and enzymes. [70] The WBC count in lavage effluent was formerly touted to predict small bowel injury but has since been proven unreliable. [71] It is insensitive in the immediate postinjury period, as 3 to 5 hours are necessary before the test becomes positive (Table 46-7) (Table Not Available) . Moreover, a positive finding is likely to be falsely so. Therefore, the WBC level in and of itself should not determine the need for laparotomy.

**Enzymes**

Alkaline phosphatase is contained in intramural small bowel as well as in hepatobiliary secretions released into the proximal intestine. Amylase is contained in the latter only. Perforation of small bowel allows access of these 2 markers into the peritoneal cavity where they can be recovered by peritoneal lavage.  While levels of the 2 markers usually rise in

| | Positive (RBCs/mm$^3$) | Indeterminate (RBCs/$^3$) |
|---|---|---|

tandem, lavage amylase has been shown to be a more accurate marker than lavage alkaline phosphatase (see Table 46-7) (Table Not Available) . In contradistinction to the WBC count, these tests will be positive in the immediate postinjury period. However, they may not be economical if used on a mandatory rather than a selective basis. Neither is helpful in discerning the presence of pancreatic pathology.

**Miscellaneous**

Routine bile staining, Gram stain, and microscopy to identify vegetable fibers are rarely productive and are of untested accuracy.

**Summary**

DPL remains an invaluable diagnostic instrument in trauma. It should be used in common-sense fashion. Laboratory parameters are guidelines and should not be embraced to the exclusion of pertinent clinical features. CT, US, or both, can serve in lieu of or in addition to DPL in its various roles. [78] Optimal strategies depend largely on the capability of an institution's resources and personnel in each clinical scenario.

# PARACENTESIS

Ascites connotes an abnormal accumulation of fluid within the peritoneal cavity. The word derives from the Greek *askos,* which means bag or sack. It is a symptom with important diagnostic, therapeutic, and prognostic implications.

Therapeutic abdominal paracentesis is one of the oldest medical procedures, dating to approximately 20 B.C. Paracentesis was first described in modern medical literature by Saloman at the beginning of this century, and it became a valued decompressive therapy. [79] With the advent of diuretics in the early 1950s, paracentesis fell out of favor as a treatment option. Controlled clinical trials in the late 1980s and early 1990s restored its reputation by demonstrating the safety and efficacy of large-volume paracentesis. Because this mode is invasive and consumes physician hours, it is generally reserved for the treatment of patients with chronic ascites who have tense ascites or whose condition is refractory to diuretic therapy. [83] [85] However, paracentesis remains an important diagnostic agent for patients with new-onset ascites or to determine the presence of worrisome conditions, notably infection, in those with preexistent ascites. [86]

## Clinical Features

### Determination of Ascites

Small amounts of ascites may be asymptomatic. Larger collections typically cause a sense of abdominal fullness, anorexia, early satiety, and perhaps nausea and abdominal pain. Considerable accumulations create symptoms of respiratory distress by virtue of restricting lung capacity. [87]

The most predictive history and physical findings for *excluding* the diagnosis of ascites are the absence of ankle swelling and increased abdominal girth and the inability to demonstrate bulging flanks, flank dullness, or shifting dullness.  Positive predictors for

the diagnosis are a positive fluid wave, shifting dullness, or peripheral edema.

Patients who lack obvious clinical markers may benefit from the performance of ultrasonography, which can discern the presence of as little as 100 mL fluid. [92] Additionally, it is a useful adjunct to determine the location of fluid that may be compartmentalized by preexistent infection or surgical adhesions.

**Differential Diagnosis**

The etiologies of ascites can be categorized in several ways. On a structural basis, these are divided into diseases of the peritoneum and diseases not involving the peritoneum. The former group includes infections, neoplasms, collagen vascular diseases, and idiopathic causes. The latter includes cirrhosis, congestive heart failure, nephrotic syndrome, protein-losing enteropathy, malnutrition, myxedema, pancreatic disease, ovarian disease, chylous effusion, Budd-Chiari syndrome, and hepatic venous occlusive disease. Pathophysiologic categories are found in Table 46-8 (Table Not Available) . In this country, parenchymal liver pathology is overwhelmingly the most likely cause and within this group, alcoholic liver disease is responsible for approximately 80% of cases (Table 46-9) (Table Not Available) . Finally, ascites can be classified on the basis of a serum-ascites albumin gradient, that is the difference between albumin values obtained simultaneously from serum and ascites samples (Table 46-10) .

Based on a series of 1500 paracenteses performed in a predominantly inpatient hepatolgy/general internal medicine setting (B.A. Runyon, unpublished observations).

## Indications and Contraindications

Therapeutic paracentesis may be undertaken in the emergency setting to relieve the cardiorespiratory and gastrointestinal manifestations of tense ascites. Diagnostic paracentesis is indicated in any patient whose ascites is of new onset or to disclose the presence of infection in patients with known or suspected ascites, particularly in the context of alcohol-related cirrhotic liver disease. Diagnostic paracentesis is also useful in the management of the AIDS patient, in whom the etiology of ascites will be non-AIDS related in three-quarters of cases. [101]

There are few relative contraindications to abdominal paracentesis. Certain systemic and anatomic risks should be considered.

---

| Biliary ascites |
| Nephrotic syndrome |
| Serositis in connective tissue diseases |

**Systemic**

Given the predominance of alcohol-related cirrhotic liver disease as the cause for ascites, as many as two-thirds to three-quarters of patients subjected to paracentesis will have a coagulopathy. A conservative approach is to administer platelets to patients with levels <50,000/3 (i.e., <50 × 10$_9$ /L), or to give fresh frozen plasma to those with a prothrombin time exceeding 20 seconds (1.5 times the therapeutic level). [102] However, there are no controlled data to support these contentions. [103] Rather, the only prospective study to evaluate the complications of paracentesis determined that transfusion-requiring abdominal hematomas occurred in <1% of cases despite the fact that 71% of patients had an abnormal prothrombin time. [104] Because transfusion-requiring hematoma is so unlikely, even in this population, prophylactic administration of fresh frozen plasma or platelets imposes considerable cost, in addition to the risk of post-transfusion hepatitis, with little net gain.

**Anatomic**

Structural impediments to the safe introduction of a paracentesis needle can include the bladder, bowel, and pregnant uterus. The bladder is normally tucked into the recess of the pelvis. However, neuropathically distended bladders caused by pharmacologic

agents or medical conditions should preferably be emptied by voiding or by catheterization to avoid puncture. Intestines typically float in ascitic fluid and will move safely away from a slowly advancing paracentesis needle. [102] Even if penetrated by an 18- to 22-ga needle, leakage of intestinal contents will not occur unless the intraluminal pressure is 5- to 10-fold greater than normal conditions. [105] Therefore, US guidance may be indicated in cases of suspected adhesions or bowel obstruction. In second- and third-term pregnancy, an open supraumbilical or US-assisted approach is preferred.

The abdomen should be carefully inspected for evidence of abdominal hematoma, engorged veins, or superficial infection, and these sites should be strictly avoided.

## Technique

### Preliminary Actions

The operator should comply with guidelines for body fluid precautions (see Chapter 75) . The patient should be carefully draped and the skin thoroughly prepped in sterile fashion to prevent the iatrogenic introduction of bacteria into the abdominal wall tract or peritoneal cavity.

### Site of Entry

The preferred site is approximately 2 cm below the umbilicus in the midline (Fig. 46-9) . The fasciae of the rectus abdominis join to form the fibrous, thin, avascular linea alba. [102] Large collateral veins may occasionally be present and should be avoided, as should suspected areas of skin infection. If the patient has midline scarring, the preferred alternate site is in either lower quadrant, approximately 4 to 5 cm cephalad and medial to the anterior superior iliac spine (see Fig. 46-9) . The importance of remaining lateral to the rectus sheath is to avoid the inferior epigastric artery. Patients with a large quantity of ascites can readily undergo the procedure in the supine position with the head of the bed slightly elevated. Those with lesser amounts of fluid may profit from a lateral decubitus position with introduction of the needle into the midline or dependent lower quadrant (Fig. 46-10) . Some clinicians prefer to use the lateral decubitus position routinely because the bowel tends to float upward and away from the path of the needle. Rarely, patients may need to be placed in a facedown, hands-on-knees position. [104] In the patient with multiple abdominal scars or suspicion of compartmentalized abdominal fluid for any reason, US guidance is prudent.

### Procedure

Following sterile preparation of the skin, local anesthesia is administered at the paracentesis site. A standard 3.8 cm (1.5 in.) metal needle is sufficient in most cases. [93] An 8.9 cm (3.5 in.) spinal needle may be required in obese patients. Plastic sheath cannulas tend to kink and run the risk of being sheared off into the peritoneal cavity. A steel needle can be left in the abdomen during a therapeutic tap for intervals of an hour or more without injury. A smaller-gauge needle (20- to 22-ga), is appropriate for diagnostic taps, as these lessen the likelihood of postprocedural ascitic fluid leak

through the wound site. However, large-volume therapeutic paracenteses benefit from 18-ga needles, as this permits expeditious outflow. [107]

The needle can be inserted directly perpendicular at the preferred site. Certain authors prefer the "Z-tract" method wherein the skin is pulled approximately 2 cm caudad in relation to the deep abdominal wall by the non-needle-bearing hand while the paracentesis needle is being slowly inserted (Fig. 46-11) . [108] The skin is not released until the needle has penetrated the peritoneum and fluid flows. When the needle is removed following the procedure, the skin will slide to its original position and help seal the tract. In any case, slow insertion of the needle in 5-mm increments is preferred. This allows the operator to detect undesired entry of a vessel and helps prevent unnecessary puncture of small bowel. Continuous suction should be avoided as it may attract bowel or omentum to the end of the paracentesis needle with resultant occlusion. Once fluid is flowing, the needle should be stabilized to ensure a steady flow. If flow ceases, the needle should be gently rotated and advanced inward using 1- to 2-mm increments.

## Complications

Complications can be divided into systemic, local, and intraperitoneal categories.

### Systemic

An oft-cited but poorly documented concern is hemodynamic compromise caused by overzealous removal of ascitic fluid. Because upward of 6 L has been reported to be removed in <15 minutes without complication, certain authorities decry this issue as folklore. [109] [110] Others believe that rapid total paracentesis is accompanied by marked cardiovascular and humoral changes, some of which are explained by mechanical factors directly or indirectly related to relief of abdominal pressure. [111] Other changes, including systemic vasodilation and humoral deactivation, are of a nonmechanical nature. Because fluid and electrolyte shifts may accompany the removal of large amounts of fluid, certain authors recommend routine administration of colloid. [84] While albumin was the de facto choice, colloid dextran 70 is currently favored due to cost and infection concerns. However, it is not clear that routine usage is justified. [114]

### Local

Local complications include persistent ascitic fluid leak at the wound site, abdominal wall hematoma, and localized infection. Persistent fluid leak can be corrected with a single suture at the site of puncture. An abdominal wall hematoma requiring transfusion is very uncommon, but careful observation in such cases is necessary.

### Intraperitoneal

Intraperitoneal complications include perforation of vessels and viscera. [115] In experienced hands, these are uncommon, and in most circumstances they are self-sealing and clinically inconsequential. However, generalized peritonitis and

abdominal

wall abscess have been reported after paracentesis in rare cases. The most common cause of postparacentesis intraperitoneal hemorrhage is bleeding due to a coagulopathy, rather than large-vessel injury per se.

## Interpretation

Ascitic fluid should undergo gross inspection. Routine laboratory testing includes a differential cell count, albumin assay, and cultures (Table 46-11) .

### Inspection

Ascitic fluid is typically translucent and yellow. A dark greenish-brown hue may reflect biliary perforation. Cloudy fluid generally indicates particulate matter, including neutrophils: fluid with counts >5,000/muL (i.e., >5,000/mm3 ) are cloudy and those >50,000/muL are purulent. An opaque, milky appearance may indicate elevated triglyceride levels. [116] A blood-tinged appearance requires at least 10,000/muL RBCs. This may reflect an iatrogenic complication, malignancy, hemorrhagic pancreatitis, or tuberculous peritonitis, although the last diagnosis creates hemorrhagic-appearing fluid in <5% of cases. [104]

### Cell Count

Several milliliters of ascitic fluid are sufficient to obtain a differential cell count. Cirrhotic ascites should generally contain <250 WBCs/muL (Table 46-12) (Table Not Available) . However, because cells may exit through the peritoneal cavity more slowly than fluid does, the WBC count can rise in the ascitic fluid during the procedure. [117] Thus, an upper limit for uncomplicated cirrhotic ascites is reported as 500 cells/muL. [119] [120] Lymphocytes should predominate, and clinical signs or symptoms of peritoneal infection should be absent. [121] In cases in which spontaneous bacterial peritonitis is a clinical consideration, the WBC criterion is 250 WBCs/muL with >50% polymorphonuclear leukocytes.

### Albumin

A serum-ascites albumin gradient can be obtained by simultaneous measurement of ascitic and serum-ascites albumin gradient. A serum-ascites albumin gradient >1.1 g/dL indicates portal hypertension with >95% accuracy (see Table 46-10) . [123] [124]

### Culture and Gram Stain

The most valuable method for determining the presence of infection is culture. The sensitivity of this test is markedly increased by the direct inoculation of blood culture

bottles at the bedside in contrast to simply delivering the ascitic fluid to the laboratory. [108] [125] Approximately 10 bacteria/muL of fluid is required for a positive Gram stain. Thus, the Gram stain is notoriously insensitive in spontaneous bacterial peritonitis in which the medium concentration of bacteria is 10-3 organisms/muL of fluid. [125] The Gram stain can only be expected to be helpful in cases of free gut perforation.

**Miscellaneous**

Optional tests include measurement of total protein, glucose, lactate dehydrogenase, and amylase. These will be beneficial in selected circumstances and need not be obtained on a routine basis. Immunosuppressed patients, including those with AIDS, should undergo microbiologic testing for opportunistic infections, including tuberculosis. [101] Cytologic analysis is recommended in patients with suspicious constitutional symptoms and signs. [126] Triglyceride and bilirubin studies are indicated if the gross appearance of the fluid is suggestive of increased levels. [127]

## Summary

Abdominal paracentesis is a straightforward, commonly used procedure in the emergency department, with few relative contraindications. The imperative of paracentesis is to disclose the presence of infection in the peritoneal cavity. It is also useful in the diagnosis of other conditions and contributes to the relief of manifestations of tense ascites.

# Chapter 47 - Abdominal Hernia Reduction

**Lee E. Payne, Jonathan M. Glauser**

The emergency physician plays an important role in evaluating and treating the patient with abdominal hernia. One must distinguish abdominal hernia from other potential causes of groin or abdominal swelling. If a hernia is present, the physician must determine if incarceration or strangulation has occurred. An incarcerated hernia that cannot be reduced is a surgical emergency. In many instances the skilled emergency physician will be able to reduce an incarcerated inguinal hernia, allowing for a less urgent surgical repair. Special concern is warranted in neonates, and infants who may present with irritability as their only symptom of incarcerated hernia. Finally, those patients with a newly diagnosed or an easily reducible hernia must be given timely and appropriate referral for future surgical repair.

## EPIDEMIOLOGY

Abdominal hernia is a common problem in the general population, and multiple varieties exist, including inguinal hernias (direct and indirect), femoral hernias, incisional hernias, ventral hernias, lateral abdominal wall hernias, internal hernias, and post-traumatic hernias. Although the exact prevalence of hernias is unknown, Zimmerman and Anson estimate that approximately 5% of the total adult male population is afflicted. [1] Hernias of all types are 5 times more common in males.

Herniorrhaphy is one of the most common procedures in the United States, with 500,000 performed annually. Groin hernias include indirect and direct inguinal hernias, as well as femoral hernias. The most common hernia for both sexes is the indirect inguinal hernia, accounting for 90% of cases in children and young adults. [2] The male-to-female ratio for inguinal hernia is 9:1 secondary to the anatomic differences in embryologic development. The causes of abdominal wall hernia change with increasing age. Congenital inguinal hernias are common in children and young adults, whereas acquired hernias rise in frequency in the elderly. [3] [4] Inguinal hernias still make up nearly 50 to 60% of hernias in older males, but there is an increase in acquired hernias in older males as well. [3] Acquired hernias are associated with age-related decreased tissue elasticity and conditions that

increase intra-abdominal pressure, including chronic constipation, chronic cough (e.g., with chronic obstructive pulmonary disease), bladder outlet obstruction, and kyphoscoliosis. [2] Direct hernias are unusual in women, whereas femoral hernias occur more commonly in women than in men. Inguinal and femoral hernias are much more likely to incarcerate due to the anatomic structures involved when compared with other categories of abdominal hernia.

In the past 20 years, neonatal intensive care units have improved the long-term survival of premature infants. The occurrence rate of hernias in the premature infant is near 30%.  The rate of incarceration, strangulation, and gonadal infarction for premature infants is twice the rate for the general pediatric population. [7] This fact should heighten

the emergency physician's awareness to the potential presence of incarcerated inguinal hernia in children who present to the emergency department (ED) with a history of premature birth and irritability.

# CLASSIFICATION OF ABDOMINAL HERNIAS

Detailed discussions of the historical development of the treatment of hernias, including recognition, preoperative management, and operative repair, can be found elsewhere.

A hernia can be defined as a potential weakness in the abdominal wall, and this defect permits protrusion of peritoneum and abdominal contents. If a contained viscus can be returned from the defect in the abdominal wall to the abdominal cavity, the hernia is defined as *reducible*. When the contents of the hernia sac cannot be reduced, the hernia is considered *incarcerated*. For the purposes of this chapter, a hernia is defined as incarcerated when the patient, family, or physician on initial evaluation (before medication and other techniques described later), is unable to reduce the hernia sac. When there is ischemia of the contents of the hernia sac, the herniated tissue is said to be *strangulated*. A *sliding* hernia occurs when a portion of the wall of the hernia sac is composed of an organ (e.g., the cecum or ovary). If only a portion of the antimesenteric wall of the bowel is incarcerated or strangulated, the hernia is known as a *Richter* hernia.

Groin hernias can be categorized as femoral or inguinal hernias; inguinal hernias can be either direct or indirect (Figs. 47-1 (Figure Not Available) and 47-2) (Figure Not Available) .

## Direct Inguinal Hernia

A direct inguinal hernia represents a weakening of the abdominal wall (transversalis fascia) that permits protrusion of peritoneal contents through the Hesselbach triangle. The triangle is bounded laterally by the inferior epigastric artery, inferiorly by the inguinal ligament, and medially by the lateral margin of the rectus muscle sheath. The key to diagnosis of a direct inguinal hernia is the observation that the hernia does not traverse the inguinal canal. In the rare situation in which the hernia sac enters the scrotum, the hernia sac must pass through the external ring separate from and behind the spermatic cord. In contrast with other groin hernias, the direct hernia represents a diffuse weakness of the abdominal wall. The absence of a narrow neck with the direct hernia sac makes incarceration unusual. When incarceration does occur, it is usually associated with rare entrapment of the hernia sac at the external ring.

## Indirect Inguinal Hernia

An indirect inguinal hernia represents the passage of the hernia sac (peritoneum and contents) through the internal inguinal ring. During fetal development of the male gonads, the processus vaginalis is formed, allowing the descent of the testes into the scrotum. Failure to completely close this opening after birth allows a hernia or a hydrocele to develop. The peritoneal contents may progress a variable distance down

the inguinal canal, even into the scrotum. The internal ring is defined medially by the inferior epigastric artery. Indirect hernias frequently are associated with scrotal swelling, and incarceration can develop as a result of swelling at either the internal or the external ring. The scrotal anatomy defining inguinal hernia and hydrocele is presented in Figure 47-3 (Figure Not Available) .

### Femoral Hernia

The weakness in the transversalis fascia that causes a femoral hernia is similar to the weakness that causes a direct inguinal hernia, but it is inferiorly rather than anteriorly directed. The peritoneum and contents herniate beneath the inguinal ligament in a small potential space medial to the femoral vein. The resulting hernia sac has a small neck, although once the sac enters the subcutaneous (SQ) tissue of the thigh, it may enlarge considerably and even double back on top of the external oblique aponeurosis, thus masquerading as an inguinal hernia. The narrow neck makes incarceration common with this type of hernia and preoperative reduction unlikely.

### Ventral Hernia

Ventral hernias are frequently caused by postincisional weakness of the anterior abdominal wall. Umbilical hernias represent another common ventral hernia and rarely pose a problem. An *epigastric* hernia may penetrate through a defect in the linea alba above the umbilicus. The *Spigelian* hernia is a rare defect located at the inferior one third of the rectus abdominis where the arcuate line meets the lateral border of the rectus muscle.

### Other Hernias

Lateral abdominal wall hernias are uncommon but may develop following renal surgery. A rare site of abdominal weakness and herniation is the *Petit triangle.* This triangle is bounded anteriorly by the external oblique muscle, inferiorly by the iliac crest, and posteriorly by the latissimus dorsi muscle. Injury to the abdominal wall can cause traumatic hernia, with attendant risk of associated trauma and bowel incarceration. [12] Other hernias that are not discussed further include perineal hernias through the levator ani or through the sciatic foramina, obturator hernias into the medial thigh through the obturator foramen, diaphragmatic hernias, and internal hernias (e.g., bowel herniation through the foramen of Winslow).

## DIFFERENTIAL DIAGNOSIS OF GROIN MASSES

While inguinal hernia is a common diagnosis in a patient presenting with a groin mass, other diagnoses, some potentially dangerous, may masquerade as a groin mass. An enlarged inguinal lymph node, a lipoma, a hydrocele of the spermatic cord, a saphenous vein varix, a psoas abscess, or an incarcerated ovary can all present as a mass in the groin. [13] More serious diagnoses may present incidentally within the hernia sac itself; these include blood from a ruptured spleen, [14] appendicitis or appendiceal abscess, [15] tuberculous peritonitis, [16] or torsion of an undescended testis. The emergency

physician must be cognizant that a diagnosis distant from the groin swelling may be the cause and search for other findings prior to attributing the mass to inguinal hernia.

Inguinal lymphadenopathy is common and can have many causes. Lymph nodes are usually multiple; are found distal to the groin crease; and, in general, are equally mobile in all directions, unlike a femoral hernia, which tends to have decreased mobility in the transverse direction. Finding an inflammatory lesion on the lower extremity distal to the mass lends credence to the diagnosis of lymphadenopathy. Ulceration of the urethral meatus can rarely cause adenopathy about the inguinal ligament, so the genitalia must also be examined. In most circumstances, however, inguinal nodes are unusual in the anterior abdominal wall immediately superficial to the inguinal ligament.

Lipomas in the SQ fat can usually be separated from the underlying fascia and are not associated with a hernia sac neck extending under the inguinal ligament. A saphenous vein varix may reduce in size with pressure or protrude when the patient coughs or stands upright, similar to an inguinal hernia, but it usually has a softer consistency than a hernia. Furthermore, as the varix enlarges and displaces SQ fat, it appears bluish beneath the skin.

Differentiating between incarcerated inguinal hernia and acute hydrocele of the spermatic cord may be difficult in an infant presenting with a tender, hard bulge at the external inguinal ring. It may be helpful to palpate the internal inguinal ring with an examining finger in the rectum while another finger examines the spermatic cord. Bowel should be felt entering and exiting the internal ring, if the mass is an incarcerated hernia. Scrotal hydroceles are usually benign and can generally be dealt with electively. Acute hydroceles within the scrotum rarely become hard or painful, unlike those within the inguinal canal. Rapid expansion of the hydrocele within the rigid walls of the inguinal canal can lead to testicular infarction from pressure on the spermatic cord at the internal or external inguinal ring. This condition can mimic torsion of the testis if ischemia has produced tenderness in the testicle. The testicle is at risk, even though the hydrocele may transilluminate. In the case of testicular torsion, the cord may be shortened on the affected side.

Although Doppler ultrasound and radionuclide scanning examinations may be helpful (see Chapter 59) , surgical exploration is often necessary to differentiate these conditions. In general, an acute hydrocele of the cord should be treated aggressively, as an incarcerated hernia or a testicular torsion, unless the emergency physician can definitively conclude otherwise.

Psoas abscesses are uncommon and are only rarely confused with a femoral hernia. The margins of the abscess are softer and more ill defined than those of a hernia. Furthermore, psoas abscesses lie in a position lateral to the femoral artery, whereas hernias are medial.

## PATIENT PRESENTATION

**Children**

Inguinal hernias are prone to incarceration. The overall rate of incarceration in children is 10 to 12%.  The rate of incarceration in premature infants and term children in the first few months of life is near 30%.  Often the hernia has gone unnoticed by the child's parents and has developed since birth. In 1 series of 908 patients receiving herniorrhaphies, incarceration was the first sign of the presence of an inguinal hernia in 65% of the 85 patients who presented with incarceration. [21] In a small infant, irritability may be the main parental concern, and the physician must be certain to examine the groin to evaluate the child for a potential hernia. Any child presenting with irritability must be completely undressed and a thorough examination performed to avoid missing the diagnosis. Very large hernias containing several loops of bowel almost never incarcerate and even more rarely strangulate due to the large size of the hernia neck.

An incarcerated hernia presents as a tender mass in the inguinal canal. The skin over the mass may be edematous, erythematous, or blue. [19] Duration of incarceration in pediatric patients has not been shown to predict the presence of strangulated bowel, but prolonged incarceration should increase one's level of concern for strangulation. Findings suggestive of compromised blood supply to the bowel include abdominal distention, bilious vomiting, tachycardia, constipation and obstipation, blue discoloration of the skin, and radiographic evidence of an obstructive pattern on abdominal plain films. [19] Leukocytosis and fever are unreliable predictors of strangulation. [22] Obvious signs of strangulation contraindicate attempted reduction and warrant immediate operative intervention.

Inguinal hernias are rare in females but, when present, are more likely to incarcerate than similar hernias in males. [19] In addition, the rate of emergency operation for incarceration is higher for female infants. [19] In female infants, a sliding hernia may occur, with the ovary and/or the fallopian tube herniating into the inguinal canal. The herniated ovary is usually palpable as a mobile nodule measuring 1 × 2 cm. Although unusual, infarction of the herniated ovary may occur as a result of torsion or compression of the pedicle. [19] This condition may mimic inflamed lymphadenopathy, although the location of the mass would be atypical for adenopathy. Some authors recommend investigation for testicular feminization in female patients presenting with inguinal hernia. An undescended testicle may be present in the inguinal canal, even though the patient is a phenotypic female. Patients with testicular feminization have a 50% incidence of inguinal hernia, while females with inguinal hernia have an approximate incidence of testicular feminization of 1%. [23]

The importance of attempting early reduction for incarcerated inguinal hernias lies in the observed complication rates. The complication rate for elective herniorrhaphy is reported to be 1.7 to 4.5%, while the rate following emergency surgery is 22 to 33%. [6] [17] In children, the success rate for reduction of incarcerated hernia is 70 to 90%.Some have recommended elective surgical repair within 24 to 48 hours after successful reduction, as the rate of recurrent incarceration is high. [19]

**Adults**

Although inguinal hernias still predominate, other hernias become more common in the adult patient and thus have slightly different presentations and complications. Controversy exists regarding attempted reduction of incarcerated hernias in the adult patient. Although the potential complications include reducing necrotic bowel, reduction en masse, or rupture of the bowel wall, most authors agree that a gentle attempted reduction is warranted, as it appears unlikely that strangulated bowel will be able to be reduced.

Unusual conditions (e.g., a Richter hernia, which may mimic a groin abscess because of the absence of bowel obstruction symptoms, [25] and traumatic abdominal wall hernias, which may mimic a hematoma following injury) may be confusing. As in the pediatric patient, intra-abdominal hemorrhage and a variety of other more unusual diseases and pathologic conditions can present within an inguinal hernia and warrant the emergency physician's attention. [14]

Whereas incarceration occurs in approximately 6 to 10% of indirect inguinal hernias in the adult, [28] 14 to 56% of femoral hernias incarcerate. The femoral hernia may be difficult to diagnose and may present first with incarceration. The clinical presentation includes ill-defined groin pain; centralized abdominal pain; and pain that is increased by coughing, sneezing, or lifting. [32] Signs of intestinal obstruction may also be present. [33] A femoral hernia presents a special problem, in that the small neck present in the femoral canal and the usual generous overlying SQ tissue make a complete reduction virtually impossible. Therefore, patients with femoral hernias are best referred on an emergency basis to a surgical consultant for evaluation and consideration of operative reduction and simultaneous hernia repair. Attempts at reduction are best deferred until such consultation has been obtained.

Incisional hernias infrequently incarcerate or strangulate. Reduction of these hernias is generally routine or spontaneous, although sedation may be required. Incarceration in these cases usually results from adhesions of the contents of the sac either to each other or to the sac itself. Occasionally feces within the loops of bowel in the hernia prevent reduction.

If *strangulation* occurs, most commonly the clinical picture is one of intestinal obstruction. In fact, 20 to 25% of the adult cases of bowel obstruction may be caused by incarcerated hernia. [34] The patient experiences severe pain, vomiting, distention, and obstipation. The duration of incarceration is important in the adult, as patients who have had the incarceration for >24 hours have a higher likelihood of strangulation. [18] The patient may be febrile and may have a

leukocytosis, although these findings may be absent. [18] No impulse may be transmitted to the hernia sac on coughing, and the overlying skin often becomes inflamed and edematous. These features may be less marked if only omentum is contained within the sac. Ultimately gangrene of the bowel or the omentum occurs if strangulation is not

relieved and the involved gut perforates into the sac.

## INDICATIONS AND CONTRAINDICATIONS

Whenever possible, incarcerated hernias should be reduced. Reduction minimizes inflammation and tissue edema, thus preventing strangulation. Some clinicians state that it is impossible to reduce a strangulated hernia because of the extensive inflammation, edema, and tenderness. Fortunately, most patients present early after incarceration, and the question of whether strangulation has occurred is rarely an issue. In most cases the patient presents within hours of the incarceration without fever, leukocytosis, or other evidence of generalized toxicity. In that circumstance, reduction of the hernia is indicated. Depending on one's location and practice situation, it may be prudent and appropriate to involve a surgical consultant prior to an attempt at reduction. Given that the condition will require the consultant's services if the reduction is unsuccessful, when possible, it is advised that the treatment plan be discussed with the consultant early in the course of evaluation.

Peritonitis and other clinical evidence of strangulation (e.g., fever, marked leukocytosis, toxic appearance) are contraindications to an attempt at a nonsurgical reduction of an incarcerated hernia. In addition, immediate surgical repair of a traumatic hernia is recommended both for prevention of delayed morbidity from herniation and for evaluation of underlying organ injury. [26] Similarly, an ovary or an undescended testis in an incarcerated inguinal hernia represents an indication for surgical reduction.

## PROCEDURE

When clinically indicated, gentle reduction of incarcerated hernias should be attempted. Adequate sedation must be given to allay anxiety and to minimize discomfort (see also Chapter 35) . In recent years more emphasis has been placed on sedation of patients, particularly children, for painful procedures. The relief of pain and prevention of suffering is one of the emergency physician's most important responsibilities. The decision to use sedation, which agents to use, and the most appropriate route of administration, is complicated and involves many factors, including the patient's age, underlying disease states, intended duration of sedation, availability of reversal agents, and potential complications. The physician and nursing staff must be familiar with sedation techniques and recovery and capable of performing airway management procedures should a complication arise. Each ED should have available staff and standardized procedures for adequate monitoring, evaluation, and postsedation recovery. [35]

There is no lower age limit for sedation in children, but children below the age of 3 months, and particularly premature infants, require skilled observation due to the potential for apnea. [36] [37] Some authors recommend against the use of morphine in infants and premature neonates, due to exaggerated effects on the respiratory centers. [7] If patients are carefully selected, the staff are well prepared, and standardized procedures are in place, most pediatric patients can safely undergo ED sedation for incarcerated hernia reduction.

The sedation needed for hernia reduction should be sufficient to inhibit straining or struggling. If relaxation alone does not produce reduction, a period of protection from pain is needed as the hernia is manually reduced. There are several agents and routes of administration that can provide the needed sedation for this procedure. In most situations, IV administration of medication is preferable and is most likely to produce safe and controlled sedation. The combination of an IV opioid agent and an IV benzodiazepine agent (e.g., fentanyl and midazolam) is commonly used. This combination, when used cautiously, provides an excellent mixture of analgesia, anxiolysis, and amnesia. Dosing for this combination and for other agents is discussed in Chapter 35 .

Following sedation, the patient is placed in a head-down tilt of approximately 20° for groin hernias but with no tilt when other hernias are treated. A pillow may be placed under the buttocks. For infants, the legs should be swaddled and secured to prevent slippage. This technique is successful in spontaneously reducing 80% of pediatric incarcerated hernias over a 2-hour period without manipulation. In addition, the application of a cold pack or a padded ice bag to the hernia, covered with cloth or gauze (to prevent cold injury to the skin), may reduce local blood flow and diminish intraluminal gas pressure while the analgesic is taking effect.

If, after 20 to 25 minutes, spontaneous reduction has not occurred, gentle manipulation can be added. Fraser [38] has described the unilateral frog technique, depicted in Figures 47-4 (Figure Not Available) through 47-6. The patient is placed in the supine position and the pelvis firmly grasped by an assistant to prevent lateral movement of the hips (see Fig. 47-4) (Figure Not Available) . The ipsilateral leg is then externally rotated and completely flexed and placed in the frog position (see Fig. 47-5) (Figure Not Available) . This has the anatomic result of having the external inguinal ring more closely override the internal inguinal ring. The physician then places the first 2 fingers of the "guiding" hand over the hernial bulge, overriding the external inguinal ring in such a manner as to prevent the hernial sac from subluxating over the margin of the ring. The apex of the hernia is then grasped between the first 2 fingers of the "reducing" hand, and prolonged, firm, steady pressure is applied (see Fig. 47-6) (Figure Not Available) . The reducing hand should stay in place as long as possible; in fact, feeling stiffness in the first 2 fingers and an ache in the thenar eminence of the reducing hand is indicative of the correct position. These maneuvers, if successful, often result in a gurgle that signifies hernia sac reduction. A slow, steady, atraumatic manipulation is preferred. Repeated forceful attempts at reduction are contraindicated. Reduction of other abdominal wall hernias is accomplished in a fashion similar to that described for inguinal hernias.

Once reduction occurs, corrective surgery should be considered within 24 to 48 hours, after local edema has subsided. [19] The risk of recurrent incarceration is high, and relatively urgent surgery is indicated. Fortunately, the complications of surgery performed during this time frame are the same as for elective herniorrhaphy. If reduction cannot be achieved, emergency surgery is indicated after dehydration and electrolyte imbalances are corrected. Nasogastric suction is indicated if obstruction is present.

## COMPLICATIONS

An attempt at manual reduction of a hernia may be unsuccessful or only partially successful. The physician must recognize a partial reduction and obtain appropriate consultation. Persistent attempts at reduction produce patient discomfort and may delay operative intervention for relief of bowel obstruction or organ ischemia. Hernia reduction en masse may occur when the hernia sac is displaced into the preperitoneal space, giving the clinician the impression that reduction has been achieved. The hernia sac remains incarcerated, outside the abdominal cavity, and at risk for strangulation. This is a rare phenomenon and can occur spontaneously, without attempted reduction. Testicular infarction and subsequent atrophy may occur after an incarcerated hernia or (as mentioned above) with an acute hydrocele of the spermatic cord. This is presumably secondary to ischemia and venous engorgement limiting testicular blood flow.

## CONCLUSION

By far the greatest challenge in the immediate management of groin lumps is the differential diagnosis of conditions that may mimic a groin hernia. Reduction of groin and other abdominal wall hernias is usually straightforward. Once the hernia is reduced, the patient and family must be told that straining at stool, urination, or coughing may produce another prolapse of the hernia sac. The patient or family should rapidly reduce any recurrent herniation to avoid recurrent incarceration and the need for a return to the ED. A demonstration of the reduction technique to be used by the patient or family usually aids in gaining cooperation. The emergency physician should not overlook the need to evaluate and treat potentially complicating conditions (e.g., urinary tract infections, bladder outlet obstruction, constipation, and respiratory infections) that may increase intra-abdominal pressure and produce recurrent herniation. Appropriate referral for these related problems and subsequent care of the reduced hernia is recommended.

Finally, the emergency physician must be aware that to the patient, the development of hernia symptoms is often associated with employment-related activities. Although physical exertion can certainly exacerbate a preexisting weakness in the abdominal wall and can lead to frank herniation, most frequently the abdominal wall defect is congenital in origin. Therefore, to minimize confusion in worker's compensation cases, the physician should be careful to note that the patient's hernia became symptomatic during an activity rather than stating that the hernia was the result of an activity.

# Chapter 48 - Rectal Procedures

**Scott M. Davis**

Anorectal disorders are infrequent but by no means rare complaints in the emergency department. The emergency physician should have the ability to diagnose and treat common anorectal complaints. This chapter will discuss four procedures that are well suited to the emergency department setting: anoscopy, excision of thrombosed external hemorrhoids, removal of foreign bodies, and reduction of rectal prolapse.

Many anorectal conditions are painful and consequently prompt emergency evaluation. Bleeding, although usually not life threatening, is also worrisome to patients. The emergency physician should realize that patients are often self-conscious concerning anorectal complaints. By presenting to a public facility, the patient may have already subjected him- or herself to a great deal of embarrassment, and therefore, the physician should maintain a sense of objectivity and professionalism. A nonjudgmental and nonthreatening approach will enhance the physician-patient relationship and the probability of patient cooperation during any subsequent procedure.

Patients may be particularly anxious concerning anorectal procedures, especially if they are already in pain. As for most procedures, it may be difficult, if not impossible, to adequately examine and treat a patient who is not able to cooperate because of severe pain and/or anxiety. Therefore, *the emergency physician should consider the liberal use of analgesia and sedation prior to any invasive anorectal examination or procedure*. The common practice of coating the anoscope or examining finger with lidocaine jelly or ointment immediately prior to a procedure provides lubrication, but it offers no analgesia. Hence, parenteral benzodiazepines and opioids should be instituted in appropriate situations. The use of parenteral analgesia and sedation is outlined in detail in Chapter 35 .

## ANATOMY

The terminal portion of the gastrointestinal tract is divided into the sigmoid colon, the rectum, and the anus (Fig. 48-1) (Figure Not Available) . The anus constitutes the terminal 4 cm of the gastrointestinal tract. The rectum extends proximally an additional 12 to 15 cm from the anus and joins the sigmoid colon. The junction between the anus and rectum is called the *pectinate line*. This line divides the anus, which is covered by squamous epithelium, from the rectum, which is covered with mucous membrane. This explains why painful anorectal lesions usually involve the anus, as it is innervated by cutaneous fibers. Superficial (mucosal) rectal lesions usually cause little pain, as the rectum is innervated by visceral fibers.

At the pectinate line, there are anal crypts with mucus-secreting glands. This site is where most anorectal abscesses are believed to arise. Above the pectinate line is the internal hemorrhoidal plexus, where internal hemorrhoids usually become symptomatic with painless bleeding. The external hemorrhoidal plexus, where external hemorrhoids originate, is below the pectinate line. Because the lesions are covered with skin, they

usually cause significant pain.

# ANOSCOPY

## Indications and Contraindications

Anoscopy is used to visualize the anal canal. It is inadequate to properly evaluate for rectal pathology, as only the most terminal portion of the rectum can be visualized. Anoscopy is used most often to diagnose anal foreign bodies, infections, anal tears, or internal hemorrhoids.

Anoscopy can be helpful in evaluating the following conditions: bright red blood per rectum; recent change in stool character, such as diarrhea or constipation; pain on defecation; rectal discomfort; anorectal drainage; and conditions related to the anorectal area, such as warts, fistulae, anal discharge, or pruritus.

There are few contraindications to anoscopy, with imperforate

anus being the only absolute contraindication. Anal stenosis or severe pain are relative contraindications.

## Equipment and Setup

There are various designs of anoscopes available. One style consists of a stainless steel or clear plastic tube, with a removable obturator inside (Fig. 48-2 *A* and *B*). This style requires an external light source to visualize the anal canal. A second popular style of anoscope has an integrated light source which eliminates the need for a head lamp or other light source operated by an assistant to illuminate the anal vault during the procedure (Figs. 48-2 *C* and (Figs. 48-3 ).

Additional equipment required may include lubricants, topical anesthetic agents, cotton swabs, forceps, or culture media, depending on the situation.

## Technique

### Preparation

Appropriate sedation and analgesia as previously described should be instituted prior to the procedure, especially for particularly painful disorders. Mild pain relief may be afforded by prior application of a topical anesthetic such as lidocaine jelly (2%) for painful anal conditions such as external hemorrhoids or anal fissures. *Topical agents should be administered 5 to 10 minutes prior to the procedure for optimal effect.* It is common for the physician to underestimate the degree of pain produced by anoscopy for many common anorectal conditions.

**Positioning**

The examination can be performed with the patient in either the lateral decubitus position (Sims position) or the knee-chest position. The choice of position is dependent on the preference of the physician and the tolerance of the patient (Fig. 48-4) (Figure Not Available) .

In the lateral decubitus position, the patient is placed on his or her left side. The knees and hips are flexed, and the patient's buttocks are positioned just over the edge of the bed. The left lateral position is best for a right-handed examiner.

The knee-chest position may be done on a bed or, preferably, on a tilt table. It may be difficult for ill or elderly patients to maintain this position.

**Procedure**

A routine digital rectal examination should be performed prior to anoscopy. One must determine the presence or absence of fecal impaction, mass, enlarged prostate, or stricture. The well-lubricated finger is introduced to check for bleeding, mass, or foreign body and to localize pain or pathology. The axis of the anal canal should also be noted to properly direct the anoscope on insertion. Although digital rectal examination has been reported to cause cardiac dysrhythmias such as ventricular fibrillation, this is quite rare. [13] This should be kept in mind when dealing with patients with significant underlying diseases, such as severe coronary artery disease, or a history of cardiac dysrhythmias. One may wish to monitor such patients. In addition, the digital rectal examination does *not* significantly elevate levels of prostate-specific antigen (PSA). [14]

After the digital examination, the physician inserts a well-lubricated anoscope. With the obturator inserted completely into the anoscope, the examiner gently advances the instrument while the patient bears down slightly against the instrument. Once the instrument dilates the anal sphincters at the anal orifice, the anoscope usually passes gently into the anorectum. During insertion, the physician's thumb is placed on the obturator to secure it in place. If the obturator falls back, the anal mucosa may be pinched, causing pain or bleeding. Consequently, the obturator should not be reinserted unless the entire anoscope has been completely removed from the patient. The instrument should be inserted until the outer flange impinges on the anal verge (Fig. 48-5) . [5]

Once the anoscope is inserted to the hilt, the obturator is completely removed. The anal canal is then visualized as the anoscope is gradually removed. If discharge is present, the mucosa should be swabbed clear and appropriate cultures taken. If bleeding or debris is present, this may be swabbed to aid visualization.

As the anoscope is withdrawn, it may be rotated in a circular fashion so the entire wall can be visualized. Near the last stage of withdrawal, reflex spasm of the anal sphincters may cause the anoscope to be expelled quickly. To obtain an adequate view, the

physician may need to repeat the procedure, reinserting the anoscope several times as necessary.

The following pathologic entities should be looked for: internal and external hemorrhoids, anal fistulae, anal fissures, sentinel tags, tumors, blood or pus, ulceration, parasites, or mucosal irregularities. [5]

**Figure 48-4** (Figure Not Available) Positions for performing sigmoidoscopy or anoscopy. *(From Hill GJ II: Outpatient Surgery. 3rd ed. Philadelphia, WB Saunders, 1988. Reproduced by permission.)*

### Complications

Anoscopy is a safe procedure, and complications are unusual. Irritation of local tissues is the most common complication and can result in increased bleeding or abrasion of the anorectal wall.

Use of sterilized instruments is imperative, as transmission of infectious diseases (e.g., hepatitis B, condylomata acuminata, herpes virus, or human immunodeficiency virus [HIV]) could occur.

## MANAGEMENT OF HEMORRHOIDS

Hemorrhoids have been known to mankind for centuries. [10] Hemorrhoids are varicosities of the venous plexus in the wall of the anorectum (Fig. 48-6 *A*). There are two types of hemorrhoids: internal and external. *Internal hemorrhoids* originate *above* the pectinate line and are covered with the columnar epithelium of the gastrointestinal tract. They usually present with painless bleeding, often following a bowel movement. Internal hemorrhoids may prolapse out of the rectum spontaneously or during defecation; when prolapsed, these hemorrhoids can be painful or bleed (usually bright red blood).

*External hemorrhoids* arise *below* the pectinate line and are covered with squamous epithelium (see Fig. 48-6 *B*). They may be pruritic, but patients usually become symptomatic when the external hemorrhoids become either inflamed or thrombosed. Pain may arise quite suddenly. Patients often report a mass or lump in the rectal area, and bleeding is uncommon but may occasionally be noted if the external hemorrhoid spontaneously ruptures. Because they are covered with skin, pain is the main hallmark of thrombosed external hemorrhoids. A thrombosed hemorrhoid appears as a tender purplish mass distal to the pectinate line and is usually visible when a patient's buttocks are spread. The "thrombosed" external hemorrhoid actually most often represents a rupture of one of the veins of the external hemorrhoidal plexus into the surrounding connective tissue. This condition is more accurately referred to as an *anal hematoma* or *external anal thrombosis*.

### Indications and Contraindications

There is little the emergency physician can or needs to do in the emergency department

for patients with internal hemorrhoids. Suppositories (such as Anusol-HC) and sitz baths may be helpful. When the prolapsed tissue is inflamed and painful, appropriate analgesic agents may be prescribed. Reduction of prolapsed hemorrhoids gives immediate relief, but they often recur with the next bowel movement. These patients should be referred for definitive therapy (i.e., ligation).

Nonoperative treatment of the external anal thrombosis will eventually result in spontaneous resolution over a week or so, leaving a residual skin tag. However, operative treatment is often required for pain management. More conservative therapy also puts the patient at risk of developing an impaction due to fear of painful defecation and the use of opioid analgesics.

Surgical excision is recommended for large, painful, thrombosed external hemorrhoids and can provide almost immediate relief to the patient. [17] The examining physician must be certain that a thrombosis exists prior to excision, because cutting into a nonthrombosed venous plexus can result in significant hemorrhage. A diagnosis of thrombosis can usually be made easily on clinical grounds by palpation of a firm, tender hemorrhoid, often noted to have a bluish discoloration. This presentation contrasts with that of an inflamed but *not* thrombosed hemorrhoid, which is often soft and distensible. [15] A small, tolerable, thrombosed hemorrhoid can be managed satisfactorily with conservative therapy consisting of stool softeners, sitz baths, anesthetic cream, and oral analgesics.

**Equipment and Setup**

Excision of a thrombosed hemorrhoid should be a relatively painless procedure, except for the transient pain associated with local anesthesia. Since significant pain as well as apprehension are involved with this procedure, the physician should use analgesia and sedation as outlined in Chapter 35 .

Other needed items include antiseptic skin preparation, appropriate drapes, tape, local anesthetic, and a standard suture or incision-and-drainage tray, with appropriate instruments (i.e., scalpel, tissue scissors, small curved hemostat).

**Technique**

The patient may be placed prone on the stretcher or in the left lateral decubitus position, depending on patient comfort. However, the latter position may require an assistant to provide adequate visualization.

The buttocks may be taped open to expose the anus (Fig. 48-7) . Benzoin will enhance tape adherence. Topical anesthetics may be used to decrease the pain of the initial injection.

After appropriate analgesia and sedation have been administered, local anesthesia is introduced by injecting a local anesthetic, preferably a long-acting preparation such as bupivacaine (Marcaine). A 25-ga needle is inserted at the center of the hemorrhoid, just

under the skin, but *not into* the hemorrhoid itself (Fig. 48-8) . Blanching should determine the success of infiltration. For a large clot or multiple small clots, a field block may be necessary, but this technique will be more painful (Fig. 48-9) . [15]

When anesthesia is achieved, the skin is elevated with a forceps. An elliptical incision is made around the clot and directed radially from the anal orifice (Fig. 48-10) . [18] Either a scalpel or tissue scissors may be used to make the incision. *A simple linear incision should not be used,* because it may close prematurely, preventing proper drainage. The flap of skin is then picked up and excised to expose the underlying clot; multiple separate clots may be present. The clot(s) can be removed with forceps or digital pressure (Fig. 48-11 *A- C*). Gentle probing and blunt dissection should be performed with a hemostat to be certain that all thrombi are exposed and removed. No other incisions are necessary, as this is a simple "unroofing" procedure. Bleeding is usually mild, and suturing is unnecessary. A small piece of surgical foam (Gelfoam) may be placed directly in the wound to promote hemostasis. Gauze pads placed over the area with the buttocks taped together are usually adequate as a dressing. [19]

## Postprocedure Care

Patients should be advised to rest several hours after the procedure to minimize bleeding. Warm sitz baths at least 4 times per day for at least 2 days may be started after the anesthetic has worn off. A cotton vaginal pad or gauze dressing may be placed over the anal region, although bleeding and drainage should be minimal.

Oral analgesia should be offered for a few days as needed. A hemorrhoidal cream (e.g., Preparation H, Anusol-HC) or an anesthetic cream (e.g., Xylocaine cream or jelly) may be beneficial for some patients. Although a stool softener is often recommended for several days to decrease straining and pain associated with defecation, this is generally not indicated unless opioid analgesics are prescribed and the patient has had significant prior constipation (as is common in the elderly population). Patients should avoid prolonged walking or sitting for a few days. Following a bowel movement, the patient should be instructed to wash the area with soap and water and to avoid toilet paper for a few days. Antibiotics are not indicated. [6]

Long-term recommendations to decrease the incidence of hemorrhoidal problems include increasing dietary fiber and possibly the use of stool softeners. Patients with particularly severe problems or multiple recurrences should be referred to a general or colorectal surgeon.

## Complications

It is important to remove the skin over the excised clot in the elliptical manner shown (see Fig. 48-10) . A simple stab incision with expression of the clot leads to a higher incidence of infection because the skin edges close prematurely. Such a limited excision also may lead to a higher incidence of recurrence as well as the creation of residual skin tags.

Postoperative bleeding may occur but is usually minimal. Bacterial infection is quite uncommon. A postoperative check is recommended in 2 to 4 days. The patient should be warned that hemorrhoids may recur in the future, although excision usually resolves that specific hemorrhoid.

# MANAGEMENT OF RECTAL FOREIGN BODIES

Patients with rectal foreign bodies often seek initial medical care through the emergency department. It is therefore imperative that the emergency physician have a basic understanding of the evaluation, treatment, and disposition of these patients. Many rectal foreign bodies may be removed successfully in the emergency department. By following appropriate guidelines, treatment in the emergency department can be cost-effective and practical.

The relatively recent increase in reported rectal foreign body cases likely represents both an increase in reporting and, more important, a true increase in incidence. The etiology of rectal foreign bodies includes (1) autoeroticism (most common), (2) iatrogenic (e.g., thermometer, rectal tube), (3) sexual or criminal assault, (4) self-administered treatment (e.g., enema), (5) accidental ingestion, and (6) concealment (e.g., body packing to conceal cocaine).

The types of foreign bodies seem limited only by the anatomic size of the rectum and the limits of human imagination. The myriad of foreign bodies that have been described include vibrators, phalluses, spray cans, hairpins, pencils, toothpicks, chicken bones, corncobs, glass jars, broomsticks, candles, flashlights, baseballs, vegetables, and electric light bulbs. Most objects are cylindric. The largest documented object was a stone that measured 25 cm in diameter. Colorectal foreign bodies constituted 13.3% of all gastrointestinal foreign bodies in 1 series. [29] Rectal thermometers are the most common object in the pediatric population. Males predominate in most series by as much as 28:1.

Older literature on this subject stressed inpatient treatment, and reports were skewed toward complicated cases and resultant complications. Most recent series show that there is a high success rate for the outpatient management of rectal foreign bodies, if proper guidelines for evaluation and treatment are followed.

**Indications and Contraindications**

Diagnosis of a rectal foreign body can usually be made easily from the history. In unclear cases, digital examination, plain

radiographs, or radiography using contrast media may help establish the presence of a foreign body. If a foreign body with a sharp edge is suspected from the history, the physician is advised to forego digital examination. Once the diagnosis is made, general principles of management include foreign body identification, foreign body removal, and

assessment for associated intraperitoneal and extraperitoneal injuries.

All rectal foreign bodies should be removed once they are diagnosed. Although some objects may pass spontaneously, *it is safest to assume that extraction is necessary*. Delayed removal may lead to obstipation, pain, and infection, with or without rectal perforation. The majority of rectal foreign bodies can be removed successfully and safely in the emergency department.  A rational approach to the removal of foreign bodies in the emergency facility is outlined in Figure 48-12 .

The majority of foreign bodies can be removed uneventfully in the emergency department if the patient has no signs of perforation and the object is palpable on digital examination. Radiographs may occasionally be needed to identify the location and type of foreign body or to rule out perforation. The specific technique for removal depends on the size, location, orientation, and composition of a particular foreign body. These techniques are described in the subsequent section.

After removal, sigmoidoscopy or anoscopy to assess mucosal integrity and evaluate for possible perforation is recommended.  Patients with normal postextraction examinations without clinical evidence of perforation may be safely released home with precautionary instructions.

Indications for hospital admission or outpatient surgery with general anesthesia in certain circumstances include (1) the diagnosis or suspicion of perforation; (2) the presence of a rectal laceration beyond the superficial mucosa, significant bleeding, a nonpalpable foreign body, or broken glass or other extremely fragile foreign material; (3) the need for any procedure that would cause undue patient discomfort; or (4) failure of emergency department extraction after a reasonable period of time. [20]

Observation in the emergency department to allow small nonpalpable foreign bodies (above the rectosigmoid junction) to pass into the lower rectum has occasionally been successful. Enemas or cathartics should not be used, because they may increase the impaction of a foreign body or cause it to move higher into the colon. [31] In the unobstructed patient, the use of oral gastrointestinal preparation solutions (e.g., GoLYTELY), may be considered if immediate surgery is not planned.

As noted above, admission to the hospital or outpatient surgical unit for removal under general anesthesia or for postremoval care may be recognized before or after attempts at foreign body removal in the emergency department. In general, any attempt at rectal foreign body removal in the emergency department is contraindicated in the following situations: (1) a patient with severe abdominal pain or signs of perforation on presentation; (2) a nonpalpable (high-lying) foreign body; (3) a foreign body that is unusually difficult to remove (i.e., routine removal could result in perforation or other significant morbidity); or (4) when there is insufficient time, experience, or equipment for the procedure.

**Equipment**

As in any procedure, a private, well-lit room with a comfortable examination table is needed. Equipment items that should be available for most extractions include lubricant, rubber gloves, examining light, anoscope, proctosigmoidoscope, local anesthetic with appropriate syringes and needles, and suitable parenteral narcotics and sedatives.

Other equipment that may be used depends entirely on the specific technique chosen for foreign body removal. Most techniques use some type of speculum to aid in visualization and then some form of clamp or snare to grasp the object. Some of the more common methods of foreign body removal are detailed later and are listed in Table 48-1 .

## Techniques

### Preparation

The general principles of management of rectal foreign bodies include proper diagnosis, subsequent removal, assessment for rectal or colonic injury, and recognition and treatment of associated injuries. The indications for radiographs before the extraction procedure are controversial. Some authorities advocate routine radiographs for all patients with rectal foreign bodies. Reports demonstrating the safety of outpatient management of uncomplicated foreign bodies suggest that such films increase the expense but add little to patient management. The decision to order films should be based on clinical judgment. Films are clearly indicated when the patient has abdominal pain, peritoneal signs, suspected perforation, or fever or when the patient's clinical history is unclear or unreliable. The setting of anticipated sharp foreign objects also warrants radiographic evaluation.

The patient may be placed prone or in the Sims position, depending on patient comfort. The knee-chest position can be used but is difficult for the patient to maintain without a proctosigmoidoscopy table with knee support.

Because patient discomfort is common during the procedure, sedation and analgesia should be used.  A combination of fentanyl and midazolam, as outlined in Chapter 35 , is a useful approach. Even with parenteral drugs, supplemental local anesthesia using a field block technique (see Fig. 48-9) may be necessary to achieve optimal dilation of the anal sphincter. The perianal field block is performed after povidone-iodine application. Anesthesia is placed in a radial fashion around the anal sphincter, using 0.5% bupivacaine or 1.0% lidocaine with epinephrine 1:200,000 (unless contraindicated). One then extends the anesthetic submucosally, anteriorly, and posteriorly. [34]

### Procedure

Gentle abdominal (suprapubic) pressure often helps deliver the foreign body into the distal rectum, where the examining

| TABLE 48-1 -- Equipment Useful for Rectal Foreign Body Removal | | |
| --- | --- | --- |
| **Speculum** | **Grasping Tool** | **Example of Foreign Body** |
| Operative anoscope | Tenaculum forceps | Cucumber |
| Operative proctoscope | Ring forceps | Banana |
| Parks retractor | Tonsil snare | Pencil |
| Deaver retractor | Obstetric forceps | Apple |
| Vaginal speculum | Spoons | Vibrator |
| | Foley catheter | Small ball |
| | Endotracheal tube | Glass jar |
| | Suction dart | Light bulb |

finger helps the distal end of the smooth foreign body navigate to the anus. Quite often the foreign body lodges against the sacrum posteriorly and requires gentle redirection.

If one is unsuccessful at digital extraction, then another technique must be chosen. The specific technique used depends on several factors, including the nature, size, shape, orientation, and composition of the foreign body; the availability of equipment; and the experience and ingenuity of the physician. Numerous techniques have been discussed in the literature; the more commonly accepted ones are described here. In general, most techniques require adequate visualization, as with a speculum, and the use of a

grasping tool.

An operative anoscope, proctoscope, or vaginal speculum may be inserted to allow adequate visualization. The object may then be grasped with a forceps or tenaculum and gentle traction applied to remove both the speculum and grasping clamp simultaneously, because the object often has a greater diameter than the speculum. A Parks retractor was used successfully to aid in foreign body removal in 1 series of 100 patients (Fig. 48-13 *A- C*). [34]

A flexible sigmoidoscope with a polypectomy snare has been used for successful foreign body removal. [35] After the tube is inserted, air is gently insufflated to distend the rectum. The object is then grasped with a polypectomy snare. Advantages of this technique include (1) the ability to distend the bowel around the object, (2) the avoidance of general anesthesia, (3) the convenience of outpatient management, and (4) the reported ability of this technique to retrieve high-lying objects.

Other grasping objects that have been used successfully include a suction dart for a glass foreign body, [36] a de Pezzer catheter attached to wall suction to produce a negative-pressure traction, [37] cyanoacrylate (Super-Glue), tonsil snares, surgical instruments such as obstetric forceps, and even spoons (Fig. 48-14) . A Sengstaken-Blakemore tube has been inserted into a hollow glass foreign body, inflated, and traction applied, allowing for successful removal. [25]

Glass foreign bodies deserve special mention. Glass may be quite difficult to grasp and, if fragile, may break during attempts at removal. In addition, glass often creates a vacuum effect in the distal colon when traction is applied, making routine removal virtually impossible. To overcome this effect, Foley catheters or endotracheal tubes can be inserted past the foreign body to insufflate air and release any suction forces. When the balloons are inflated, traction may be used to allow the foreign body to be removed (Figs. 48-15 (Figure Not Available) and 48-16) (Figure Not Available) . [38]

Difficult-to-grasp glass objects have been removed successfully with clamps covered with rubber. [39] Plaster of Paris has been used to fill a hollow object; the plaster is allowed to harden around a handle such as a wooden tongue blade, and then it is removed with traction. Some clinicians frown on using this technique, especially with glass objects, because as the plaster hardens, the heat released could cause the glass to break or produce mucosal injury.

The great majority of objects can be removed safely transanally in the emergency department.  After removal, proctosigmoidoscopy is recommended to evaluate for perforation, bleeding, and mucosal trauma. Patients with signs of perforation, unstable vital signs, abdominal pain, deep mucosal lacerations, significant bleeding, or suspicion

of perforation should be admitted. Perforation commonly occurs at the initial point of rectosigmoid angulation, approximately 15 cm from the anal verge. Perforation may occur prior to medical evaluation; thus, even atraumatic foreign body removals can be problematic. [5]

The emergency physician should set a realistic time limit, such as 30 minutes, at which time referral to a consultant for treatment or admission to the hospital becomes appropriate if extraction of the foreign body has been unsuccessful.

Once the patient is admitted, a high-lying foreign body may advance over 8 to 12 hours of observation to become a low-lying foreign body that can be removed transanally. If this is unsuccessful, then regional or general anesthesia is used along with abdominal and rectal palpation to maneuver the foreign body. If these attempts fail, then laparotomy should be performed, in which the surgeon "milks" the object in the colon distally. Colotomy is only rarely necessary and is done as a last resort. [10]

**Complications**

The most feared complication of rectal foreign bodies is bowel perforation. The risk of perforation is related to the force of object introduction and the sharpness of the object. The duration of foreign body impaction may also be a factor for large objects. Perforation may occur during insertion or removal of the object.

Perforation above the peritoneal reflection leads to free air below the diaphragm with signs of an acute abdomen. In suspicious cases, water-soluble contrast material may be used to clarify the diagnosis. [33] If perforation is below the peritoneal reflection, symptoms may be insidious, and patients may present with signs of pelvic abscess or sepsis days after the injury. It is therefore commonly recommended that patients treated for foreign body removal undergo proctosigmoidoscopy to rule out associated complications. Other complications that occur include bleeding, mucosal laceration, a torn anal sphincter, or object fragmentation with retention of the foreign body.

When intraperitoneal or retroperitoneal perforation is diagnosed or suspected, the emergency physician should institute appropriate antibiotic coverage. Bowel anaerobes are the primary contaminant; therefore, the choice of antibiotic should reflect an appropriate broad-spectrum drug. Currently accepted antibiotic regimens include ticarcillin-clavulanic acid, ampicillin-sulbactam, piperacillin-tazobactam, imipenem, cefoxitin or cefotetan, or, alternatively, metronidazole or clindamycin together with an aminoglycoside. [40]

**Conclusions**

The majority of rectal foreign bodies can be removed safely in the emergency department. "Body packers" and removal of this class of foreign bodies are discussed in Chapter 45 in conjunction with bowel decontamination. The emergency

physician must be knowledgeable in the evaluation of patients with rectal foreign bodies, the techniques for removal, and the potential for complications.

# RECTAL PROLAPSE (PROCIDENTIA)

Rectal prolapse, also known as *procidentia,* is a relatively uncommon condition in which some or all of the layers of the rectum protrude through the external anal sphincter. Definitive treatment of rectal prolapse is usually surgical, but the acute prolapse may be reduced in the emergency department. Failure to reduce the prolapse can result in long-term complications of atonic anal sphincters with resultant incontinence, or, at worst, actual gangrene of the bowel wall.

There are three types of rectal prolapse:

> *Type I prolapse,* or false procidentia, involves protrusion of mucosa only. It is often associated with hemorrhoids, and protrusion is only 1 to 3 cm (Fig. 48-17 (Figure Not Available) *A*).

> *Type II prolapse* is a true intussusception of all layers of the rectum, without an associated cul-de-sac sliding hernia (see Fig. 48-17 (Figure Not Available) *B*).

> *Type III prolapse* is a sliding hernia of the cul-de-sac. The pouch of Douglas is the hernia sac, pressing on the anterior wall of the rectum, forcing the rectal lumen to protrude through the anus. This condition gives the appearance that the rectum has been turned inside out (Fig. 48-18) .

The diagnosis of partial (mucosal) prolapse may be made by digital examination. Palpation of the prolapse between the examiner's gloved finger and thumb reveals the absence

**Figure 48-17** (Figure Not Available) *A*, Type I procidentia (rectal prolapse). *B*, Intussusception of sigmoid colon beyond the anus. *(From Kratzer GL, Demarest RJ: Office Management of Colon and Rectal Disease. Philadelphia, WB Saunders, 1985, pp 221-222.)*

**Figure 48-18** Complete rectal prolapse.

of a muscular wall. Normal anal sphincter tone also suggests mucosal prolapse.

Other entities that may mimic a prolapse include hemorrhoidal tissue mass or a large rectal or polypoid lesion protruding through the anus.

Rectal prolapse may be either congenital or acquired. It is often idiopathic in children, although it has a high incidence in association with pinworms, paraplegia, and cystic fibrosis. [10] In adults, rectal prolapse can be associated with mental retardation, organic brain syndrome, polio, stroke, and chronic psychiatric and neurologic conditions.

**Indications**

Acute prolapse should be reduced in the emergency department, although all patients

should be referred for subsequent surgical evaluation.

**Technique**

Reduction of Type I prolapse usually can be easily accomplished manually with gentle pressure on the mass. In children who are anxious, sedation may be necessary. With the child on the parent's lap, firm manual compression is applied for 5 to 15 minutes. After reduction, a pressure dressing is applied, and the child is sent home. A stool softener is recommended. The condition is usually self-limited. Increased bulk in the diet may help to decrease straining at the stool.

Reduction of a complete prolapse in an adult may be more difficult. Parenteral sedation and analgesia are usually required for success and are recommended. The patient is placed in the prone position, and the buttocks are taped apart (see Fig. 48-7) . Steady, gentle pressure to the area is begun, starting with the least prolapsed part (Fig. 48-19) . It may be helpful to place 2 gauze pads on the prolapse at the 3 o'clock and 9 o'clock positions, as the bowel wall is quite slippery. The thumbs are placed near the bowel lumen, and the fingers grasp the exterior wall. Then with thumb pressure, the sides are gently rolled inward to force the prolapse back through the anus. Reduction is most likely to be successful with slow, gentle pressure in a relaxed, nonstraining patient.

Definitive therapy of rectal prolapse in the adult is surgical. Patients with unsuccessful reductions need urgent surgical referral. Those patients successfully reduced should have subsequent surgical referral arranged. [10]

**Complications**

Complications include ulceration and occasionally bleeding. Inability to reduce the prolapse can result in gangrene of the bowel wall. Atony of the anal sphincters with resultant incontinence may occur, and the incidence increases with delay in reduction.

## CONCLUSIONS

Anorectal disorders are not a rare problem facing emergency physicians. Anoscopy, excision of thrombosed external hemorrhoids, removal of rectal foreign bodies, and reduction of rectal prolapse are all procedures that the emergency physician may be called on to perform.

# Chapter 49 - Out-of-Hospital Splinting

**Mohamud R. Daya, Ronald J. Mariani**

## CERVICAL SPINE

Trauma patients frequently sustain injuries to the cervical spine. These injuries are particularly devastating when associated with injury to the spinal cord. In the United States, approximately 12,000 spinal cord injuries are incurred per year. [1] Most of these are a result of motor vehicle crashes. The remainder are due to falls, recreational activities (especially diving), and penetrating trauma. It is estimated that 40% of cervical spine injuries are associated with neurologic deficits and that up to 25% of such deficits are a result of improper handling during evaluation, extrication, and transport of the patient. [2] [3] Therefore, it is critically important that the cervical spine be immobilized early and effectively.

Because the minimum degree of motion required to cause spinal cord injury has not been defined, the goal of immobilization is to maintain the head in a neutral position with zero degrees of motion in all directions. [4] To immobilize the entire cervical spine, an orthotic device must fix the head, hold the occiput and mandible, and restrict motion at the cervicothoracic junction. [5] This approach follows the basic orthopedic principle of immobilizing the joint above and below a suspected injury. In addition, to be useful in the out-of-hospital setting, a cervical immobilization device must be portable and easy to apply and must allow access to the upper airway.

At present, the standard technique of spinal immobilization involves early manual stabilization of the head and neck relative to the long axis of the body. Manual stabilization is usually followed by the application of a cervical collar. Although its use is controversial, a cervical collar has value as an early adjunct in the sometimes complex process of immobilization and extrication. There are several types of collars, all of which provide various degrees of comfort and support, but even the ones with the best features provide less than adequate immobilization when used independently.

The choice of devices used in addition to cervical collars depends on the victim's position of origin and the complexity of the disentanglement process. If the victim is found in a sitting position, as in an automobile, some version of the short spine board is commonly used. The most effective of these are wraparound corset-type devices, designed to immobilize the neck and place handles on the patient.

Following the use of these intermediate spine immobilizers, the patient is usually fastened to a full-length spine board or similar rigid device in preparation for transport. Complete cervical immobilization must also incorporate lateral stabilization of the head in the form of lightweight bulky objects such as foam blocks, towel rolls, blanket rolls, or cushions and tape. This can also be accomplished using factory-made devices such as the HeadBed (Laerdal Medical Corp, Wappingers Falls, NY) or Bashaw Cervical Immobilization Device (CID) (Bashaw Medical, Inc, Pensacola, Fla).

**Background**

Since 1965, an entire industry aimed at out-of-hospital preservation of life and limb has evolved. Specially manufactured spinal immobilizers were developed for field use during the late 1960s and early 1970s. Many variations of these early devices have been developed to solve specific out-of-hospital problems. In addition, recent advances have produced more versatile plastics and stronger adhesives.

It should be stressed that although there is widespread agreement about the basic steps of spinal immobilization, out-of-hospital care is a setting only for people who can adapt. Because of the variety of circumstances that confront rescuers on a daily basis, flexibility is mandatory.

A pioneer in the use of a spine board for cervical immobilization after injury was J. D. Farrington. [6] Farrington emphasized that spinal fractures were frequently mishandled and made worse by rough or hasty movement at the scene. He outlined the use of a backboard, sandbags, and tape for the out-of-hospital extrication and care of patients with suspected spinal injuries. He fashioned extrication collars using universal dressings held in place by soft roller bandages and advocated manual traction during the extrication phase. [7]

Manual traction is no longer recommended, because it may aggravate an underlying spinal injury. [8] In addition, although sandbags are effective devices for lateral immobilization, they may cause significant movement of the neck if the board is suddenly tilted (e.g., to decrease the risk of aspiration in a vomiting patient). As a result, sandbags have been replaced by more lightweight devices such as foam blocks, the HeadBed or Bashaw CID. Despite these modifications, the original Farrington method of splinting the head and torso to a rigid object remains the preferred technique for effective spinal immobilization.

**Indications**

An extrication collar should be used as a primary adjunct in cases involving trauma to the head and neck. In the absence of visible trauma, patients should be immobilized whenever the mechanism for a potential cervical spine injury exists. The most common mechanism of injury involves sudden deceleration of an automobile, resulting in hyperflexion and hyperextension forces. Patients under the influence of alcohol or drugs lack the self-awareness to recognize their own spinal injury and should be immobilized routinely. Likewise, every unconscious trauma patient should be immobilized to avoid aggravating an underlying spinal injury. Any awake and alert trauma patient who complains of spine pain, paresthesia, weakness, or absent movement should be immobilized carefully to avoid secondary injury to the spinal cord.

It is not uncommon to encounter patients in the field who are both conscious and oriented but unaware of their own neck injuries. The sensory impact of having one's automobile forcibly disassembled by rescue personnel who are using modern tools that

produce noise in excess of 80 dB may result in considerable distraction. In addition, the presence of other painful injuries or concern over other victims can easily mask the manifestations of an occult cervical spine injury.

Serious cervical cord injuries can also occur in the absence of demonstrable fractures. Spinal cord injury is common in elderly patients with cervical spondylosis, in whom an arthritic osteophyte may sever a portion of the cord as permanently as a fracture or dislocation. In such cases, there is often little or no subjective pain, and the mechanism of injury may appear seemingly minor. [9]

Therefore, a high index of suspicion for possible spinal injury must be maintained at all times. In all cases, the medical record must include documentation of the neurologic examination before and after spinal immobilization.

The purpose of an extrication collar is to assist in splinting the head and neck either therapeutically or prophylactically in a neutral position. [5] The collar is useful for the following reasons:

1. It provides airway protection by limiting flexion in a patient whose unsupported jaw and neck position threatens patency.
2. It helps reduce cervical spine motion, especially flexion, but also rotation, lateral bending, and extension. In this regard, however, it serves only as an adjunct.
3. If properly chosen, it can support the weight of the head while the patient is sitting and help to maintain the alignment of the cervical spine once the patient has been moved to a supine position.
4. An equally important function is to serve as a reminder to the patient and rescuers that the integrity of the basilar skull and cervical spine are suspect because of the mechanism of injury.

The cervical collar does not provide complete immobilization of the head and neck. The collar was designed as an adjunct and was never intended to provide definitive immobilization in itself. Complete immobilization is not possible until the patient is properly secured to a long backboard-type device. Nonetheless, the collar should go on first and remain in place during the entire procedure.

**Contraindications**

There are few circumstances that preclude the use of an extrication collar. The presence of a surgical airway (cricothyroidotomy or tracheostomy) may require modification of the cervical support technique.

In addition, cervical dislocation with fixed angulation may prevent effective application of factory-made collars. This situation is rarely encountered and can be managed with an improvised cervical immobilizer, such as a version of a horse collar or prolonged manual positioning without traction. [10]

A third circumstance that could preclude the use of a collar is massive cervical swelling

(e.g., secondary to hemorrhage or tracheal injury). In these circumstances the compressive effect of a collar may impede air exchange, decrease cerebral perfusion, or increase intracranial pressure. [11]

Finally, the presence of an impaled foreign body such as a knife, a piece of glass, or metal can also make cervical spine immobilization using extrication collars difficult.

Note that improvised cervical support may work better than a manufactured collar, depending on the size and shape of the patient. This is particularly true in the pediatric population, as collars come in limited sizes and may not be well tolerated. In such circumstances, prolonged manual in-line stabilization is often necessary. Adaptability is a trait of well-trained and experienced field personnel.

## Equipment

Traditionally, cervical collars have used 4-point support structures for the bottom of the collar: namely, at the 2 trapezius muscles posteriorly and at the 2 clavicles anteriorly (Fig. 49-1) (Figure Not Available) . Newer rescue collars also use the sternum as a fifth support structure (Fig. 49-2) (Figure Not Available) . Current collar designs support the head with wing-like flaps on the collar's upper posterior edges. Anteriorly, the collar supports the mandible. The collar's flaring design generally prevents compression of the thyroid cartilage and cervical vessels, even when the collars are applied firmly.

Soft collars, although comfortable, have no role in spinal immobilization, because they provide minimal support and do not reduce cervical motion to any significant degree. [3] [12] However, the semirigid collar must be comfortable to ensure patient compliance. Dick and Land described the subjective characteristics of an "ideal collar." [13] These features included the following:

1. It should support the weight of the head in a neutral position.
2. It should prevent lateral, rotational, and anteroposterior movement of the head.
3. It should be comfortable, translucent on radiographs, and compact.
4. It should be easy to apply.
5. Its price should be such that it can be carried in sufficient numbers in various sizes by any ambulance.
6. It should not interfere with the position or function of important airway structures, nor adversely affect cerebral circulation in any way.
7. Simplicity of design should permit its application by 2 rescuers in less than 60 seconds, in darkness, rain, or cold weather, without manipulation of the head or neck.
8. It should be available in the smallest number of sizes possible.

Other investigators have attempted to evaluate cervical collars in an objective fashion. The accepted gold standard for comparison is the halo brace, which restricts motion to 4% flexion-extension, 1% rotation, and 4% lateral bending. [5] A number of studies have evaluated neck motion in volunteers immobilized supine on a backboard with various collars in place. Overall, these studies merely confirm the fact that cervical collars alone are inadequate to immobilize the cervical spine completely. At the present time, there is

no out-of-hospital device or technique that approaches the halo in its ability to immobilize the cervical spine. [5]

Little information is available regarding the proper selection and application of spinal immobilization devices for children. Half of the total growth in head circumference is achieved by the age of 18 months, giving children a disproportionately large head compared with the rest of the body. Prior to age 8 years, these anatomic and developmental differences result in a higher incidence of upper cervical spine injuries (C1-2). Because injuries in this area are frequently unstable, proper cervical immobilization in the neutral position is critically important. Because the head is large, positioning the child's body on a standard backboard may force the neck into flexion or a relative kyphosis. The clinical significance of this is currently unclear, but theoretically, adult-type immobilization devices may be hazardous for use in young children. The standard backboard may be modified to adapt to the child's larger head size. As a rough guide, the external auditory meatus should be on the same level as the mid-shoulder. Suggested modifications include a cutout in the backboard that accommodates the occiput or a pad under the back at the level of the chest (Fig. 49-3) (Figure Not Available) . If not modified, the standard backboard in conjunction with the disproportionately large head of a child may force the neck into hyperflexion, possibly aggravating a cervical spine injury. [20] Nypaver and Treloar showed that all children required elevation of the back (mean height, 25.4 ± 6.7 mm) for correct neutral position on a spine board. Children <4 years old required more elevation than those 4 years old. [21]

In the only study addressing pediatric cervical spine immobilization, Huerta and coworkers evaluated the performance of infant and pediatric collars using a mannequin model. [22] They concluded that the high-cut collar (Fig. 49-4) (Figure Not Available) in conjunction with a rigid backboard and lateral neck stabilizers provided the most effective spinal immobilization. In some children, these devices may provoke struggling because of fear, which has the potential to aggravate an underlying injury. In these situations, manual immobilization may be more effective and less frightening for the child.

**Procedure**

Application of an extrication collar is a straightforward procedure (Fig. 49-5) (Figure Not Available) . A collar should be treated as a splint. The normal axiom in splinting is to immobilize the joint above and below the area of injury. Because no collar performs this function perfectly, a rescuer should be charged with maintaining manual cervical stabilization in the neutral position during collar application and until the patient can be fully immobilized in a corset-type device or on a full backboard. The rescuer's intentions should be thoroughly explained to the patient throughout the procedure.

The neck should be examined before application of the collar for swelling, ecchymosis, deformity, or penetrating wounds. Once the collar is in place, a conscious patient should be cautioned repeatedly against movement of the head. Any persistent complaints of pain or dyspnea by the patient should be investigated by removal and possible replacement of the device while manual stabilization is maintained. The collar size

should be determined using the manufacturer's suggested guidelines. For example, the Stifneck collar (Laerdal Medical Corp, Wappingers Falls, NY) is available in various sizes and uses the distance from the top of the shoulder to the chin to determine size (Fig. 49-6) (Figure Not Available) . The tallest collar that does not cause hyperextension should be used. For extremely short necks, a special extrication collar such as the No-Neck by Stifneck is recommended (Fig. 49-7) (Figure Not Available) .

In cases in which an extrication collar of the proper size is not available, an improvised device should be made from available materials (Fig. 49-8) (Figure Not Available) . Once the patient is in the supine position on the backboard, lateral stabilization should be added, using foam blocks and tape or a factory-made lateral neck stabilizer (Fig. 49-9) (Figure Not Available) . Because immobilization on a flat backboard has been shown to place most adult patients into relative cervical extension, it is recommended that occipital padding (mean, 3.8 cm) be added to restore neutral position in adults. [24]

## Complications

Improper application of an extrication collar can occur if the wrong size is used or too little care is exercised during placement. The best means of preventing either error is strong physician involvement in the training and continuing education of rescue crews, with vigorous feedback in cases of correct and incorrect application.

A collar that is too small for a patient may be either too tight for the girth of the neck (with obvious complications) or too short to provide adequate immobilization. Too large a collar commonly results in hyperextension, which can exacerbate a pre-existing spinal injury.

Improper or prolonged application of an extrication collar may impede venous return and raise intracranial pressure. This is sometimes manifested by facial flushing and is more common with the short collar types. [11] The clinical significance of the elevation of intracranial pressure produced by cervical immobilization is unknown; a collar was found to elevate intracranial pressure by only 2 cm $H_2O$ in 1 study. [25]

The long-term use of the Philadelphia extrication collar as part of the treatment plan for an underlying cervical spine injury has been associated with pressure ulcers of the scalp. [26] Because some collars (e.g., Philadelphia [Philadelphia Cervical Collar Co, Westville, NJ] and Stifneck) have been shown to exert higher capillary closing pressures at contact points, it is suggested that collars with favorable skin pressure patterns and superior patient comfort (e.g., NECLOC, Jerome Medical, Moorestown, NJ) be used in these settings.

One final complication should be mentioned. The patient who, for whatever reason, actively resists placement of an extrication collar or other splint should not be forced to wear it. Immobilization of the resisting patient cannot be accomplished without considerable muscular exertion not only by rescuers but also by the patient. If fractures do exist, it is possible that this kind of struggling can cause further damage. If the patient

permits manual stabilization, this should be maintained as an alternative.

**Summary**

The use of a good cervical collar is an important first step in the immobilization of patients with potential cervical spine injuries. The use of a cervical collar does not constitute complete immobilization. Full support must be provided by means of a full backboard and lateral support for immobilization of the head and neck.

# THORACOLUMBAR SPINE

Adequate full-body thoracolumbar spinal immobilization is probably best done by means of a full-length spine board (also called a *backboard*). Full-body spinal immobilization should include early application of a cervical collar, lateral immobilization of the head and neck, and ample belting of the entire body to the backboard. Proper belting minimizes movement whenever the backboard is used to transport the patient over long distances. In addition, this will help limit spinal movement associated with backboard tilting, which may be necessary in the likelihood of emesis or during transport of pregnant females in the second and third trimester.  Transferring a victim from a location and position of origin to a backboard may require the use of an intermediate spine immobilizer. This can be done using a short spine board or a corset-type device. Corset-type devices have extensions that engage the head and neck and are equipped with weight-bearing loops that allow easier handling of the patient. Intermediate immobilizers or extrication splints should be used when a patient must be removed from a confined environment or when circumstances require movement in or from a sitting position.

In some circumstances, a threatening environment (fire, hazardous material incident, extreme weather) or patient condition (compromised airway, shock) may necessitate rapid extrication using a manual technique. Rapid manual extrication may also shorten on-scene times and has been encouraged by out-of-hospital trauma care courses. [1]

When extrication is not required by a patient's location, position of origin, or route of egress, the patient is most often found lying at ground level. With an extrication collar in place and in-line manual cervical immobilization, the patient can be logrolled onto a backboard. Visual inspection of the back should be carried out during the logrolling process while the body is kept in a single plane.

McGuire and colleagues evaluated the safety of the logroll maneuver in three different settings: a volunteer with a stable spine, a cadaver with a surgically created unstable thoracolumbar injury, and a patient with a T12-L1 fracture-dislocation. [27] Radiographic studies on the volunteer demonstrated mild lateral movement during logrolling. The cadaver demonstrated a 2.1-cm anteroposterior displacement and a 5-mm lateral displacement during the logroll. The injured patient demonstrated no anteroposterior displacement but did experience a 7-mm lateral displacement when logrolled onto the side. Suter and coworkers studied variations of the logroll maneuver in healthy volunteers to determine the effect of axial traction and subject arm positioning on

thoracolumbar movement. [28] Their study demonstrated significant thoracolumbar movement during the logroll maneuver that was consistently minimized by positioning subjects with the arms extended at the sides and the palms resting on the thighs. These studies raise concern about the safety of the logroll maneuver and suggest that extreme caution be used during transfer of patients with suspected spinal injuries.

An optional but effective means of moving a supine patient is provided by a type of stretcher that breaks apart longitudinally and can be slid beneath a victim without disturbing their position. The halves of this scoop stretcher are anatomically contoured to enhance comfort and limit lateral movement of the immobilized patient. Unfortunately, visual inspection of the back is not possible with the use of a scoop stretcher.

A third means of both immobilizing and moving a trauma victim consists of a specially designed full-body splint, complete with factory-made straps or harnesses. There are several such immobilizers, most of which are highly effective and provide good lateral stability as well as anatomic conformity. One such device that is popular in European countries is the vacuum stretcher. A full-body splint that has recently been marketed in the United States (Evac-U-Splint [Hartwell Medical, Carlsbad, Calif]) offers fast, full-body immobilization that supports the entire patient without creating pressure points (Fig. 49-10) (Figure Not Available) . In general, the patient must either be logrolled or lifted, using a scoop stretcher or full backboard, onto one of these devices.

## Background

As recently as 1965, the principle of "rapid transportation above all" held widespread acceptance among rescuers, who had little or no orthopedic training, and among physicians whose emergency care experience, by modern standards, was just as limited. The most commonly agreed-on means of getting a sitting patient out of a wrecked automobile was to use some version of a chair-carry. If the patient originated in a position other than the sitting position, the patient was first placed into a sitting position and *then* moved by means of a chair-carry or simply dragged out of the vehicle.

Col. Louis Kossuth, commander of the U.S. Air Force's Medical Service School at Gunter Air Force Base in Alabama, made note of several automobile crashes in which he thought patients were handled roughly by bystanders who were trying to help. [29] Finding the medical literature at that time lacking, he made recommendations regarding how these victims should be handled. He experimented with a set of canvas splints reinforced with semirigid steel stays as slats, similar to the modern Kendrick extrication device (KED) (Ferno Model 125, Ferno-Washington, Inc, Wilmington, Ohio). In addition, Kossuth probably developed the first modern-type spine board. [7]

In 1967 and 1968, Farrington wrote 2 classic articles that showed the use of an extrication collar, spinal traction, 9-foot webbing straps, and both short and long spine boards to remove people in every conceivable position from automobiles. [6] [7] Much of today's extrication theory is essentially identical to what was taught by Farrington.

In 1967, the Committee on Trauma of the American College of Surgeons listed the minimum amount and type of equipment that should be carried in ambulances. This list

included both short and long spine boards, with accessories. [30] A similar document published the following year by the National Academy of Science also provided a list of medical requirements for ambulance equipment and recommended short and long spine boards. [31]

In 1969, St. Louis surgeons Klippel and Conrad described the use of a full-length spine board that was capable of being broken down into separate components for the upper and lower halves of the body. The lower portion included a simple traction device that could be used to simultaneously splint a fractured femur of either lower extremity. [32]

## Indications and Contraindications

Any mechanism capable of causing injury to the cervical spine should prompt rescuers to immobilize not only the head and neck, but also the entire body. The motion of any vertebral joint is impossible to isolate. For complete spinal immobilization, the head, neck, and torso must be fastened into a single common plane. Extrication devices (e.g., short spine boards) will accomplish this to some extent, although movement of nonimmobilized lower extremities can lead to secondary movement of the pelvis and lumbar spine. Movement of the lumbar spine may also induce thoracic movement to some extent. Considering the fact that the most feasible position for transport is the supine position, fullbody

**Figure 49-10** (Figure Not Available) The Evac-U-Splint mattress. *(Courtesy of Hartwell Medical, Carlsbad, Calif.)*

immobilization is best achieved using the long spine board.

Mechanisms that arouse suspicion of injury to the thoracolumbar spine should also prompt full-body spinal immobilization. These include penetrating and blunt injuries to the thorax, abdomen, pelvis, and spine. Full-body immobilization should be considered whenever the mechanism for spinal injury exists, even in the absence of signs and symptoms. In such cases, the possibility of occult injury is best ruled out through clinical and/or radiographic examination at the hospital.

The only contraindication to full-body immobilization of a patient whose mechanism of injury suggests spinal injury is *the existence of a greater threat*. The threat to a patient's life may exceed the threat of *possible* spinal injury under the following circumstances:

> *Hazards on the scene.* Problems with traffic control in the direct vicinity of the patient's location such that the patient or rescuers are likely to be injured. Such hazardous situations include leaks of fuel or other flammable substances, fire, hostile crowds, partially collapsed structures, or unstable vehicles.

> *Ongoing gunfire at the scene.* Gunfire is always considered an indication for rescue personnel to stay away from a scene.

> *Overwhelming casualties.* Rescuers may have to improvise in cases in which

casualties exceed available resources. In such cases, proper spinal immobilization may merit a lower priority than usual.

*Weather extremes.* Under conditions of extremely adverse weather, the urgency to move the victim may supersede the priority of normal treatment, including immobilization.

*Patient noncompliance.* A competent rescuer can do much to make an immobilization device comfortable by means of padding and reassurance. If this fails, immobilization that is applied by force may cause more harm than no immobilization at all.

## Equipment

### Cervical Extrication Splints

There are a large variety of short spine boards available for out-of-hospital use (Fig. 49-11) (Figure Not Available) . Although these devices have not been compared scientifically, some useful and important features of cervical extrication splints have been identified.

The device should not produce jostling or change the position of the head, neck, shoulders, or torso during application. In conjunction with a good cervical collar, a properly applied cervical extrication splint should effectively limit lateral, flexion, extension, and rotational motion of the head, neck, and torso. A cervical extrication splint should be comfortable, since it may be left on a patient for prolonged periods. Simplicity of design should allow rapid placement of the device by 2 rescuers in any situation, without causing movement of the head, neck, or torso.

The cervical extrication splint should be compact enough to allow its use in many types of extrication situations. Cost should be reasonable, so that at least 1 device can be carried in every ambulance. Ideally, the device should also be translucent so that radiographs can be readily obtained in the emergency department (ED). Lastly, the cervical extrication splint should be designed to allow for repeated sanitation.

One commonly used device that meets all of these criteria is the KED (Fig. 49-12) (Figure Not Available) . The KED was developed by Rick Kendrick, an emergency medical technician (EMT)-firefighter from El Cajon, Calif, as a result of the frustration of rescuers who experienced difficulty when removing victims from wrecked race cars. The device consists of 2 layers of nylon mesh impregnated with plastic and sewn over plywood slats to provide rigidity. It has a nylon loop behind the patient's head that is continuous with the pelvic support straps for additional strength. Part of its anterior thoracic panels can be folded backward to fit the obese, pregnant, or pediatric patient. Properly applied, the KED is a snug-fitting, highly adaptable immobilizer that can be used under even the most adverse of circumstances.

**Full-Body Spinal Immobilizers**

There are 3 basic classes of full-body spinal immobilizers, each with its own advantages and disadvantages. [33] It should be stressed that it is more important for a rescuer to achieve results than to be particular about using a specific piece of equipment.

**Full-body spine boards (backboards).**

Backboards are made of wood or plastic and can be either rectangular or tapered in shape (Fig. 49-13) (Figure Not Available) . Most rescuers prefer the tapered type, because it takes up less horizontal room when angled into a narrow doorway (such as that of an automobile). In addition, the slight narrowing of these boards on either end enhances the effectiveness of strapping.

Many boards also feature runners, usually about 2.5 cm thick, on their underside that serve both as stiffeners and as spacers. These raise the board slightly off the ground so that rescuers can get their fingers under the board during lifting. The runners, however, may make it more difficult to slide a patient onto the board.

Advantages of boards over full-body splints include their ease of storage, low cost, and extreme versatility. The backboard can be used to slide a victim out of an automobile or to protect a victim during removal of a windshield. Boards provide insulation against electrical hazards and can be used as improvised shelter in bad weather. Finally, they may be useful as ramps in muddy conditions.

Disadvantages of boards as immobilizers, although few, deserve mention. Board-like splints, as a class, are the least comfortable of all immobilizers. One prospective study demonstrated that standard spinal immobilization (hard backboard, rigid cervical collar, lateral immobilization device) of healthy volunteers, was associated with a variety of symptoms, including headache, backache, and jaw pain. [34] These findings may have clinical implications, since pain generated by the application of a backboard can be difficult to separate from other sources of pain in the trauma patient. Discomfort may be minimized by using padding at points of contact between a bony prominence and the board or the cervical collar. Alternatively, patient discomfort can be reduced, without compromising cervical spine immobilization, with the use of a pad (1.3 cm closed-cell foam padding) along the entire board. [35]

Backboards have also been shown to produce higher sacral interface pressure than a conforming support surface such as the vacuum-type splint. [36] The duration of contact pressure and the degree of contact pressure are considered important determinants of pressure necrosis in spinal cord injuries. [37] A further disadvantage of the backboard is its slippery surface, which makes it an unstable carrying device in rough terrain.

**Scoop stretchers.**

If a trauma victim has to be slid out of a tight location, a smooth backboard is probably

the best immobilizer. If the victim is not in a tight location, the scoop stretcher is an ideal field immobilizer (Fig. 49-14) (Figure Not Available) . The scoop stretcher is comfortable, rigid, adaptable to patients of various lengths, and provides unobstructed radiographic transparency of the entire spine. If necessary, it can be almost instantly applied or removed without disturbing the position of the victim. The stretcher also provides good lateral stability due to the trough-like shape of its top surface, and it is stable enough to be used for carrying purposes. For optimal protection of a potential spinal injury, the scoop stretcher should be placed on a backboard before moving the patient.

The scoop interferes slightly with the ischial section of a half-ring traction splint but works well with Sager-type devices. The scoop has no adverse effect on other immobilizers and does not interfere with cardiopulmonary resuscitation (CPR). The Ferno-Washington model 65 scoop (Ferno-Washington, Inc, Wilmington, Ohio) is the most widely used stretcher of this type.

**Full-body splints.**

There are various devices that take the concept of full-body immobilization 1 step further than the spine board. Los Angeles County Fire Department paramedic Larry Miller designed a narrow spine board shaped like the human body, with handles on both long edges and a system of harnesses to provide immobilization. The Miller body splint consists of a polyethylene shell injected with a closed-cell foam that is radiographically translucent and provides buoyancy in water (Fig. 49-15) (Figure Not Available) . The full-body splint features a removable head harness, a thoracic harness, and pelvic as well as lower extremity belts. The space between its lower extremities facilitates wrapping with bandage material in the event of fractures. In addition, it is shaped so that it can easily fit into a basket-type rescue stretcher such as the Stokes.

A recent innovation in the area of spinal immobilization in the United States is the vacuum mattress splint (see Fig. 49-10) (Figure Not Available) . It consists of a vinyl-coated polyester envelope filled with thousands of 1.1-mm diameter polyester foam spheres. A manual or electric vacuum pump is used to evacuate the interior to a pressure of about one-fourth atmosphere. This reduction in internal pressure causes the mattress to conform to the contours of the patient's body. Vacuum splints are more comfortable, quicker to apply, and allow less slippage on lateral tilting than wooden spine boards. [38] [39] The vacuum splint has also been shown to produce lower sacral interface pressure and may be the preferred immobilization device in patients with spinal cord injuries. [36]

**Lateral neck stabilizers.**

Sandbags, which were used as lateral neck stabilizers for years, are no longer recommended for use in the field. Lighter objects such as blocks (10 cm × 10 cm × 15 cm) made of medium-density foam rubber are commonly used. Foam blocks are lightweight, inexpensive, and disposable and do not slip on the backboard. More recently, cardboard devices that have the same advantages as foam blocks have been

developed to provide lateral stabilization (Fig. 49-16) (Figure Not Available) .

Another commercial device is the Bashaw CID. It is a lateral neck stabilizer designed to quickly and easily fasten the patient's head to a scoop stretcher or spine board (Fig. 49-17) (Figure Not Available) . The CID is made of a Herculite nylon and polyethylene foam platform that is fastened to the stretcher, either by elastic belts or by nonelastic belts with buckled closures. Its pillows are then attached to the nylon platform by means of large Velcro interfaces. A similar device called the Universal Head Immobilizer is also manufactured by Ferno (Fig. 49-18) (Figure Not Available) .  Mosesso and colleagues compared 6 out-of-hospital cervical immobilization devices and concluded that the devices were similar in their ability to immobilize the cervical spine, although the Bashaw CID was less effective than the other 5 devices in limiting rotational movement. [40]

## Procedure

Despite the presence of a field cervical collar, manual cervical stabilization should be continued until the patient is fully immobilized in either a cervical extrication splint or a full-body splint (e.g., a backboard or vacuum stretcher). The splinting technique used will depend on the patient's position of origin.

### Sitting Position

The extrication splint should be stored so that its straps are secured in their individual retainers to reduce their likelihood of becoming entangled during application. At least 2 rescuers should be used to apply an extrication splint to a sitting patient.

When used, the device is opened, butterfly style, and gently slid behind the victim with a rocking motion. If necessary, the patient can be very carefully rocked forward a few degrees to facilitate placement of the splint.

Once behind the victim, the splint's pelvic support straps should be freed from their retainers and allowed to dangle at the patient's sides. Next, the lateral thoracic panels are brought around the chest just beneath the patient's shoulders. While grasping these panels, a rescuer *slides the splint upward until the top edges of the panels firmly engage the patient's axillae*.

Now the thoracic straps can be used to secure the splint, beginning with the middle strap, then the bottom strap, and finally the top strap. The straps should be fastened snugly but not so tightly as to interfere with respiration.

The pelvic support straps are fastened next. They can be slipped, 1 at a time, beneath the patient's lower extremities and *brought directly beneath the pelvis using a back-and-forth motion*. If the pelvic straps are not applied properly, they allow considerable slippage when the patient is lifted. The free end of each of these straps mates with a buckle located at the patient's hip on the outside of the splint. Once a strap is ready to be buckled, it can either be attached to the buckle on its own side or moved

across the patient's lap and engaged with the opposite buckle. The latter method is preferred by most people, because it allows the patient's knees to remain together without discomfort to the patient.

Next, the head is fastened. When using the KED, the head panels are wrapped snugly around the head and neck by 1 rescuer while another rescuer applies the diagonal head straps. It may be necessary to place padding behind the head to maintain a neutral position. The forehead can be used as a point of engagement for 1 strap, and the cervical collar itself can be used for the other.

Finally, all buckles should be tightened until the entire splint is firmly in place, while avoiding respiratory discomfort. The patient can now be moved. If the patient is to be lifted from a vehicle, the ambulance cot, with a spine board on it, should be brought as close as possible. While 1 rescuer supports the patient's knees, the other rescuer uses the handholds on the splint to lift the patient. The patient should be rotated and laid in a supine position onto a backboard.

The pelvic straps should then be loosened to allow the legs to be lowered onto the backboard. The legs can then be extended and secured to the backboard or left in the flexed position with a pillow placed under the knees for support.

Some type of lateral immobilizer should be applied for the head and neck, and the body should be belted into place on the board. Once the patient is on the board, the thoracic straps of the cervical extrication splint should be loosened.

**Recumbent Position**

A patient who is found in a recumbent position should be placed in a supine position, if not already in one. If repositioning is necessary, the back should be examined in the process. Physical examination, spinal immobilization, airway management, and transport are easier to accomplish with the patient in the supine position.

Patients who are found supine do not require the use of a cervical extrication splint. They should, however, receive initial manual cervical stabilization and an extrication collar. After that, they are usually fastened to a full-body spinal immobilizer, such as a scoop stretcher, a backboard, or a full-body splint.

**Scoop stretcher.**

A patient who is in a supine position can be moved by means of a scoop stretcher. In the conscious patient, rescuers should explain to the patient that they are about to apply a scoop-type stretcher, which may be cold to the touch, beneath his or her body. An extrication collar is applied, and manual cervical stabilization is maintained until the patient is completely secured to the stretcher. Another rescuer places the scoop on the ground next to the patient and opens the latches that regulate its length. The length should be adjusted so that the scoop stretcher fits the full length of the patient's body.

The latches that regulate the length of the device should then be engaged.

Next, the latches at each end should be released, allowing rescuers to separate the stretcher into 2 halves. Each half is then placed next to the patient. One rescuer then gently pushes half the stretcher under 1 side of the patient. In some cases it may be necessary to have another rescuer rock the patient to allow proper positioning. The same procedure takes place with the opposite half of the scoop until both halves are aligned beneath the patient. The latch at the head of the device should be engaged first. The lower end of the stretcher is then brought together, and the foot latch is engaged to complete the integrity of the stretcher. The patient's torso should be strapped into place and the head immobilized using a suitable lateral neck stabilizer. The patient can then be lifted onto another device (e.g., Stokes stretcher or backboard) for transport. After placement on another device, the scoop stretcher can be removed without disturbing the patient's position, if necessary.

**Full-body spine boards (backboards).**

There are several ways of placing a patient onto a spine board. The precise technique used will depend on the space available and the position of the patient within that space.

For *lengthwise extrication*, as from an automobile seat, the patient can be slid, either feet first or head first, onto the backboard. It is important that the patient be moved as a unit during this process.

The end of the backboard should first be placed on the seat or doorsill of the automobile. One rescuer should then stabilize and maintain the backboard level at its opposite end, while other rescuers (at least 2) lift and slide the

body onto the board. Manual cervical stabilization should be maintained throughout the procedure, and rescuers should avoid spinal compression or traction. Once the patient is completely on the board, the board can be slid out and placed on a waiting stretcher.

When space permits, *lateral extraction* is preferred. With the patient in the recumbent position, rescuers may logroll or slide the patient onto the board. As mentioned previously, extreme caution should be used with the logroll maneuver. The logroll maneuver requires the presence of at least 3 rescuers. One rescuer is positioned at the patient's head and applies manual cervical stabilization. It will be this person's responsibility to oversee and direct body movement throughout the procedure. The backboard is then positioned next to the body. To minimize thoracolumbar movement, the patient's arms should be extended at the sides with the palms resting on the lateral thighs. [28] If 1 arm is injured, the backboard should be placed against this side, so that the patient can be rolled onto the uninjured extremity. The other rescuers should be positioned on the side that the patient will be rolled *toward,* with 1 rescuer at the midchest and the other at the legs. The rescuer at the chest should reach across the victim, taking hold of the shoulder and hips, while the other rescuer grasps the hips and lower legs. When everyone is ready, the rescuer at the head gives the command to roll the patient. The patient's back should be examined at this point. The backboard is then

slid under the patient, and when everyone is ready, the rescuer at the head gives the command to lower the patient onto the board. The patient should then be centered and securely strapped to the board.

Alternatively, during lateral extraction, a recumbent patient can be slid sideways onto the spine board. This improvised technique also requires the presence of 3 or 4 rescuers, 1 of whom can maintain control of the patient's head and neck.

Various techniques can be used to secure a patent onto the backboard. The effectiveness of 4 different strapping techniques in reducing lateral motion of volunteers restrained on a backboard was studied by Mazolewski and Manix. [41] These investigators found that the addition of an abdominal strap significantly reduced lateral motion without compromising respiration. Aside from this study, there is little scientific basis for the various strapping techniques, and in many cases the methods used are determined by local protocol.

When strapping a patient to the board, the first step is to secure the body in place. One method involves using 2 straps crossed over the chest to secure the thorax in place. This can be augmented by a third strap placed just under each axillae and across the chest. Additional straps are then placed at the hips and lower legs (Fig. 49-19) . After the body has been strapped to the board, the head can be secured. If necessary, padding should be placed under the occiput to maintain the head in neutral position. A lateral neck stabilizer (e.g., foam blocks or a Headbed device) is then applied and the head secured in place using tape or straps. Most taping techniques involve the use of 1 piece across the forehead and 1 piece across the cervical collar. Note that this method of securing a patient to a backboard is designed for horizontal lifting only.

### Standing Position

The standing patient with a potential spine injury must be immobilized and placed in the supine position. One technique for placing these patients on a backboard that is quick, safe, and effective is presented here (Fig. 49-20) (Figure Not Available) . [42] The tallest rescuer should be positioned behind the patient to manually stabilize the head while a second rescuer applies an extrication collar. The first rescuer must maintain manual cervical stabilization until the patient is completely secured to the board. The backboard should be centered behind the patient between the arms of the rescuer who is stabilizing the neck. Facing the patient, 1 rescuer on each side should each reach under the patient's arm and grab the backboard by a handhold at or above the patient's axillae. The patient's elbows are then brought closer to the body. If an additional rescuer is available, this rescuer should be positioned at the feet to prevent the board from sliding out, particularly on slippery surfaces. The patient should be slowly tilted back by lowering the head of the backboard. The rescuer at the head should step back during this process while maintaining the patient's head and neck in neutral alignment. When the backboard is completely horizontal, the patient can be secured to the backboard in the normal fashion.

## Complications

In general, complications are more likely to occur as a result of failure to immobilize spinal injuries before movement than from the technique of immobilization. When complications do arise, they may be related to improper choice or use of equipment. The wide variation of situations that are encountered routinely in the field call for a common-sense approach to spinal immobilization.

Victims are generally belted in place on a spine board to prevent sliding during transport. If too few straps are used or if the straps are loosely applied, motion during transport can occur. Patients who are strapped too firmly in place may complain of extreme discomfort and even panic. Excessive strapping can interfere with respiratory function in both children and adults.

Once strapped into place, an unresponsive patient who vomits should be protected from aspiration. The traditional means is to logroll the board and patient as a unit to the side. Although this procedure may be associated with some spinal movement, the airway takes higher priority.

**Summary**

The wide variety of circumstances in which a traumatized patient is likely to be involved mandates the need for many approaches to full-body spinal immobilization. The overall goal of rescuers is to fasten the victim to a board-like full-body immobilizer. After early application of an effective cervical *collar*, this process involves the following steps:

1. Application of a cervical *extrication splint* that serves to immobilize the cervical and thoracic spine. This sort of device is often used when the patient is first encountered in a confined environment, such as a wrecked automobile or bathtub.
2. Placement of the patient on a full-body spine board, a scoop stretcher, or a factory-designed full-body immobilizer.
3. Application of lateral immobilization support devices for the head.
4. Use of straps to fasten the patient securely to the backboard.
5. Placement of the immobilized patient into a rescue litter, such as a Stokes basket stretcher, if complex terrain must be traversed.

## UPPER EXTREMITY SPLINTING

Fractures and dislocations of the upper extremity are extremely common injuries. Although upper extremity injuries are rarely life threatening, it is important to assess and manage these injuries properly. Appropriate splinting of a minor fracture or dislocation, in addition to decreasing pain, reduces the incidence of serious complications and the risk of permanent disability.

The rescuer must not let obvious injuries to the extremities be a distraction to the care of more life-threatening injuries. In some situations it may be necessary to rapidly secure the patient to a long backboard that supports and splints every bone and joint of the body in one efficient step. [1] Injuries to nerves or blood vessels are a frequent

complication of upper extremity trauma. Circulation, motor function, and sensation distal to the injury must be assessed early and monitored closely.

The purpose of splinting is to prevent motion of broken or dislocated bone ends. Carefully applied splints decrease pain while minimizing further damage to muscles, nerves, and blood vessels. Splinting also reduces the risk of converting a closed injury to an open one. [46]

## Indications and Contraindications

Indications for splinting an extremity are usually clear. Pain with or without deformity following trauma should arouse suspicion for underlying bone or joint injury. Other signs include swelling, discoloration, deformity, crepitus, or loss of neurovascular function. The absence of these findings does not always rule out an underlying fracture or dislocation. Whenever a musculoskeletal injury is suspected, a prophylactic splint should be applied and maintained. The old axiom, "if in doubt, splint," should be followed.

There are no contraindications to splinting suspected upper extremity fractures or dislocations. However, in the setting of multisystem trauma with life-threatening injuries, rapid transport may be more important than extremity splinting. Averting loss of life takes precedence over averting loss of limb.

## Equipment

Various splints are currently available for immobilizing upper extremity injuries. They can be divided into 2 basic types: rigid and soft. [1]

*Rigid splints* are made of many different materials, including cardboard, plastic, aluminum, wire, and wood. These splints must be fastened to the injured extremity using tape, gauze, cravats, or Velcro straps. They are nonflexible and, when applied, immobilize the limb in a rigid fashion to maintain stability. Although some rigid splints are prepadded, many others require the use of cotton or some other soft material. When applying rigid splints, the fingertips should be left exposed so that distal circulation can be monitored.

Cardboard splints are excellent for long-bone fractures of the upper arm. They can be formed into any desired shape and are inexpensive. Plastic, aluminum, wire, and wood splints, although less malleable, are also good choices. An inexpensive aluminum splint that is popular in wilderness medical kits is the SAM splint (The Seaberg Company Inc, South Beach, Ore). The SAM splint is foam padded for comfort, water resistant, lightweight, radiolucent, and reusable. These characteristics also make it an ideal tool for disaster medicine. [47]

Vacuum splints (Fig. 49-21) (Figure Not Available) are a special type of rigid splint in which the air is evacuated from a closed bag containing tiny foam beads. This compresses the contents into a solid mass, resulting in a rigid splint. Injuries can be

encased and immobilized in the position in which they are found, thereby reducing patient discomfort. Flexibility of the splint before removal of air allows molding of the splint to conform to the patient's position. Vacuum splints are radiolucent and do not apply external pressure to the injured extremity.

*Soft splints* include air splints, pillows, slings, and swaths. Immobilization with pillows, slings, or swaths alone is usually inadequate, because they allow significant flexibility and motion. These splints are therefore most effective when used with some form of a rigid device.

Air splints are soft splints that become rigid when inflated. Besides providing immobilization, they help compress underlying soft tissue to reduce local hemorrhage. These devices are sensitive to differences in atmospheric pressure and temperature. Therefore, their inflation must be constantly monitored to ensure that the underlying tissue is not subject to pressure-induced ischemia. One study suggests a maximum splint pressure of 15 mm Hg to reduce the risk of ischemia. [48] With long ambulance transports, the splint should be deflated for 5 minutes every 1.5 hours. [49] A significant disadvantage is that pulses can no longer be monitored once the air splint is in place. Air splints are designed to conform to a specific shape when inflated and should not be used on angulated fractures. In addition to being radiolucent, some types can be inflated with a refrigerant to provide concurrent cooling.

Pillow splints (Fig. 49-22) can be fashioned from any soft bulky material and are excellent choices for hand or wrist injuries. These splints are extremely comfortable and can be easily applied.

Slings and swaths are usually used in combination with a rigid or soft splint. When used alone, they can effectively immobilize injuries to the shoulder, clavicle, or humerus.

**Procedures**

To apply a splint properly to an injured extremity, several general rules must be followed. Communication is important to ensure that the patient understands what is being done at all times. If necessary, clothing should be removed to adequately visualize the injured extremity. Manual stabilization of the fracture site helps limit unnecessary movement and prevent further injury. The neurovascular status (i.e., pulse, motor, and sensation) should be checked before and after the application of a splint. With a severely angulated extremity, traction not exceeding 10 lb of pressure may be applied to reduce the deformity. If resistance or pain is encountered, the extremity should be splinted in the position found. Open wounds should be covered with a sterile dressing before a splint is applied. The splint (Table 49-1) should be applied using the orthopedic principle of immobilizing the joint above and below a suspected fracture site. Cooling and elevation of the injured area may help reduce local swelling. Once the splint has been applied, the distal neurovascular status should be assessed frequently. Any deterioration requires immediate evaluation of the splint to determine if excess pressure is being applied.

**Rigid Splints**

To apply a rigid splint, an assistant should provide support and gentle traction above and below the injury. The splint is then applied on the side of the extremity away from any open wounds. The splint should be large enough to immobilize the joint above and below a fracture or the bone above and below a dislocation. The splint should be well padded

| TABLE 49-1 -- Management of Specific Upper Extremity Orthopedic Injuries | | |
|---|---|---|
| **Site** | **Injury** | **Suggested Immobilization Techniques** |
| Clavicle | Fracture | Sling and swath |
| Shoulder | Dislocation | Sling and swath as it lies |
| Humerus | Fracture | Cardboard or vacuum splint with sling and swath |
| Elbow | Fracture or dislocation | Cardboard or vacuum splint as it lies |
| Forearm | Fracture | Cardboard, malleable metal, air, or vacuum splint with sling and swath |
| Wrist | Fracture | Pillow, cardboard, malleable, metal, or vacuum splint applied in position of presentation |
| Hand | Fracture | Pillow splint in position of function |

| Finger | Fracture | Tongue depressor or small malleable metal splint |
|---|---|---|

to reduce the risk of pressure necrosis. The splint is then secured to the extremity using gauze or tape (Fig. 49-23) .

Vacuum splints are applied in much the same manner as other rigid splints. While an assistant stabilizes the injured site and applies traction, the splint should be wrapped around the extremity and secured with the attached straps.  The air is then evacuated from the splint by means of a hand pump until the splint becomes rigid.

**Soft Splints**

The application procedure for an air splint depends on whether the splint is equipped with a zipper. If the splint does not have a zipper, it must first be placed on the rescuer's arm until the bottom edge lies above the wrist. Next, the rescuer grasps the hand of the patient's injured extremity, while the free hand is used to provide support and gentle traction above the injury (Fig. 49-24 *A*). An assistant should then slide the splint onto the patient's arm (see Fig. 49-24 *B*). After making sure that the splint is not wrinkled, it should be inflated until finger pressure makes a slight dent (see Fig. 49-24 *C*). Zippered air splints should be opened and placed around the injured area. The zipper should be closed and inflation accomplished as discussed previously. With air splints that completely enclose the hand, distal circulation must be assessed by checking capillary refill at the nailbeds.

Pillow splints are applied by encasing the injury in the pillow and securing with tape, cravats, or gauze (see Fig. 49-22) . If possible, the nailbeds should remain exposed to allow for assessment of circulation.

To apply a sling, an assistant should support the injured arm in a flexed position across the patient's chest. The long edge of the triangular bandage should then be placed lengthwise along the patient's side opposite the injury, with its tip over the uninjured shoulder (Fig. 49-25) . The other tip is then brought over the injured shoulder to enclose the arm in the sling. The sling should be adjusted so that the arm rests comfortably with the hand higher than the elbow. The sling is then tied together at the side of the neck, and the knot is padded for patient comfort. The point of the sling at the elbow should be drawn around to the front and pinned. With the sling properly applied, the patient's arm rests comfortably against the chest with the fingertips exposed (Fig. 49-26) .

To apply a swath, a cravat of sufficient length should be placed under the uninjured arm and over the injured arm at the level of the midhumerus. This should then be fastened circumferentially around the thorax so that the injured extremity is secured snugly to the chest (Fig. 49-27) . In adults, 2 cravats may have to be tied together in an end-to-end fashion to produce a swath of sufficient length.

**Complications**

Potential complications of upper extremity splinting include pressure necrosis, conversion of a closed injury into an open one, and loss of neurovascular function. With the use of air splints, there is the additional risk of pressure-induced tissue ischemia and compartment syndrome.

**Summary**

Injuries to the upper extremities, although not life threatening, can have significant immediate or long-term effects. A high index of suspicion for underlying neurovascular injury should always be maintained. Neurovascular status must be checked before and after application of splints and monitored frequently throughout transport.

## LOWER EXTREMITY SPLINTING

Many of the principles, techniques, and complications discussed with upper extremity splinting also apply to injuries of the lower extremity (Table 49-2) ; the pillow splint is 1 example (Fig. 49-28) . In addition, the pneumatic anti-shock garment (PASG) can also be used as an effective splinting device for lower extremity injuries (see Chapter 30) . Prolonged use of the PASG as a splinting device is discouraged, since it has been associated with an increased incidence of compartment syndrome. [50] The following discussion is limited to lower extremity traction splinting.

The use of traction and counter traction for the alignment and reduction of fractures dates from the time of Hippocrates. [51] In the late 1800s, Sir Hugh Owen Thomas developed the first full-ring traction splint for the definitive management of fractured femurs. [51] Since the Thomas full-ring splint was not an emergency treatment device, it was later modified by his nephew, Sir Robert Jones, and other surgeons to a half-ring splint that made it easier to apply in the field. During World War I, the modified splint was credited with reducing the mortality rate associated with fractured femurs from 80 to 15%. [52] Since then, several additional modifications that carry the name of their inventors (e.g., Glenn Hare, Joseph Sager, Allen Klippel) have furthered the development of lower extremity traction splints.

In the setting of a fractured femur, muscle spasm and fragment overlap may cause the thigh to lose its cylindrical shape and adopt a more spherical appearance. [51] The resultant decreased tissue pressure and increased volume may allow 1 to 2 L of blood to accumulate at the fracture site. Traction splints are designed to restore the cylindrical shape of the thigh, which in turn increases tissue pressure and inhibits further hemorrhage.

**Indications and Contraindications**

Application of a lower extremity traction splint is indicated whenever a fractured femur is suspected. This should be clinically suspected when there is shortening, angulation, crepitus, swelling, or ecchymosis of the thigh with pain. The use of a traction splint will help align the fracture fragments, relieve pain, prevent damage to neurovascular structures, and reduce blood loss.

It is controversial whether traction should be applied to an open femur fracture. Concern has been expressed that the use of traction may allow contaminated bone fragments to retract into the wound. Should traction produce bony retraction into the wound, this information must be relayed to the receiving physician. A workable compromise is to use the splint to apply sufficient traction to achieve stabilization without retraction. Alternatively, a vacuum splint or the PASG can be used to immobilize the bony fragments in the position of presentation. In any case, stabilization of the fracture site to prevent further hemorrhage, neurovascular damage, or soft tissue injury should take precedence over the theoretical risk of increased contamination.

**Equipment**

Although the lower extremity traction splints currently in use have been updated slightly, the product comparison by Dick is useful (Fig. 49-29) (Figure Not Available) . [53] Except for Sager-type devices, most traction splints produce flexion at the hip joint because of their half-ring design. This flexion of up to 30° does not allow complete fracture alignment, unless the patient is in a reclining position about 30° from horizontal or the injured extremity is elevated to create the same angle.

**Procedure**

When possible, the splinting procedure should be explained to the patient. There is always pain associated with the application of a traction splint, but the patient should be reassured that the resultant stabilization of the fracture site will help reduce subsequent discomfort. The area of injury should be exposed and the distal neurovascular status assessed before application. Open fractures should be managed as discussed previously. If the injured leg is markedly deformed, it should first be straightened using manual traction and maintained in that position by an assistant until a splint has been applied.

If the splint has an adjustable bar, the noninjured extremity can be used for length adjustment. The splint should extend approximately 25 to 30 cm beyond the heel. With the extremity slightly elevated, the *half-ring splint* (e.g., Hare splint [Dyna-Med, Carlsbad, Calif]) is placed under the injured leg and brought to rest firmly against the ischial tuberosity. *Sager-type devices* (Sager splint [Minto Research and Development, Redding, Calif]) should be placed either against the symphysis pubis or positioned laterally against the greater trochanter of the femur (Fig. 49-30) . When the padded end of a Sager-type device is placed in the groin, one should ensure that the genitalia are carefully protected. Once the splint is properly positioned, the thigh strap should be

firmly secured.

A harness is then placed around the ankle immediately above the medial and lateral malleoli and attached to the distal end of the traction splint. Traction is then applied gradually to approximately 10% of body weight or a maximum of 22 to 25 lb (10 to 12 kg). For the *Sager-type devices*, the inner shaft of the splint must be extended until the desired amount of traction is achieved (see Fig. 49-30) , whereas the *Hare splint* uses a ratchet mechanism to apply traction to the ankle strap.

Before movement, supportive straps are applied around the thigh, knee, and distal leg to vertically stabilize the extremity. After application of the splint, the distal neurovascular status should be rechecked. The loss of pulses with application of a traction splint requires that the position of straps and the amount of applied traction be reassessed immediately. Once the splint is applied, the position of the splint and the patient's neurovascular status should be rechecked following any patient movement. Removal of a traction splint should be done in reverse order of application.

### Special Considerations

The traction splints in common use can be applied before application of the PASG. Except for Sager-type devices, application of the PASG over a traction splint is awkward and associated with uneven pressure distribution. In addition, Sager-type devices are advantageous in that they can be applied *before* or *after* application of the PASG.

Unless the patient is found in an extremely cold environment, the shoe on the injured extremity should be removed before splinting to allow for assessment of neurovascular status. Furthermore, this facilitates monitoring of changes in color, temperature, or pulse distal to the injury en route to the hospital. The shoe can be removed by cutting the shoelace and pulling forward on the tongue of the shoe. The underlying sock can then be removed using scissors to prevent movement of the fracture site. Removal of the shoe and sock of the noninjured foot will allow comparison of the distal extremities.

The use of Sager-type devices is not recommended in the presence of an associated distal tibia-fibula or ankle fracture in the same extremity. In these circumstances, the amount of traction required to realign the fractured femur can distract the distal fracture site. Similarly, splints that incorporate part of the foot in their design may not be usable in the presence of an unstable foot fracture in the same extremity. A cardboard splint or the PASG should be considered in these settings.

### Complications

Complications are generally the result of incorrect application and include ongoing hemorrhage, perineal injury, movement at the fracture site, or neurovascular compromise. Once the fracture site is stabilized, additional traction is unnecessary and potentially dangerous.

**Summary**

A properly applied traction splint will limit hemorrhage and movement associated with femur fractures. Careful monitoring of distal neurovascular status is imperative with the use of these splints.

# HELMET REMOVAL

Although originally developed for protection of the head during combat, helmets are commonly used by athletes (e.g., football and hockey players) and motorcyclists. The use of helmets has been shown to reduce the incidence and severity of head injuries associated with motorcycle crashes. Increasing use of helmets in other sporting activities (e.g., kayaking, lacrosse, and roller blading) and by bicyclists and moped riders will further increase the frequency of appearance and the spectrum of injuries associated with helmet use in the out-of-hospital setting. Most modern helmets consist of an inner layer of foam material covered by a hard plastic shell. Helmets can be modified by additional padding so that they conform tightly to the individual's head. Although earlier studies suggested that the use of motorcycle helmets may be associated with an increased incidence of cervical spine injury, this concern has not been substantiated in the recent literature.

Careless removal of a helmet must be avoided, as this may exacerbate an underlying cervical spine injury. In 1980, the American College of Surgeons endorsed the helmet removal technique discussed in this chapter. [59] As the rapid transport of injured patients from the out-of-hospital setting to the hospital is stressed, the desirability of helmet removal in the field setting is likely to receive greater scrutiny.

**Indications and Contraindications**

There are 2 schools of thought with regard to helmet removal in the out-of-hospital setting. One theory suggests that removal of helmets is rarely necessary, since the helmet itself provides for excellent spinal immobilization. The other philosophy recommends routine removal of the helmet so that the patient is completely exposed and the rescuer has full access to the head and neck for airway management, hemorrhage control, and cervical spine stabilization. Since it is difficult to monitor the airway with a helmet in place, most rescuers prefer to remove the helmet whenever possible.

If local protocols do not allow for helmet removal, the airway may be accessed by lifting away the visor or by removing the face guard using bolt cutters or a screwdriver. Cervical spine immobilization can usually be maintained with a properly fitting helmet by using tape, foam blocks,

and a backboard. In these cases the helmet will have to be removed in the ED to allow for complete examination of the head and neck and to help facilitate ancillary studies.

The only absolute contraindication to helmet removal is neck pain associated with the procedure. Other relative contraindications to helmet removal include unfamiliarity with the technique and lack of sufficient assistance. [57]

## Procedure

Proper removal of a helmet requires at least 2 individuals along with manual stabilization of the cervical spine throughout the procedure.  Although a 1-person technique of helmet removal has been described, it is best for 2 rescuers to remove the helmet, especially in the setting of an unconscious or uncooperative patient.

One rescuer establishes neutral position by placing his or her hands on each side of the helmet with the fingers on the victim's mandible (Fig. 49-31) (Figure Not Available) . The second rescuer then cuts or releases the chin strap and assumes manual stabilization by placing 1 hand on the patient's mandible and the other hand on the occiput. The first rescuer then gently removes the helmet by grasping it at the base and expanding it laterally to clear the ears. Some helmets may need to be tilted backward to allow the chin guard to clear the nose. The second rescuer must be prepared to assume the weight of the head as the helmet is removed. The first rescuer then reassumes the responsibility for manual stabilization and neutral positioning while the second rescuer applies a rigid extrication collar. Both rescuers should *avoid in-line traction* during helmet removal to reduce the risk of subluxation or distraction of an unstable cervical spine. [60]

In a volunteer study, Meyer and Daniel have shown limited motion of the cervical spine with this removal technique. [61] The presence of a folded sheet or jacket placed behind the patient's shoulders was also found to limit any cervical motion associated with helmet removal. [61] In contrast, Aprahamian and colleagues demonstrated that manual helmet removal adversely affected a surgically created unstable cervical spine injury in a cadaver model. They recommended the use of a cast-cutter saw to divide the helmet into 2 pieces in the coronal plane and thereby facilitate

removal. Following division of the helmet shell, the inner foam material may be cut with a scalpel or other sharp blade. Although this approach does provide an alternate method of removing the helmet, the intense vibrations produced during use of the cast cutter may exacerbate an underlying spinal injury. In addition, the technique would be slow and difficult with modern, well-fitting, high-quality helmets. [57] Alternatively, immediate removal of the chin piece using a cast-cutter or other saw may permit rapid airway access and allow for safer removal of the entire helmet.

## Complications

Underlying cervical spine injuries may be exacerbated by failure to adhere to proper helmet removal techniques. Although no controlled studies have demonstrated the safety of manual cervical stabilization, its efficacy during endotracheal intubation of the

trauma patient suggests that little movement is likely during helmet removal.

**Summary**

Airway management and cervical spine stabilization may be complicated by the presence of a helmet. Out-of-hospital helmet removal can be accomplished in a safe and effective manner using a 2-person technique.

# Chapter 50 - Management of Amputations

**William C. Dalsey**

"Injury occurs to the hand more frequently than to any other part of the body and the first person caring for an injured hand will probably determine the ultimate stage of its usefulness." [1] Rapid and appropriate emergency care of a patient with an amputated part is crucial to the salvage and preservation of function. This chapter discusses the acute care of amputated parts before they are replanted and specifically addresses the management of distal digit amputations and dermal "slice" wounds.

Amputation may be partial or complete. Injuries with interconnecting tissue between the distal and proximal portions, even if there is only a small piece of bridging skin, technically are considered incomplete, or partial, amputations. Complete amputations are replanted, whereas partial amputations are revascularized. This distinction is arbitrary; for emergency physicians, treatment for both injuries is very similar. The prognosis and outcome of partial and complete amputations are similar, although partial amputations often have better venous and lymphatic drainage, and functional recovery may be more complete if there is less anatomic damage.

The peak incidence of traumatic amputations occurs between the ages of 20 and 40 years, [2] [3] and men predominate over women at a ratio of 4:1. Local crush injuries are the most common mechanism of injury, and sharp guillotine amputations are the least common. [4] [5] [6] [7] Partial amputations occur as often as total amputations. [8] Power saws and lawn mowers are frequently the instruments of destruction. [8] Proximal amputations are less common than distal amputations.

The media have exaggerated somewhat the success of replantation and have often generated unrealistic expectations from the public. The technical limitations of successful repair of vessels that are <0.3 mm in diameter usually preclude replantation of digits distal to the distal interphalangeal joint. [9] Successful revascularization of amputated parts often ensures viability, but neurologic, osseous, and tendinous healing are critical for ultimate function. If there is incomplete neurologic recovery, limited range of motion, and intolerance to cold, the replanted part may have little functional value for the patient. Rehabilitation from replantation surgery may be prolonged, often requiring >1 year and repeated surgical procedures. The emergency physician should be aware of the limitations of replantation surgery and should not encourage unrealistic expectations in injured patients or their families.

## BACKGROUND

The possibility of restoring viability and function to traumatically severed parts has fascinated physicians for centuries. Physicians have attempted to replant parts with little more than a few sutures and secure bandaging and occasionally have had spectacular results. One of the earliest medical reports was by Fiorvanti, who in 1570 reported the successful replantation of a soldier's nose, which was severed by a saber, after first cleansing it with urine and then carefully bandaging it.  In 1814, Balfour reported the

successful replantation of a finger, which was severed by a hatchet, [12] using only meticulous alignment and secure bandaging. The ability to consistently replant amputated parts awaited the development of modern microvascular surgical techniques. The first reported successful upper limb replantation was by Malt and McKhann in 1962. [13] Later that year, a successful replantation of a hand and arm was reported by Chen and Pao. [14] Developments in microsurgical techniques, advanced optics, and microsurgical instruments have created the ability to consistently replant amputated parts with a high degree of success. Since 1965, when Kleinert and Kasdan reported the first successful microvascular anastomosis of a digital vessel, [15] there have been several large series of replantations, with success rates ranging from 70 to 90%. [16] To the original pioneers in replant surgery, survival of the replanted tissue was the criterion for success, but with further refinements, today's surgeons emphasize functional recovery as well as viability. The replantation of a part that is painful or useless or that interferes with function is a disservice to the patient and is less desirable than early restoration of function without replantation.

## INDICATIONS

Preservation of the amputated part is generally indicated when replantation or revascularization is a potential therapeutic method for care of the injured part. Revascularization and reanastomosis of partially and completely amputated parts should be provided when there is hope of preservation or restoration of function. Aesthetic considerations, patient avocations, and occasionally religious or social customs may also influence the decision to proceed with surgery. [29] [30] [31] Ultimately, the decision must be reached by both the operating microsurgical team and the patient after a rational explanation of potential results and successes.

Indications for replantation of fingers and hands have been proposed and are generally accepted, although they should not be applied rigidly to all circumstances. Successful functional recovery is more likely in distal than in proximal extremity amputations and in multidigit amputations, single-digit thumb amputations, or transmetacarpal amputations. [32] [33] Generally these are indications for replantation (Table 50-1) . Single digits proximal to the distal interphalangeal joint and distal to the flexor digitorum superficialis may be replanted successfully, with good functional recovery.

Successful replantations have been reported in patients from the ages of 1 to 84 years. There are no fixed age limits for replantation, although particularly good results have been reported in children owing to their regenerative capacity and adaptability to rehabilitation. The decision to replant is made on a case-by-case basis by the microsurgical team, which must weigh all the factors involved.

## CONTRAINDICATIONS

There is no contraindication to managing the amputated part and stump as though replantation were going to occur, even

| TABLE 50-1 -- Replantation of the Amputated Extremity |
|---|
| **Indications** |
| Young stable patient |
| Thumb |
| Multiple digits |
| Sharp wounds with little associated damage |
| Upper extremity (children) |
| **Absolute Contraindications** |
| Associated life threats |
| Severe crush injuries |
| Inability to withstand prolonged surgery |
| **Relative Contraindications** [*] |

| |
|---|
| Single digit, unless thumb |
| Avulsion injury |
| Prolonged warm ischemia (12 hr) |
| Gross contamination |
| Prior injury or surgery to part |
| Emotionally unstable patients |
| Lower extremity |

\* If the victim is a child or if there are multiple losses, salvage replantations are attempted, and the relative contraindications are ignored.

when replantation is considered unlikely by the emergency physician. The care of the entire patient must take precedence over that of the amputated part, although the requirements of the amputated part and stump can often be handled by ancillary personnel during resuscitation and transportation of the patient. Contraindications to replantation are listed in Table 50-1 and are discussed in the following sections. Note that even when replantation is contraindicated, tissue (skin, bone, tendon) from the amputated part may be useful in restoring function to other damaged parts. Never discard amputated tissue until all possible uses of the severed parts are considered. For example, even though an amputated fingertip is not suitable for replantation, the skin may be an ideal donor source for a skin graft to the stump.

## GENERAL CONSIDERATIONS

### Mechanism of Injury

The potential for successful replantation in terms of survival as well as useful function is directly related to the mechanism of injury. Guillotine injuries, which are sharp, are the least common but have the best prognosis owing to the limited area of destruction.

Crush injuries, which are the most common, produce more tissue injury and therefore have a poorer prognosis. The avulsion injury has the worst prognosis, because a significant amount of vessel, nerve, tendon, and soft tissue injury invariably occurs.

**Ischemia Time**

The time that an amputated part can survive before replantation has not been determined. After 6 hours, additional delay may decrease the success rate of revascularization and lead to diminished function. Skin, bone, tendons, and ligaments tolerate ischemia much better than do muscle and connective tissue. Therefore, as a general rule, the more proximal the amputation, the less ischemia time the amputated part can tolerate. Attempts to extend viability during ischemia have shown that the most important controllable factor is the *temperature* of the amputated part. Warm ischemia may be tolerated for 6 to 8 hours. [41] When the part is cooled properly to 4 °C, 12 to 24 hours of ischemia may be tolerated with distal amputations.  There is a report of a successful digital replantation after 33 hours of cold ischemia. [42] The way in which hypothermia protects tissue from ischemia is currently under investigation. It has been postulated that hypothermia may limit metabolic demand, thereby preserving intracellular energy.  Other investigations suggest that the effect is due to the retardation in development of an acidotic pH. [47] Hypothermia may also prevent the no-reflow phenomenon that can follow low-flow states.

Delay in replantation of proximal arm and leg amputations containing significant amounts of muscle tissue can lead to the buildup of toxic products. In such cases, when blood supply is restored, the absorbed toxins have been reported to cause respiratory failure, renal failure, cardiovascular collapse, and even death.

Perfusion techniques such as those used in organ transplants to extend anoxic time have not yet been developed. In the past, surgical teams used intraoperative perfusion as a technique to help cool the amputated part. The benefits of intraoperative perfusion with cold hypertonic solutions are

currently being investigated. Perfusion should not be attempted by emergency physicians. The risk of damage to vessels and the potential delay in care and rapid transport of the patient and the amputated part override the theoretic benefits of emergency department (ED) cold perfusion at this time.

## SPECIAL CONSIDERATIONS

**Hand Function**

Hand function is often determined in part by pinch and grasp functions. If the index finger is removed, the pinching function of the index finger is adequately provided by the middle finger. Power in grasping and gripping is mainly considered an ulnar function of the fourth and fifth digits. An effective grip that provides the ability to hold a variety of objects is a central function of the ring and middle fingers. In addition to its function in pinching, the thumb is the major opposing force for successful grip and grasp. The

thumb is the most important digit for adequate hand function, and its loss results in 40 to 50% disability. Such disability requires aggressive attempts to replant amputated thumbs. If this is impossible or unsuccessful, pollicization of other digits or toe transfers are secondary alternatives.

## Lower Extremity Amputations

There are few reports of successful replantation of amputated parts of the lower extremity. [63] [64] Indications for replantation of amputated parts of the lower extremity are different from those for replantation of amputated parts of the upper extremity. The goal of all replantation is restored function. If this cannot be achieved, a patient is substantially better off with a prosthesis.

The lower extremity is primarily used for weight bearing and allows the individual to ambulate. Lower limb prostheses, especially those used below the knee, are well tolerated and functional. Prostheses provide a secure stance and permit locomotion. Lower extremity replantation generally requires skeletal shortening, and distal nerve regeneration is often imperfect. Both deficits may produce dysfunction. A patient with a replanted lower extremity with significant shortening and without sensation functions better with a prosthesis. This is not necessarily true of someone with an upper extremity replant. For these reasons, lower limbs are not generally replanted except under ideal circumstances, usually in children, although there are documented cases of successful lower extremity replantation in adults. [63] [64] The final decision regarding replantation should be left to the replantation team.

## Fingertip Amputations and Dermal "Slice" Wounds

Proper treatment of distal fingertip injuries is controversial. Fingertip amputations often heal by normal wound contracture, but occasionally this practice may result in the loss of functional ability to palpate. The basic goals of treatment are to provide tissue coverage, an acceptable cosmetic result, and an early functional recovery. In distal amputations in which the wound area is <10 mm [2] , this is not a problem (Fig. 50-1) (Figure Not Available) . Larger dorsal wounds also heal well by secondary intention. The challenging problem of fingertip injuries occurs when loss of skin and soft tissue from the fingerpad is significant. Volar skin is unique in its combination of toughness and sensitivity. Wounds with significant volar tissue loss frequently require additional treatment. Children, with their regenerative capacity, often progress very well when significant volar wounds are allowed to heal primarily. For older people and for amputations that involve a more significant amount of the distal digit, a wide variety of techniques for managing the injured fingertip have been advocated, including partial-thickness skin grafts; full-thickness skin grafts; V-Y, Kutler, Kleinert, and island advancement flaps; and various local and distal flap coverage techniques. These procedures are designed to preserve length and to provide soft tissue coverage of exposed bone and sensation to the fingerpad. Each of these procedures has its own indications, complications, and limitations. [70] Discussion of these procedures is beyond the scope of this chapter. Most of these techniques are best performed by a specialist in the operating room as primary procedures under ideal circumstances or as delayed

procedures when necessary.

In most complete fingertip amputations distal to the distal interphalangeal joint, the emergency physician can provide adequate care initially with conservative wound management. Although thinking has changed significantly over the years, many hand surgeons still advise skin grafting to shorten the time for wound healing. Although complete transverse amputations could be handled conservatively, wound healing may take several weeks, and these patients may benefit from operative treatments. Patients with complete transections should be referred for consultation to coordinate their initial care and subsequent follow-up.

Incomplete transections and small distal amputations without significant soft tissue loss may heal well with conservative therapy started by the emergency physician. Nonoperative treatment in selected patients provides excellent functional and cosmetic results, minimizes recovery time, and has few complications. Children have excellent regenerative capacity and also respond extremely well to conservative treatment. Necrotic or grossly contaminated tissue should be debrided, and the wound should be irrigated thoroughly. If bone is left exposed without soft tissue coverage, the patient will need an operative procedure; alternatively, the bone may be rongeured (shortened) to allow soft tissue coverage and primary healing with better functional recovery. The nailbed tissues should be preserved, because the presence of a nail affects the cosmetic result. After cleansing and cautious debridement, an occlusive dressing is placed directly over the wound. Tetanus prophylaxis, wound dressings, and bandages, along with placement of a protective splint, complete the initial management of these injuries. Amputations that involve the distal phalanx are frequently treated as contaminated open fractures, with IV antibiotics given initially, followed by a course of oral antibiotics. [75] Wounds managed conservatively must have serial dressing changes and cleansing. Soaking wounds, cleansing, and replacement of dressings help provide superficial debridement, which may aid healing and minimize the chance of secondary infection. Wound contraction and healing usually result in acceptable cosmetic and functional recovery in 2 to 3 weeks. Patients should have appropriate follow-up to ensure adequate healing and recovery.

Partial fingertip amputations distal to the distal interphalangeal joint can also be managed successfully by the emergency physician. These wounds are treated in a manner similar to that for complete amputations. However, when the amputation has substantial undamaged tissue connecting the fingertip, careful alignment and stabilization are provided by sutures or bandaging and protective splinting. Partially amputated fingertips, especially in children, may occasionally survive and regain vascularization and sensation. If the distal tissue becomes ischemic and necrotic, the amputation becomes complete.

Injury to the nailbed requires special attention to ensure proper alignment. If the nailbed tissues are not aligned properly, permanently disfigured nails may result. Removal of the nail helps provide adequate visualization for the placement of sutures and also minimizes the risk of contamination of the wound.

Dermal "slice" wounds (type 1 in Fig. 50-1) (Figure Not Available) are managed by

gentle wound cleansing and application of an antibiotic ointment and a nonadherent dressing, followed by a pressure dressing (e.g., tube gauze). At a dressing change 48 to 72 hours after the initial treatment, the patient can be instructed on daily changes of nonadherent dressings for 10 to 14 days until functional epithelialization of the wound occurs. A protective finger splint or guard also minimizes the risk of further injury and pain from trauma to the sensitive wound area. Protection allows an earlier return to function and employment. Wounds larger than 10 mm [2] and those with deep loss of digit pulp tissue may be candidates for skin grafting (see Chapter 38) .

### Penis, Ear, and Nose Amputations

Replantation of the penis, ear, and nose generally results in better function and cosmesis than a prosthesis or reconstructive surgery. The amputated parts and wounds should be handled as they are for digital replantations.

Penile amputations are an uncommon problem. Most cases result from self-inflicted trauma in patients who are severely psychologically disturbed. Successful replantation has been reported using microsurgical techniques. Preservation or reconstruction of the urethra to maintain a competent urinary stream is critical for success.

Ears and noses frequently are partially amputated and occasionally are totally amputated. Whenever possible, these body parts should be replanted unless they are severely traumatized and there is gross contamination. These wounds frequently heal well, and patients with such wounds have a high survival rate and a low incidence of total necrosis. Replantation of these parts requires good suture technique and careful placement but does not necessarily require skill in microsurgical techniques.

## ASSESSMENT OF THE PATIENT

The initial care and treatment of the patient who has had a body part amputated are the same as those for any trauma patient. The physician must not be distracted by the amputated extremity or the excitement of others from assessing and stabilizing the patient's airway, breathing, and circulation

. Amputations are generally not life-threatening injuries, and other potentially more serious injuries must first be assessed and treated. Hemorrhage from amputated limbs is often limited by the retraction and spasm of severed vessels. Therefore, partial amputations may result in more serious hemorrhage than if the vessels were totally severed. Usually hemorrhage can be controlled adequately with direct pressure and elevation. Vascular clamps and hemostats have no role in the ED management of these injuries and may cause additional injury that may make replantation impossible. A proximally placed blood pressure cuff inflated 30 mm Hg above systolic pressure can be used for short periods of time (<30 minutes) to control severe bleeding, if necessary.

After the initial primary assessment and treatment and subsequent stabilization of the patient, care of the stump and amputated part can be initiated safely. In addition to the general history obtained from all trauma patients, particular attention should be focused

on the exact mechanism of injury, the time and duration of injury, handedness, allergies, medications, illness, prior injury to the affected part, care of the stump and amputated part before arrival in the ED, occupation, avocations, and tetanus history.

Tetanus prophylaxis and broad-spectrum systemic antibiotic therapy (e.g., cephalosporins) should be initiated. Analgesic medications may be necessary, especially with crushing injuries, for managing patient discomfort. The dose of IV opioids should be titrated to the clinical condition. In fingertip amputations, digital or regional nerve blocks are ideal for pain relief but may make functional and neurologic evaluation by a consultant impossible. Some physicians recommend the early use of aspirin, low-molecular-weight dextran, or both for amputation patients, but such attempts to maintain small vessel perfusion are controversial and have not proved efficacious in preoperative treatment.

Amputation patients often experience denial, shock, disbelief, and feelings of hopelessness about their injury; some have even become suicidal. Patients should be treated with supportive and realistic reassurance, but unrealistic medical promises should be avoided. It is important that the emergency physician (or other nonreplantation specialist) not speculate on the specifics of the ultimate prognosis.

Examination of the stump may be brief and should primarily be an assessment of the degree of damage to the surrounding tissue. Gross contamination can be removed by irrigation with normal saline. Local antiseptics, especially hydrogen peroxide or alcohol, should *not* be used, because they may damage viable tissues. Similarly, tissues should not be manipulated, clamped, tagged, or further traumatized in any way. It is important to assess the degree of contamination, the level of injury, and any concomitant injury, such as crushing or multiple levels of injury or amputation. The amputated part should also be examined for the degree of tissue injury, contamination, and possible distal injuries. Radiographs of the amputated part and proximal stump to the level of at least 1 joint proximal to an extremity injury should be obtained. Preoperative laboratory studies and IV access in an uninjured extremity should also be initiated.

The neurologic status of the stump or distal extremity in partial amputations should be assessed by pin prick and 2-point discrimination tests. The presence of sweat may indicate autonomic-neurologic functioning. Vascular competence can be assessed by noting the color, temperature, capillary refill, and presence of pulses. An Allen test at the wrist or a modified Allen test at each digit may aid in determining the existence of an arterial injury (see Chapter 19) . The neurovascular status should be carefully and clearly documented in the medical record. Motor and tendon function should be evaluated immediately. The regional microvascular resource center should be contacted as soon as possible to arrange transportation and to provide adequate time for mobilization of the replantation team.

## CARE OF THE STUMP AND AMPUTATED PART

The stump can be evaluated, and primary care can be rendered during the secondary assessment of the trauma victim (Table 50-2) . If replantation is proposed, the goals of initial care include control of hemorrhage and prevention of further injury or

contamination. All jewelry should be removed. The stump should be irrigated with normal saline to remove gross contamination. Debridement and dissection should be done by a specialist. Do not clamp arterial bleeders. The stump wound should then be covered with a *saline-moistened* sterile dressing to prevent further contamination and to limit damage from desiccation. The stump should be splinted for protection and for the prevention of further injury from concomitant fractures or compromise of blood flow owing to change in position. Splinting and elevation may reduce the extent of edema and help control bleeding.

Care of the amputated part follows the same general guidelines as that for the stump. Gross contamination can be eliminated by irrigation with saline. All jewelry should be removed. The amputated part should be handled minimally to prevent further damage and should be wrapped in a saline-moistened sterile dressing. *Direct immersion in saline or hypotonic fluids should be avoided*, because it may cause severe maceration of tissue and may make replantation more difficult technically. The amputated part should be cooled as soon as possible. The ideal temperature is 4 °C. Care must be taken to prevent the freezing of tissues. Amputated parts should not be placed directly on ice, because tissue that is in direct contact with the ice may freeze. Currently, the recommended method for cooling amputated parts is to place the part, which is wrapped in saline-moistened gauze, in a water-tight plastic bag and immerse the bag in a container of ice water (Fig. 50-2) (Figure Not Available) . A guideline is to use half water and half ice; excessive ice should be avoided. Cooling coils and refrigeration devices have occasionally been used

| TABLE 50-2 -- Axioms for Care of Amputations | |
|---|---|
| **Do's** | **Dont's** |
| Splint and elevate | Apply dry ice or freeze tissue |
| Apply pressure dressing | Place tags on tissue |
| Protect from further trauma or injury | Place sutures in tissue |
| | Sever skin bridges |

| Protect from further contamination | Initiate perfusion of amputated part |
|---|---|
| Provide analgesia | Place tissue in formalin or water |
| Supply tetanus prophylaxis and antibiotic therapy | |
| Obtain radiographs | |

but are generally not available and offer no significant advantages. The tissue containers should be labeled with the patient's name, the amputated part contained within, the time of the original injury, and the time that cooling began.

Treatment for partial amputations with vascular compromise is the same as that just described. Clean the wound with normal saline irrigation. Place a saline-moistened sponge on the open tissue, and wrap the injury in a sterile dressing, incorporating a splint to protect it from further injury. Ice packs or commercial cold packs should be applied over the dressing to cool the devascularized area (Fig. 50-3) (Figure Not Available) .

## COMPLICATIONS

The care of amputated parts should not lead to avoidable complications if the aforementioned principles are followed. Improper management of the parts or stump with subsequent additional injury of the tissue from overzealous hemostasis or cleansing should be avoided. Furthermore, desiccation, maceration, or freezing of tissue from improper storage should not occur. The physician must consider expediting the preoperative work-up of the patient and immediate notification of the replantation team as crucial factors in the patient's care.

Despite optimal initial care, replantation itself may be associated with acute or long-term complications. There is the usual risk of anesthesia and protracted surgery. Postoperative complications include vascular thrombosis, hemorrhage, infection, and reaction to accumulated toxins. It is not unusual for second and third emergency operations to be required to reestablish adequate blood flow. Patients are often placed on anticoagulants, which create an additional risk. Toxins accumulate in ischemic amputated parts, despite cooling. The amount of toxin is directly proportional to the amount of muscle mass and the duration of ischemia. Reports of significant pulmonary failure, electrolyte disturbance, and even death have been reported in replantation

efforts.

Later complications include a significant percentage (60%) of patients with cold intolerance, limited function, anesthesia, pain, paresthesias, malunions, and nonunions. Repeated operative procedures may be required to obtain a functionally useful result. To minimize the morbidity from amputations, proper initial care is essential and may be the most important determining factor in the patient's eventual outcome.

# Chapter 51 - Extensor Tendon Injuries in the Hand and Wrist

**Peter E. Sokolove**

Hand injuries are commonly seen in the emergency department. Extensor tendons are quite superficial, covered only by skin and a thin layer of fascia, and are thus highly susceptible to injury. These injuries may result from lacerations, bites, or burns, but they also may be caused by closed injury with even seemingly superficial lacerations. While some extensor tendon injuries must be managed by a hand surgeon, others may be treated in the emergency department. Extensor tendon injuries are not benign and must be managed with care. The emergency physician must understand the anatomy, principles of treatment, repair technique, and postrepair care of these injuries to ensure the best possible patient outcome.

## FUNCTIONAL ANATOMY

There are 12 extrinsic extensors of the wrist and digits, all of which are innervated by the radial nerve. The muscles that give rise to these tendons originate in the forearm and elbow. The extrinsic extensor tendons reach the hand and digits by passing through a fibro-osseous tendon sheath (retinaculum) located at the dorsal wrist. This synovium-lined sheath provides for smooth gliding of the tendons and prevents bowstringing when the wrist is extended. The dorsal retinaculum contains 6 compartments or subdivisions (Fig. 51-1) . These compartments are numbered from the radial to the ulnar side of the wrist.

The first compartment contains 2 tendons, abductor pollicis longus (APL) and extensor pollicis brevis (EPB). The APL tendon, the most radial of the extensor tendons, inserts on the base of the first metacarpal. It can be palpated just distal to the radial tubercle and also causes radial wrist deviation. The EPB travels with the APL through the first compartment but inserts on the proximal phalanx of the thumb. It can be palpated over the dorsum of the first metacarpal when the thumb is extended against resistance. Both of these tendons can be tested by having the patient spread the fingers apart against resistance.

The second compartment also contains 2 tendons: the extensor carpi radialis brevis (ECRB) and the extensor carpi radialis longus (ECRL). These two tendons arise from the lateral epicondyle of the elbow. The ECRL inserts on the base of the second metacarpal, while the ECRB inserts on the base of the third metacarpal. Both tendons are powerful wrist extensors, and the ECRL also allows some radial wrist deviation. Wrist extension plays an especially important role in the mechanics of the hand, because hand grip strength is maximal only when the wrist is extended.

The third compartment contains only 1 extensor tendon: the extensor pollicis longus (EPL). This tendon crosses over the ECRB and ECRL and travels along the dorsum of the thumb to insert on the distal phalanx. The EPL forms the top of the anatomic "snuff

box," while the bottom is formed by the EPB. The EPL can be visualized when the thumb is extended, and its strength can be tested by having the patient hyperextend at the interphalangeal (IP) joint against resistance. The intrinsic extensor of the thumb can provide some degree of extension at the IP joint. Therefore, if EPL injury is suspected, it is important to compare extension at the IP joint with that of the unaffected thumb.

The fourth and fifth compartments contain the 6 tendons that extend the index through little fingers. Each finger has its own extensor digitorum communis (EDC) tendon. The index and little fingers have an additional independent extensor tendon--the extensor indicis proprius (EIP) for the index finger and the extensor digiti minimi (EDM) for the little finger. The fourth compartment contains the EIP and EDC tendons, while the fifth compartment contains only the EDM tendon. These 6 tendons can be seen over the dorsum of the hand, where they are poorly protected and prone to injury. In this region there are tendinous, ligamentous, and fascial connections between these tendons known as the *juncturae tendini. Because of these interconnections, a patient may be able to extend a digit, albeit weakly, even when there is a complete laceration of its EDC tendon.* In order to avoid missing a tendon injury on the dorsum of the hand, it is important that the examiner test for tendon *strength* and not just for active extension. The course of the extensor tendons along the fingers is more complex, but a basic understanding of this anatomy is essential for the emergency physician to evaluate and treat extensor tendon injuries (Fig. 51-2) (Figure Not Available) . The EIP tendon joins the EDC tendon at the level of the metacarpophalangeal (MCP) joint in the index finger. The EDM tendon parallels the course of the EDC tendon; the 4 EDC tendons eventually insert at the base of the proximal, middle, and distal phalanges. The most proximal insertion of the EDC tendon is at the level of the base of the proximal phalanx. The tendon actually inserts in 2 ways. First, there is a loose dorsal insertion just distal to the MCP joint. In addition, the EDC tendon inserts into the volar plate via the sagittal bands. The sagittal bands are circumferential structures at the level of the metacarpal head that serve to keep the EDC tendon centered over the metacarpal head, as well as to provide a stable connection with the volar plate located on the palmar side of the hand. After its primary insertion at the level of the MCP joint, the EDC tendon then extends dorsally along the digit. The EDC trifurcates over the proximal phalanx (Fig. 51-3) (Figure Not Available) . Its major central slip inserts on the base of the middle phalanx (Fig. 51-4) . The lateral branches of the EDC tendon join with the lateral bands from the interossei and lumbricals to form the co-joined lateral bands. The two co-joined lateral bands then fuse together over the middle phalanx to form the terminal extensor mechanism (TEM), which inserts into the base of the distal phalanx (Fig. 51-5) . The triangular ligament is a connection between the 2 co-joined lateral bands that assists in keeping these structures on the dorsal aspect of the digit.

The sixth dorsal compartment of the wrist contains only 1 tendon: the extensor carpi ulnaris (ECU). This tendon originates at the lateral epicondyle of the elbow and inserts at the base of the fifth metacarpal. The ECU functions as a wrist extensor and ulnar deviator. It can be palpated just distal to the tip of the ulna, and its strength can be tested by forced ulnar deviation of the wrist.

## GENERAL APPROACH TO EXTENSOR TENDON INJURIES

The key to detecting extensor tendon injuries in the emergency department is to perform a careful and thorough history and physical examination. Closed injuries may appear innocuous at first but may result in tendon injuries that often lead to severe deformities or dysfunction if undetected. Closed injuries are also commonly associated with fractures. A hand radiograph is recommended in closed hand injuries when a fracture is suspected or in open-hand injuries where fracture or a foreign body is suspected. It is generally accepted that all open injuries that result from glass should be radiographed. Plain radiographs have a sensitivity of approximately 99% for detecting a 2-mm glass foreign body, as long as it is not obscured by bone. [3]

Open injuries to extensor tendons are quite common, especially on the dorsum of the hand, where they are superficially located. *All dorsal wrist, hand, and digit lacerations should be assumed to have an underlying tendon laceration until proven otherwise.* Digital extension can still occur with partial tendon lacerations of up to 90%. Complete lacerations of an EDC tendon on the dorsum of a hand can also still allow digital extension through the juncturae tendini.

After assessing the strength and neurovascular status of the injured hand, it is imperative that the emergency physician visually inspect the wound thoroughly. Inspection should include an assessment of the degree of wound contamination, as well as a search for foreign bodies and occult tendon lacerations. Since an extensor tendon is a mobile structure, it is imperative that if it is exposed, it is visualized

in its entirety through a full range of motion. *It is especially important to examine the tendon in the position of injury, as frequently the tendon injury does not lie directly under the skin wound.* Examination of the wound must occur under the best possible conditions--with a good light source, a bloodless field, and adequate local anesthesia. If the examining physician suspects, but is unable to locate, a tendon laceration, or if a patient is uncooperative with the examination, the patient should be referred for follow-up in 1 to 2 days for a repeat examination. Interim wound care with skin closure and splint application is advised. Inability to rule out a tendon injury in the emergency department and the mandate for follow-up should be clearly documented on the medical record and disposition instructions.

## PREPARATION FOR REPAIR

Prior to attempting repair of an open extensor tendon injury in the emergency department, it is essential that the treating physician be prepared and have the proper equipment available. Patients should be placed supine on a gurney that ideally has an arm board attached. Bright overhead lighting is important for wound exploration so that the presence of tendon injuries and foreign bodies can be adequately assessed. Instruments should include, at a minimum, a needle holder; 2 skin hooks and retractors; sharp (i.e., "iris") and blunt-nosed scissors; several small hemostats; and one pair of small, single-toothed (i.e., Adson) forceps.

The choice of suture material depends on the location of the tendon injury. For the repair of *complete* tendon injuries on the dorsum of the hand, nonabsorbable, synthetic,

braided sutures are preferred. [2] Polyester sutures, such as Ethibond or Mersilene, are recommended. Nylon sutures are acceptable but are less ideal, as colored nylon may be visible under the skin. Chromic and plain gut should be avoided because they will dissolve before adequate tendon healing has occurred. Silk is not desirable because of its reactivity. Most extensor tendons on the dorsum of the hand will accommodate 4-0 sutures, but 5-0 suture material may be needed for smaller tendons. Small, "plastic repair," tapered needles should be used to avoid tearing the tendon. *Partial* tendon injuries of the digits are best repaired with synthetic, absorbable sutures such as polyglactin (i.e., Vicryl).

It is imperative that the physician use adequate anesthesia so that thorough wound exploration can occur. A field block or regional nerve block (see Chapter 32) can be used on the dorsum of the hand, while local anesthesia or a digital nerve block can be used on the fingers. It is best to use 1% lidocaine *without* epinephrine delivered via a 25- to 27-ga needle. It is important to liberally anesthetize the area around to the wound, since many lacerations *must be extended to afford access to the surgical field*. It is a common error to neglect to extend a laceration and to attempt examination, cleaning, or repair through a small initial skin laceration.

Following the administration of anesthesia, a tourniquet must be placed on the involved limb. It is absolutely essential that adequate control of blood flow be obtained before attempting to repair a tendon laceration. It is very difficult to find the proximal end of a retracted tendon in a bloody field. The patient's arm should be elevated for at least 1 minute prior to tourniquet application to allow blood to drain by gravity. A blood pressure cuff is placed on the mid to upper arm, wrapped in several layers of cast padding, then inflated to 260 to 280 mm Hg. Once inflated, the tubes are clamped tightly using a hemostat. The use of cast padding during inflation helps avoid inadvertent unraveling of the cuff. The use of a hemostat to clamp the blood pressure cuff tubes helps avoid a slow leak in the cuff with resultant deflation. A blood pressure cuff tourniquet is generally well tolerated by patients for approximately 15 to 20 minutes. If tendon repair cannot be accomplished in this amount of time, it is likely that the injury is too complex for repair in the emergency department.

## PATTERNS OF INJURY AND MANAGEMENT

The treatment for extensor tendon injury depends primarily on whether the injury is open or closed, as well as the anatomic location of the injury. The most widely accepted classification system is that developed by Verdan, which divides the hand and wrist into 8 anatomically based zones (Fig. 51-6) (Figure Not Available) . It is quite useful for emergency physicians to become familiar with this classification, because in many instances the zone of injury can help determine whether tendon repair should be attempted in the emergency department.

One must keep in mind that repair of lacerated extensor tendons within 72 hours of injury is still considered primary closure. Therefore, while emergency physicians may repair many extensor tendon injuries immediately, some injuries are best managed with delayed repair. In these cases, initial care in the emergency department should consist of sterile skin prep, copious wound irrigation and inspection for foreign bodies, skin

closure, splint application, and a referral to a hand specialist for further care in 1 to 2 days.

**Zone 7 and 8 Injuries**

Zones 7 and 8 consist of the area over the wrist and dorsal forearm, respectively. Extensor tendon lacerations in these regions can be quite complex and are therefore not repaired in the emergency department. Because of the close proximity of extensor tendons in the distal forearm, lacerations such as stab wounds may appear innocuous but often result in multiple tendon lacerations. At the wrist level, extensor tendons are covered by a retinaculum that is lined with synovium. While this tissue allows smooth gliding of tendons during normal activity, the presence of synovium increases the risk for adhesions following tendon repair. In addition, lacerated tendons in the wrist and distal forearm may retract away from the site of initial injury. This may make tendon retrieval and repair quite difficult and may necessitate incision of the retinaculum and exploration of 1 or more of the compartments.

As a result of the potential complexity of these injuries, all tendon lacerations in zones 7 and 8 require formal surgical exploration and repair. Emergency department management of these patients includes local wound care (see Chapter 36) with primary repair of the skin (see Chapter 37) and placement of a volar splint with 35° of extension at the wrist and 10° to 15° of flexion at the MCP joints (see Chapter 53) . Many hand surgeons recommend prophylactic antibiotics for all open tendon lacerations, while others prescribe them selectively for patients with wounds where contamination is suspected or significant injury to the surrounding tissues is present. There are no prospective data proving or disproving the value of prophylactic antibiotics in either circumstance. These patients should be promptly referred to a hand surgeon so that repair may be undertaken within 1 week of injury.

**Zone 6 Injuries**

Zone 6 consists of the area over the dorsum of the hand. Extensor tendon injuries in this region frequently result from lacerations due to broken glass or another sharp object. Common pitfalls in emergency department management of these injuries are usually related to failure to recognize that the tendon has been injured. It is important to remember that these tendons are superficially located, partial tendon lacerations may occur, and weak extension of a digit is possible in the presence of a complete tendon laceration because of transfer of extensor function through the juncturae tendini. Lacerations of the EIP or EDM tendons are evidenced by an inability to independently extend the index or little fingers, respectively. All of these pitfalls can be avoided if a careful physical examination is performed, including a thorough wound exploration under sterile conditions using a tourniquet, adequate local anesthesia, and good lighting.

Extensor tendon injuries in zone 6 are usually appropriate for repair in the emergency department. Because of the juncturae tendini, extensor tendons in zone 6 are less likely to retract than those in zone 7 or 8; however, the severed tendon may retract when the injury is more proximal. The distal end of a severed tendon is usually easy to find by

passively extending the patient's affected digit to bring the end into view. Retrieval of the proximal portion of a severed tendon is sometimes required and usually can be accomplished in the emergency department. Prior to searching for the proximal end of the tendon, the physician should have a 4-0 nylon suture loaded onto a needle holder. When the proximal end is located, this suture should be placed as a holding suture as far proximal as possible so that the tendon is not lost again. It is often necessary to use a scalpel to extend the wound proximally in a direction parallel to the course of the injured tendon to obtain adequate exposure. One should then begin to search for the tendon by lifting up this overlying skin with a forceps and inspecting the proximal portion of the wound. Sometimes the blood-stained end of a tunnel can be seen; this may contain the proximal end of the tendon. By gently placing a small hemostat or toothed forceps up this tunnel, the tendon stump can often be pulled into view.

Once both ends of the injured tendon have been located, the technique used for repair is dependent on the size and shape of the tendon. While larger, round tendons can accommodate sutures that pass through the core of the tendon, smaller or flat tendons are difficult to repair using this technique. Most of the tendons in zone 6 can be repaired with either a modified Kessler or a modified Bunnell technique, using 4-0 nonabsorbable suture (Fig. 51-7) (Figure Not Available) . Smaller tendons may be repaired using a figure-of-eight or horizontal mattress suture. Small, tapered needles should be used to avoid tearing the tendon. In a cadaver study comparing these multiple suture techniques, it was found that the modified Bunnell technique provided the strongest extensor tendon repair. [5] In addition, this technique produced no gaping between the repaired tendon ends and minimized the postrepair restriction of flexion at the MCP and proximal interphalangeal (PIP) joints. It is important to passively test the degree of flexion at the MCP joint after zone 6 tendon repair to be certain that the tendon has not been excessively shortened. [6]

The approach to partial extensor tendon lacerations is not well defined, largely due to a paucity of literature on this subject; however, a logical approach may be extrapolated from data on flexor tendon injuries. It has been demonstrated that many partial *flexor* tendon lacerations do well without repair, [7] but there is still great disagreement among hand surgeons concerning the need for repair of these injuries. In a recent survey of hand surgeons, 30% of respondents repaired *all* partial flexor tendon lacerations, while 45% of respondents repaired *only* lacerations with >50% cross-sectional area involvement. [8] Except at the wrist level, extensor tendons are not covered with synovium and are less likely than flexor tendons to develop adhesions after repair. This encourages some authors to recommend repair of most partial extensor tendon lacerations. While the ideal approach to these injuries is not known, it is reasonable to consider repair of partial extensor tendon lacerations to be *optional* if <50% of the cross-sectional area is involved.

After repair of a lacerated EDC tendon in zone 6, a plaster splint should be applied so that the wrist is in 45° of extension, the affected MCP joint is in neutral (0° flexion), and the unaffected MCP joints are in 15° flexion. [2] The PIP and distal interphalangeal (DIP) joints should be allowed full range of motion. If there is an isolated EIP or EDM tendon injury, then only the index or little finger must be included in this splint.

**Zone 5 Injuries**

Zone 5 consists of the area over the MCP joint. Open injuries in this region should be considered secondary to a human tooth bite until proven otherwise. This is especially true if the injury occurs over the first or second MCP joint, as this is frequently the location of a clenched-fist ("fight-bite") injury. Emergency department evaluation must begin with a careful and persistent history and physical examination, although patients' reluctance to admit to punching someone in the mouth is notorious. The wound should be inspected through its full range of motion, since the position of the EDC tendon changes with hand position. It is generally recommended that radiographs be obtained in all of these injuries to evaluate for metacarpal head fractures, air in the joint space, or presence of a foreign body, such as a tooth fragment.

If, after a thorough evaluation, it is determined that a human bite to this region has resulted in a superficial skin laceration only, without injury to the underlying tendon or joint, outpatient management is appropriate. The wound should be copiously irrigated and left open. A volar splint is applied with the wrist in 45° of extension, the MCP joints in the neutral position (0° of flexion), and the hand dressed with a bulky dressing. Most authors recommend that 3 to 5 days of prophylactic antibiotics be given to these patients, and patients should be seen in 24 hours for a repeat examination to evaluate for wound infection. If a human bite results in tendon damage, including partial or complete laceration, the patient generally should be admitted for IV antibiotics, and delayed closure should be undertaken by a hand surgeon in 5 to 10 days. Primary closure of even seemingly clean and well-irrigated human bites in this region is not advisable because of the increased risk of wound infection, as well as the potential for septic destruction of the MCP joint if it is violated. If an *open joint* is noted by physical examination or saline arthrogram, patients should also be admitted for IV antibiotics and are generally taken to the operating room for surgical exploration and irrigation.

If a patient suffers a zone 5 tendon injury, and it can be determined with complete certainty that it was caused by a relatively clean, sharp object rather than by a human bite, primary closure is appropriate. Referral of these injuries to a hand surgeon is a common practice, given the complexities of the injury and the sequelae. Careful repair of lacerations to both the EDC tendon and the sagittal bands is necessary to prevent subluxation of the EDC tendon away from the center of the metacarpal head. Initial emergency department management is often limited to skin closure, splinting as described above, and referral to a hand surgeon within 1 to 2 days.

An acute closed injury to zone 5 may result in traumatic subluxation of the EDC tendon as a result of a tear in the extensor hood (Fig. 51-8) (Figure Not Available) . The injury results from a direct blow to the digit that causes forced flexion with or without ulnar deviation; most commonly it involves the long finger, with dislocation of the EDC tendon to the ulnar side. The subluxation becomes more prominent with flexion at the MCP joint. This injury is usually adequately treated with extension splinting for 4 to 6 weeks. Once the hand is splinted in the emergency department, these patients should be referred to a hand surgeon for follow-up within 1 week. Repetitive closed injury to the MCP joint region can produce a condition known as *boxer's knuckle*. This consists of

small tears of the EDC tendon, the sagittal bands, or the joint capsule. These patients tend to present with chronic and recurrent pain and swelling at the MCP joint region and usually have normal radiographs and no tendon subluxation. Elective repair by a hand surgeon generally results in a good outcome.

## Zone 4 Injuries

Zone 4 consists of the area over the dorsal aspect of the proximal phalanx between the MCP and PIP joints. The extensor tendon is a broad, flat structure in this region and is relatively easy to repair. Because the extensor tendon is flat and conforms to the roundness of the proximal phalanx, tendon injuries in this area usually result from a laceration and are almost always incomplete. As a result, extension at the PIP joint is usually not impaired. It is therefore imperative that all of these wounds be explored carefully, remembering that the extensor tendon lies immediately beneath the thin overlying skin. Tendons tend not to retract in this area, so close inspection will usually result in location of the injured tendon.

Central slip lacerations or any laceration that results in an extension lag at the PIP joint are usually repaired by a hand surgeon. The decision regarding whether to repair a partial tendon laceration and whether it should be repaired by the emergency physician in this zone is best discussed with the consulting hand surgeon. In general, because of the duality of the extensor system in this region, lacerations of a single lateral slip can either be repaired with 5-0 nonabsorbable suture or be left unrepaired and splinted. A running suture or simple interrupted sutures with buried knots are appropriate for this area. Postrepair splinting depends on the presence of tension at the repair site. Minor lacerations in zone 4 that do not result in tension on the repair site can be treated with a finger guard for 7 to 10 days and early range of motion. Larger lacerations or those that result in tension at the repair site are usually treated in a splint that extends from the forearm to the digit for 3 to 6 weeks. The splint should be applied so that the wrist is in 30° of extension, the MCP joints at 30° of flexion, and the PIP joint in neutral position. Fingers should be grouped so that either digits 2 and 3 or digits 3 through 5 are immobilized.

It is important to recognize that *complex partial* tendon lacerations (e.g., a laceration of a lateral slip resulting from a saw) in zone 4 may result in damage to the gliding layer located between the tendon and the bone. If the patient is still able to actively extend the digit at the PIP joint, then these *complex partial* tendon lacerations are best managed by debriding the frayed tendon ends and splinting the digit in extension rather than attempting to suture the damaged tendon. The splint should be worn for 10 days, followed by active range of motion.

## Zone 3 Injuries

Zone 3, the area over the PIP joint, is a common site of both closed and open injury. Open injury usually results from laceration with a sharp object. It is imperative that these wounds be carefully explored in the emergency department to rule out penetration of the joint capsule. Patients with wounds that are suspected of penetrating the joint are generally taken to the operating room for surgical exploration, irrigation, and treatment

with IV antibiotics.

Zone 3 tendon lacerations can result in long-term deformity if not carefully repaired, and patients with such injuries are commonly referred to a hand surgeon. Partial lacerations of the central slip or lateral bands are managed variably, and it is advisable to discuss these injuries with the consulting hand surgeon. Lacerations in this area may sometimes result in a complete central slip injury. This may present as an acute boutonniere ("buttonhole") deformity, where the PIP joint rests in 60° of flexion. The presentation may be more subtle, however, and may only be noticeable by weakened extension at the PIP joint or incomplete extension by only a few degrees.

The boutonniere deformity develops when the central slip is ruptured by an open or closed mechanism, leading to unopposed action of the flexor digitorum superficialis tendon (Fig. 51-9) (Figure Not Available) . This results in flexion at the PIP joint, protrusion of the head of the proximal phalanx between the two lateral bands, and disruption of the triangular ligament. When this occurs, the lateral bands are displaced volar to the axis of motion of the PIP joint. The lateral bands then paradoxically become flexors of the PIP joint. In addition, the extensor hood mechanism is pulled more proximally, resulting in increased tension on the terminal extensor mechanism and hyperextension at the DIP joint. Thus, the boutonniere deformity consists of flexion of the PIP joint with hyperextension at the DIP joint.

Open central slip injuries are usually managed operatively, and complex injuries may require direct attachment of the tendon to bone or tendon reconstruction. If the consulting hand surgeon chooses not to repair the tendon injury immediately, the skin should be closed and a plaster splint applied in the same fashion as described for zone 4 injuries. Thermoplastic splints allow splinting of the hand without involvement of the wrist but are generally not available in the emergency department setting. These patients should be promptly referred to a hand surgeon so that repair may be undertaken within 1 week of injury.

Patients with closed injuries to zone 3 present commonly to the emergency department. They may complain of a direct blow to the dorsal PIP joint, or they may complain of a "jammed" finger. This injury occurs when an object such as a ball delivers a sudden axial loading force with forced flexion of the PIP joint while it is extended. These patients commonly complain of a painful, swollen PIP joint, which often makes the examination difficult. Some of these injuries probably represent PIP joint dislocations that were spontaneously or manually reduced prior to the patient's emergency department presentation. [9] The tendon injury that is important to recognize in this setting is an occult isolated central slip rupture. Patients may have decreased extension at the PIP joint, but frequently extension is normal. With forced extension against resistance, patients usually have pain and may have decreased strength. With acute central slip rupture, PIP joint extension may be particularly weak when the MCP joint is flexed (Elson test; Fig. 51-10) (Figure Not Available) . [10]

The boutonniere deformity usually does not develop in patients with closed zone 3 injuries until 10 to 14 days after injury. The only way to prevent this deformity is to have a high index of suspicion for its presence and treat these patients conservatively. It is

advisable that all patients with a swollen, tender PIP joint and pain with flexion or extension be splinted and referred for follow-up within 1 week. A dorsal splint should be applied overlying the PIP joint, keeping it in full extension. This can be accomplished using an aluminum foam-backed splint or a Bunnell ("safety pin") splint, although the latter is generally not available in the emergency department. [11] The MCP and DIP joints should be left free to have full, active range of motion (Fig. 51-11) .

## Zone 1 and 2 Injuries

Zones 1 and 2 consist of the area over the DIP joint and the middle phalanx, respectively. In zone 2 the cojoined lateral bands come together to form the terminal extensor mechanism (TEM) and are held together, in part, by the triangular ligament. The TEM inserts on the base of the distal phalanx and allows extension at the DIP joint. Complete disruption of the TEM results in inability to extend at the DIP joint. Because of the unopposed action of the flexor digitorum profundus (FDP) tendon, the DIP joint rests in the flexed position. This is known as a mallet deformity of the finger (Fig. 51-12) (Figure Not Available) .

Tendon *lacerations* in zones 1 or 2 that result in a partial or complete mallet deformity should generally be repaired by a hand surgeon. This procedure usually consists of repair of the lacerated tendon as well as placement of a K-wire through the distal phalanx into the middle phalanx to stabilize the joint. Sometimes only an external splint is used after tendon repair. Occult partial tendon lacerations are important to recognize to prevent development of a mallet deformity. If there is a partial tendon laceration in zones 1 or 2 that does not result in any extension lag, the approach to repair is variable, and it is advisable to discuss the repair with the consulting hand surgeon. In general, partial tendon lacerations of <50% of the tendon area that do not result in an extension lag may be splinted in extension for 7 to 10 days with or without repair of the tendon itself. [11] Partial tendon lacerations of >50% that do not result in an extension lag may be repaired by a hand surgeon or an emergency physician who is experienced in the repair of these injuries. In either case, it is advisable to discuss whether tendon repair will occur in the emergency department or the operating room with the consultant hand surgeon.

If the zone 1 or 2 tendon laceration is repaired in the emergency department, it should be approximated using a figure-of-eight or horizontal mattress, 5-0 nonabsorbable suture. It is important that the tendon ends be approximated but not pulled too tightly; otherwise joint stiffness and limitation of flexion will occur. After repair of a partial tendon laceration, the DIP joint should be splinted in extension for 6 weeks, followed by 2 to 4 weeks of night splinting and active range-of-motion exercises. Patients should be warned after tendon repair that there is likely to be some residual loss of flexion at the DIP joint, even in the best case.

*Closed* injuries in zones 1 and 2 may result in a partial or complete mallet deformity depending on the injury pattern. These injuries are usually caused by an axial loading force with forced flexion of the DIP joint while it is being held in extension. A common emergency department presentation of this injury is a patient who complains of pain and

swelling at the DIP joint after a ball strikes his or her fingertip.

Closed tendon injuries in this region can generally be classified into three types. In the first type of injury, there is a closed rupture of the TEM. The second type of injury is an avulsion fracture of the dorsal lip of the distal phalanx. This fracture is intra-articular, but there is no volar displacement of the remaining portion of the distal phalanx. Both type 1 and type 2 injuries can be treated by splinting in full extension for 6 weeks. The splint should hold the DIP joint in extension while allowing free range of motion of the PIP joint (Fig. 51-13) . The splint can be constructed from an aluminum, foam-backed splint or from a prefabricated Stack splint.

The third type of closed injury is an intra-articular avulsion fracture of the dorsal lip of the distal phalanx *with* volar displacement of the remaining portion of the distal phalanx (Fig. 51-14) . Normally the DIP collateral ligaments hold the distal phalanx in place; however, if there is a large enough fracture fragment (usually >50% of the articular surface), then the remaining distal phalanx fragment displaces in the volar direction secondary to unopposed action of the FDP tendon. When volar displacement of the distal phalanx occurs, this injury is usually treated operatively by placement of a K-wire and open reduction and internal fixation of the fracture. It is important to remember that it is the presence of volar subluxation, not the size of the avulsion fracture, that determines the need for operative management.

Any injury, whether open or closed, that results in a complete disruption of the TEM may result in a swan-neck deformity (Fig. 51-15) (Figure Not Available) . This deformity consists of flexion at the DIP (a mallet finger), as well as hyperextension at the PIP joint. This results from a dorsal and proximal displacement of the lateral bands causing increased extension forces on the middle phalanx. This complication often can be avoided if disruption of the TEM is diagnosed and treated correctly in the emergency department.

## COMPLICATIONS

All extensor tendon repairs are subject to the usual complications of wound infection and skin breakdown secondary to prolonged splinting. Tendon rupture is a rare complication following tendon repair and may result from inadequate suture technique or premature motion against resistance. It is important when extensor tendons are repaired for at least 5 throws to be used and a square knot to be tied. All extensor tendon repairs require some period of complete immobilization during tendon healing, and it is important for the emergency physician to stress the necessity for patient compliance.

Extensor tendon injuries in zone 7 tend to have the worst prognosis. Because of the presence of a synovial lining, postrepair adhesions may occur. [6] These adhesions may lead to decreased excursion of the extensor tendons with resultant decreased mobility at the wrist. There may also be limitation of finger flexion when the wrist is flexed, as well as finger extension when the wrist is extended. Because of the lack of synovium,

the relatively simple anatomy, and the usual lack of associated injuries, zone 6 tendon injuries tend to have fewer complications than other areas of the hand. The tendons in zone 6, however, do have a tendency to shorten if the tendon ends are approximated too tightly. This may result in a restriction of PIP and MCP joint flexion that is much more pronounced than any loss of extension. [6]

Zone 5 injuries are particularly prone to infection, as injuries in this region commonly occur from a human bite. In addition, if the extensor hood covering the MCP joint is not carefully repaired, subluxation of the EDC tendon may occur. [4] If complex partial tendon lacerations in zone 4 are managed too aggressively, then tendon shortening and stiffness may result. As discussed previously, these injuries are often best managed with splinting alone. A common complication of zone 3 extensor tendon injuries is development of a boutonniere deformity. This usually results from failure to diagnose or adequately immobilize a central slip injury. Similarly, undiagnosed or improperly treated extensor tendon injuries in zones 1 and 2 may lead to either a swan-neck or chronic mallet deformity of the digit. DIP joint splinting itself may result in skin ulceration or tape allergy, usually presenting in the second week of treatment. [12] Skin breakdown may be encouraged if the DIP joint is splinted in hyperextension, because of decreased skin perfusion.

## POSTREPAIR CARE AND REHABILITATION

Proper care after diagnosis and repair of an extensor tendon injury is extremely important for optimal patient outcome. Even the best initial tendon repair can have a poor result if subsequently treated improperly. The rehabilitation of tendon injuries has evolved since 1980 to include dynamic splinting and active range-of-motion exercises to obtain maximal motion of the affected digit.

Zone 1 and 2 injuries are usually treated with static splinting as described previously. After 6 weeks, active range-of-motion exercises should begin. Night splinting is recommended for an additional 4 weeks and during any athletic activities. [9] It is advisable to give the patient a number of extra splints so that the patient (or family) can change the splint frequently to avoid pressure injury. During splint changes, it is important that the DIP joint be held in full extension either by using the other hand or by placing the finger against a table. Closed injuries of the central slip (zone 3) are often treated with a boutonniere splint for 4 weeks, followed by 2 weeks of gradual flexion exercises and night splinting. During the initial 4 weeks, the patient should be instructed to passively flex the DIP joint every hour to maintain gliding and proper position of the lateral bands.

Lacerations in zones 3 and 4 have traditionally been treated with static splinting from the forearm to digits. An alternative approach is to splint only the DIP and PIP joints in extension, and begin a "short-arc-motion" protocol within 1 to 2 days of repair. [13] This consists of active motion at the PIP joint progressing from 0° to 30° the first 2 weeks to 0° to 50° the fourth week. When compared to static splinting, this protocol may lead to better PIP and DIP joint flexion, without resulting in tendon rupture or boutonniere deformity.

Early motion following extensor tendon repair has been found to be most useful in zones 5 though 7. A dynamic extension splint is commonly used in which the wrist is extended 45°, and all finger joints rest in the neutral position (Fig. 51-16) (Figure Not Available) . A volar block allows 30° to 40° of MCP joint flexion, while a dynamic traction mechanism passively extends the digits. Dynamic splinting is started 1 to 3 days following repair. Active motion is added at 3 to 4 weeks, and resistance is added at 7 weeks. A short-arc-motion protocol with controlled active motion at the MCP joint has also been shown to be safe and effective when started 24 to 48 hours following repair. [13] Both dynamic splinting and early active motion are most beneficial when managed closely by a skilled hand therapist. Patients must be reliable and motivated to take advantage of these techniques. It is best to refer patients to a hand surgeon or hand therapist as soon as possible following repair so that rehabilitation can begin in a timely manner.

## EXTENSOR TENDON INJURIES OF

THE FOOT

The extensor tendons of the foot are less commonly injured than the extensor tendons of the hand and wrist. The most important extensors of the foot and ankle that may be presented with injuries in the emergency department are the tibialis anterior, extensor hallucis longus, and extensor digitorum longus tendons.

The tibialis anterior muscle originates on the shaft of the tibia and interosseous membrane and inserts on the medial cuneiform and the base of the first metatarsal. The tibialis anterior extends the foot at the ankle joint and inverts the foot at the subtalar and transverse tarsal joints. [14] Spontaneous rupture of the tibialis anterior tendon may be seen in both elderly and young patients who have been injured during athletic activity. Injury to this tendon commonly results from forceful attempted dorsiflexion of the ankle while it is held fixed in the plantar-flexed position. [15] Patients generally present with decreased strength of foot dorsiflexion, because toe extensors are used to accomplish this motion. Ruptures or lacerations of the tibialis anterior tendon should be referred promptly to an orthopedic surgeon for consideration of formal operative repair.

The extensor digitorum longus (EDL) and extensor hallucis longus (EHL) tendons both originate from the shaft of the fibula and interosseous membrane. The EHL tendon inserts into the base of the distal phalanx of the great toe, while the EDL tendon divides into four branches that insert on toes 2 through 5 (Fig. 51-17) (Figure Not Available) . Both the EHL and EDL tendons primarily result in extension of the toes and dorsiflexion at the ankle. The extensor digitorum brevis (EDB) and extensor hallucis brevis (EHB) muscles originate from the upper part of the calcaneus. The EHB tendon joins the lateral aspect of the EHL tendon prior to inserting on the great toe. The EDB muscle gives rise to three tendons that join the lateral side of the EDL tendons going to toes 2 through 4.

Injury to the EHL and EDL tendons may result from a sharp object lacerating the dorsum of the foot. Patients may present with weakness of, or an inability to extend, the

involved toe. Whether one should repair EHL or EDL tendon lacerations is controversial. However, many authors favor repair; failure to repair EDL tendons may result in a claw deformity of the adjacent toes. [16] Lacerations of EHL and EDL at the level of the ankle are usually repaired, while lacerations on the dorsum of the foot and the toe are managed variably. If there is any flexion deformity of the involved toe, one should probably repair the lacerated tendon. Repair is also favored when both tendon ends are easily visualized in the wound. Since management of theses injuries is controversial, it is advisable to discuss the care of these patients with the consulting orthopedic surgeon. Extensor tendon repair of the foot is usually not performed in the emergency department setting. Superficial cutaneous nerves are easily injured on the dorsum of the foot during wound exploration, which can lead to the formation of a chronic, painful neuroma. If the injury is repaired in the emergency department, the technique for repair is similar to that used for the dorsum of the hand (zone 6). A posterior splint that includes the toes should be applied following tendon repair. The ankle should be splinted at 90° with the toes in the neutral position.

# Chapter 52 - Management of Common Dislocations

**Robert McNamara**

Joint dislocations are frequently encountered in patients presenting to the emergency department. They can range from a simple finger injury to limb- or life-threatening consequences of high-energy trauma. Although the dislocated joint is most often clinically obvious, the presentation may be obscure or masked by other injuries. Emergency physicians must be capable of detecting and managing these injuries; appropriate timely referral to a consultant is generally required for complex dislocation injuries.

This chapter addresses the diagnosis and management of joint dislocations. Keys to the clinical assessment and radiographic evaluation of these injuries are discussed along with methods of reduction. The emphasis of the chapter is on simple dislocations that should be diagnosed and generally managed in the emergency department (ED). Fracture-dislocations that commonly require operative intervention and emergency orthopedic consultation are not discussed.

## PREPARATION OF THE PATIENT

Although many authors claim their reduction method is well tolerated without premedication, they generally have not quantitatively measured the discomfort of their patients. However, *verbal* techniques for alleviating anxiety and discomfort are not to be discounted as they can be of great assistance during joint reduction. In field settings, simple hypnosis techniques have been successfully used for major joint dislocations. [1] In the ED, verbal reassurance and distracting conversation are useful adjuncts.

There are no set guidelines for the use of pharmacologic adjuncts in the management of dislocations. Each patient and presentation is unique and the treating physician must use judgment as to whether premedication is required, which agent to use, and what dose to give. The calm cooperative patient often tolerates gentle reduction attempts of a major joint such as the shoulder, but even the most stoic of patients may be quite uncomfortable with the manipulations necessary for reduction of a dislocated finger. Attempting any reduction technique in an extremely anxious patient without premedication will generally frustrate the operator and further upset the patient, and it may hinder a successful outcome.

In most circumstances, analgesia and/or sedation of some sort will be used; generally the intravenous (IV) route for drug administration is the method of choice, as it allows for rapid relief of patient discomfort and facilitates repetitive dosing for the desired effect. As opioids and benzodiazepines are the most commonly used drugs in this setting, venous access also allows for rapid reversal with naloxone or flumazenil, respectively. Chapters 32 to 34 include a detailed discussion of anesthesia and analgesia for ED procedures.

Benzodiazepines are commonly used for muscle relaxation; the relatively short-acting midazolam is a popular agent. A combination of a benzodiazepine and opioid is

frequently used, but this combination increases the need for careful monitoring of cardiorespiratory status. Intramuscular ketamine can also be considered, generally in the pediatric population, to minimize emergence reactions. Respiratory depression in the setting of procedural sedation and/or analgesia generally occurs after completion of the procedure, when the patient's discomfort lessens. For this reason, close postreduction monitoring until the patient has regained alertness is essential.

Intra-articular lidocaine has been used for anesthesia prior to shoulder reduction. [2] With this approach, 20 mL of 1% lidocaine is injected intra-articularly 15 minutes prior to a reduction attempt. After local povidone-iodine preparation, a 3.8 cm, 22 ga-needle is placed 2 cm laterally and directly beneath the acromion. The needle passes from the lateral aspect of the shoulder over the humeral head in a slightly caudad direction to enter the shoulder joint. After aspirating any intra-articular hematoma, the lidocaine solution is slowly injected over 30 seconds. A previously unopened vial of lidocaine should be used for the injection and the operator should wait a few minutes postinjection for the local anesthetic to take effect. Such an approach can reduce postreduction time in the ED. [2] Distal extremity dislocations, particularly those of the digits, are quite amenable to nerve blocks for anesthesia. These may include simple digital blocks or more proximal blocks, such as at the level of the wrist (see Chapter 32) .

## GENERAL PRINCIPLES

The clinical assessment of the patient with a dislocation must include a search for other injuries, especially if the mechanism was of high energy. This is generally most important for hip, knee, and posterior sternoclavicular dislocations. For all dislocations, a detailed extremity neurovascular

examination should be conducted and appropriately documented prior to focusing attention on the injured joint.

Although most dislocations are clinically obvious, the history and mechanism of injury can be quite helpful in certain circumstances. For example, a painful shoulder joint in a seizure patient should prompt assessment for a posterior shoulder dislocation, whereas a history of the knee striking the dashboard will clue one to the potential for a hip dislocation. Some dislocations will have been reduced prior to physician assessment. A careful history will uncover these injuries and prompt the necessary assessment of the ligamentous integrity of the joint and guide proper immobilization and follow-up care. Dislocations that commonly present in a reduced state include finger dislocations, knee dislocations, patellar dislocations, and radial head subluxations.

Although the chance of a gentle reduction attempt causing a fracture is extremely low, prereduction radiographs of dislocated joints are generally recommended. Reasons for this include the difficulty in distinguishing a fracture-dislocation by clinical examination and the potential for medicolegal problems if the fracture is not identified prior to reduction attempts. More important, certain associated fractures predict a poor outcome from closed reduction and make orthopedic consultation a consideration prior to such attempts. The obvious exceptions to this rule include suspected radial head subluxation in young children, clinical circumstances in which radiographs are not readily available

(e.g., in the wilderness), and clinical conditions (i.e., vascular compromise or threatened skin penetration) that dictate the need for prompt reduction.

Postreduction radiographs are traditionally obtained, although the need for this in a clinically obvious successful shoulder joint relocation has been questioned. [3] Although postreduction films are often not clinically useful and may not be cost-effective, they are generally obtained for medicolegal purposes. Patients administered sedatives and opioids may not remember the actual successful reduction or the immediate postreduction period. A reinjury after release from the ED without the corroboration of a successful reduction can raise questions about the adequacy of the initial procedure. Occasionally a fracture is detected on postreduction radiographs that was not obvious on the initial films, or a previously noted minor fracture may be found to reside in an intra-articular location.

The proper terminology for dislocations describes the relationship of the distal (or displaced) segment relative to the proximal bone or the normal anatomic structure. The terms *anterior* and *posterior* are used in most dislocations. Therefore, if the head of the humerus lies anterior to the glenoid fossa, the injury is an *anterior shoulder dislocation*. Similarly, if the olecranon lies behind the distal end of the humerus, the injury is a posterior elbow dislocation. In the hand, wrist, and foot, one uses the terms *dorsal* and *volar*. *Palmar* and *plantar* are sometimes used in place of volar to describe the position of the dislocated part. Dislocations can be open or closed and may have associated fractures requiring separate description.

It is generally accepted that the sooner a dislocation is reduced the better. This alleviates the patient's discomfort and corrects the distortion of surrounding soft tissue structures. In some studies the success rate of relocation (reduction) is higher when attempted closer to the time of injury. [4] However, there is no reason to forego an attempt at a closed reduction due to time factors in the vast majority of dislocations. Chronic dislocations of several days, weeks, or more are often difficult to reduce in a closed manner, but such presentations are infrequent.

General points about the reduction itself include the need for patience on the operator's part and the avoidance of excessive or abrupt applications of force. Gentle and gradual application of the various reduction techniques lessen the risk of complications. The operator must clearly understand the technique to be applied, and one should not hesitate to review a description of the procedure on a regular basis. Review of the technique is most important for uncommon dislocations, but it is a good habit even for the more common dislocations performed by seasoned clinicians.

A certain percentage of all types of dislocations are not amenable to closed reduction. Inability to complete a closed reduction is generally a result of the interposition of soft tissue structures or fracture fragments and not necessarily due to improper technique. If one has achieved sedation/analgesia adequate to permit relaxation of the patient's muscle tone, reduction should be relatively straightforward. When reduction under adequate sedation/analgesia is unsuccessful, multiple attempts at closed reduction are inappropriate. Generally, orthopedic consultation should be considered after 2 failed

attempts.

Once an attempt at reduction is completed, the operator should recheck the neurovascular status. For the elbow, hand, and forefoot joints, passive range of motion is performed to assess the stability of the reduction and to ensure a smoothly gliding joint that is free of intra-articular obstruction. In addition to close monitoring of the medicated patient, proper aftercare involves adequate immobilization of the injured joint for comfort and to prevent repeat dislocation. Recommendations for follow-up care are dependent on the injury and its severity.

This chapter covers dislocations of the various joints with the exception of the wrist dislocations, which are complex and require orthopedic consultation. Assessment and management principles, including reduction methods, are presented and aftercare is discussed.

# SHOULDER DISLOCATIONS

The human shoulder joint is remarkable for its degree of possible motion. The anatomic features that allow for this mobility, however, contribute to its instability. The glenohumeral joint has the greatest range of motion of any joint in the body, largely due to the loose joint capsule and the shallow nature of the glenoid fossa. [5] Posterior dislocation is uncommon, largely due to the anatomic support of the scapula and the thick muscular support in this area. The anterior support is less pronounced, with the inferior glenohumeral ligament serving as the primary restraint to anterior dislocation. [6] The depth of the glenoid fossa is somewhat increased by the fibrocartilaginous glenoid labrum, which forms the rim of this structure.

Most shoulder dislocations are anterior (i.e., the humeral head becomes situated in front of the glenoid fossa). Posterior dislocations are the next most common, but they generally account for <2% of shoulder dislocations. [7] Uncommon variations include inferior (luxatio erecta), superior, and intrathoracic dislocations. Dislocations of all types, including the shoulder, are less common in children because of the relative weakness of the epiphyseal plate as opposed to the ligamentous support of the joint.

**Anterior Shoulder Dislocations**

Anterior dislocations of the shoulder are the most common major joint dislocation encountered in the ED. The usual mechanism of injury is indirect, with a combination of abduction, extension, and external rotation. [5] [6] Only rarely is the mechanism a direct blow to the posterior aspect of the shoulder. Occasionally, especially with recurrent dislocations, the mechanism is surprisingly minor, such as mere external rotation of the shoulder while rolling over in bed or raising the arm overhead. [8] The occurrence of a first dislocation at a younger age is associated with a high risk of recurrence. Rowe found a recurrence rate of 83% with a first dislocation before age 20 years vs 16% in patients with a first dislocation after age 40 years. [8]

The 3 types of anterior dislocations are subcoracoid (accounting for >75% of anterior

dislocations), subglenoid, and the uncommon subclavicular. [8] These are classified according to the location where the humeral head comes to rest (Fig. 52-1) (Figure Not Available) .

**Clinical Assessment**

The presentation of anterior shoulder dislocation is usually obvious (Fig. 52-2) . The patient supports the injured extremity and leans toward the injured side. Visual inspection reveals loss of the rounded appearance of the shoulder due to the absence of the humeral head beneath the deltoid region. The acromion is prominent and an abrupt drop-off below the acromion can be seen or palpated. An anterior fullness in the subclavicular region is visible in thinner individuals and is easily palpable in most others. Comparison to the uninjured side is a useful aid for both visual examination and palpation. Any attempt at internal rotation is quite painful and is resisted by the patient. The inability to place the palm from the injured extremity on the uninjured shoulder is consistent with a shoulder dislocation; postreduction, this maneuver should be possible.

A careful assessment of the neurovascular status of the affected extremity is essential. Injury to the axillary artery is rare, usually occurring in the elderly, [5] and can be quickly assessed by palpation of the radial pulse. It is important to assess the status of the axillary nerve, as this is the most common nerve lesion found in anterior dislocations. [9] The sensory component of the axillary nerve is assessed by testing for sensation over the lateral aspect of the upper arm (Fig. 52-3) (Figure Not Available) . The motor component of the axillary nerve would be tested by assessing the strength of the deltoid muscle, a difficult undertaking in the patient with a dislocated shoulder. The neurologic examination should include a complete assessment of all major nerves to the arm, as other nerve injuries such as to the ulnar and radial nerve may occur. [8] [9] The presence of a neurologic deficit does not preclude closed reduction. Nerve injuries in this setting have a good prognosis, but the patient should be informed of the findings and the need for follow-up.

**Radiologic Examination**

Associated fractures are detected in up to 24% of anterior shoulder dislocations, with fractures of the greater tuberosity being the most common. [8] The presence of a fracture of the greater tuberosity does not change the initial management of anterior shoulder dislocations, and these fractures usually heal well after closed reduction in the routine fashion. [5] Fractures of the humeral neck, however, frequently are displaced with attempts at closed reduction, the result of which is often avascular necrosis of the humeral head. [10] The fact that humeral neck fractures are a known complication of shoulder relocation [4] suggests the value of prereduction radiographs in anterior shoulder dislocations. However, it can be argued that a *clinically obvious recurrent dislocation without a high-energy injury mechanism* (a diagnosis that is usually offered by the patient) can be reduced without prior radiographs, as fracture is quite unlikely in this situation.

Anterior dislocations are not subtle on the routine anteroposterior (AP) radiograph, and this view detects the most important fracture to identify, that of the humeral neck. An

adequate AP view, when combined with the typical clinical examination, allows for successful management of most anterior shoulder dislocations. The true AP view of the shoulder is taken at a right angle to the scapula, requiring rotation of the patient to 30° to 40°, as shown in Figure 52-4 (Figure Not Available) .

The typical lateral views obtained include the scapular Y view (Fig. 52-5) (Figure Not Available) , the transthoracic view, or the axillary view. These views rarely add to the AP in the obvious anterior dislocation, but they are of value in *posterior* dislocations. The usefulness of additional views in anterior shoulder dislocations is primarily to detect fractures, and the previously mentioned lateral views (especially the transthoracic view) are quite limited in this respect. [11] The apical oblique view has been found to be more valuable in acute shoulder trauma than the oblique scapular projection. [11] This view is obtained by angling the beam 45° caudad with the patient in a 45° oblique position (Fig. 52-6 (Figure Not Available) *A* and *B*).

Postreduction radiographs are generally obtained to document the success of the reduction, and they occasionally reveal a fracture not detected on the prereduction radiographs. Harvey and coworkers have questioned the need for routine postreduction radiographs in clinically obvious successful reductions, as they rarely add new information. [3]

**Reduction Techniques**

Hippocrates (450 b.c.) is generally credited with the first detailed description of reduction techniques, and it is believed that a drawing on the Edwin Smith Papyrus (3000 to 2500 b.c.) is the earliest depiction of such a method. [5] The Hippocratic technique involves placement of the operator's foot in the axilla to effect countertraction. This technique is problematic and is not recommended by recent authors.  Likewise the Kocher method, which involves somewhat forceful leverage of the humerus, has an increased rate of complications and is generally discouraged in favor of other techniques. [5] [6]

This section discusses several methods of reduction that are well studied, proven to be safe, and easy to master. Although all techniques are generally acceptable, many authors state that their technique is quite painless, but only one study has quantified the actual pain reported by patients. [13] McNamara found that scapular manipulation was generally well tolerated; 62% of patients not receiving premedication reported no or only mild pain during the reduction. Additionally, pain ratings were not lessened in the premedicated group. [13] Unfortunately, in other reports of "painless" techniques, objective data are lacking. As noted previously, intra-articular lidocaine also may be used to reduce the pain of reduction (Fig. 52-7) . Regardless of the reduction technique used, gradual, gentle application of the technique is essential.

Operator judgment is an important part of the decision as to whether reduction should be attempted without premedication. The advantages of such an approach include the avoidance of potential complications from drug therapy and a more rapid patient disposition. Certainly the patient who is markedly intoxicated may require little if any supplemental sedative therapy. All patients who are more than mildly anxious or who are reluctant to cooperate with an attempt at reduction without medication should

receive premedication. Generally, only one attempt is made and, if unsuccessful, reduction is attempted with the use of medication. When in doubt, it is best to use pharmacologic adjuncts.

**Stimson maneuver.**

The Stimson maneuver (Fig. 52-8) (Figure Not Available) is a classic technique that offers the advantage of not requiring an assistant. The patient is placed prone on an elevated stretcher and about 2.5 to 5.0 kg (5 to 10 lb) of weight is suspended from the wrist. [5] [6] The weights can be strapped to the wrist, or a commercially available Velcro wrist splint can be placed and the weights hung from this with a hook. [14] The slow steady traction of this method often permits reduction, but it may take 15 to 20 minutes. Reduction may be facilitated by gentle external rotation of the extended arm.

Variations of this method include the recommendation for flexion of the elbow to further relax the biceps tendon and the application of manual traction instead of weights. Rollinson allowed the arm to hang under its own weight after a supraclavicular block and reported a 91% success rate with usually no more than a gentle pull on the arm after 20 minutes in this position. [17] Each of these variations of the Stimson method can be used in combination with the scapular manipulation technique described below. Indeed, a success rate of 96% has been reported using the combined prone position, hanging weights, IV drug therapy, and scapular manipulation. [14]

Disadvantages of the Stimson method include the time required and the danger of the patient's slipping off the elevated bed. A "seatbelt" strap or bedsheet may be placed around the patient and stretcher to avoid patient movement off the stretcher. Additionally, a bed that elevates to a suitable height for the patient's arm length, a convenient method to hang the weights, the weights themselves, and adequate staff to monitor the patient are often difficult to locate and organize in a busy ED.

**Scapular manipulation technique.**

This method is popular due to its ease of performance, reported safety, and acceptability to patients. No complications from this technique have been reported in the literature. Shoulder reduction using this method focuses on repositioning the glenoid fossa rather than the humeral head, and it and requires less force than other methods. [14] The success rate is high, generally >90% in experienced hands.

The initial maneuver for scapular manipulation is traction on the arm as it is held in 90° of forward flexion. This may be performed with the patient prone and the arm hanging down as described in the Stimson method, with or without flexion of the elbow to 90° (Fig. 52-9 *A*). Alternatively, this traction may be applied by the operator placing an outstretched arm over the seated patient's mid-clavicle while pulling the injured extremity with the other arm (Fig. 52-9 *B*). Regardless of the means of arm traction, slight external rotation of the humerus may facilitate reduction by releasing the superior glenohumeral ligament and presenting a favorable profile of the humeral head to the

glenoid fossa. [19]

The prone patient position is recommended for those not familiar with the technique, as it facilitates identification of the scapula for the second part of the method. Nonetheless, the technique can be performed with the patient supine, given that the patient's shoulder is flexed to 90° and the scapula is exposed during gentle upward traction on the humerus. [20] Although seated scapular manipulation offers the advantage of not requiring the patient to go through the awkward and potentially uncomfortable assumption of the prone position, it is a technically more difficult variation of scapular manipulation. When placing the patient in the prone position it is important to place the injured shoulder over the edge of the bed to allow the arm to hang in a perpendicular manner for the application of traction. [18]

After application of traction, the scapula is then manipulated to complete the reduction. Anderson and coworkers recommend manipulation of the scapula after the patient's arm is relaxed; [18] however, success is possible with no delay in the performance of this second step. [13] The manipulation of the scapula is carried out by stabilizing the superior aspect of the scapula with one hand and pushing the inferior tip of the scapula medially toward the spine (see Fig. 52-9 *A*). The thumb of the hand stabilizing the superior aspect of the scapula can be placed along the lateral border of the scapula and used to assist the pressure applied by the thumb of the other hand. The tip is pushed as far as possible in the medial direction, and a small degree of dorsal displacement of the scapular tip is also recommended. [18]

When the patient is properly positioned, with the affected arm hanging in a perpendicular fashion, the lateral border of the scapula may be difficult to find in larger subjects. This border is generally located quite lateral with the patient in this position, and it must be properly located prior to any reduction attempt. The reduction itself is occasionally so subtle that it may be missed by both the patient and the operator. A minor shift of the arm may be the only clue to the successful reduction. Careful palpation of the subclavicular area prior to repositioning the patient may be used to determine the success of the reduction.

**External rotation method.**

This method offers the advantage of requiring only one performer and no special equipment. The technique requires no strength or endurance on the part of the operator. Additionally, it has been reported to be well tolerated by patients. The actual pain experienced by patients with this technique has not been quantified, but Plummer and Clinton state it can be performed with "little, if any sedation." [12]

In this technique the basic maneuver is *slow*, *gentle* external rotation of the fully adducted arm. In 1957, Parvin described a self-reduction external rotation technique that he attributed to Boehler. [21] The patient sits on a swivel-top chair and grasps a fixed post at waist height and slowly turns the body to enact external rotation. Parvin reported that the reduction usually takes place at 70° to 110° of external rotation. [21]

More recently, this method has been described with the patient supine and the affected

arm adducted tightly to the side of the patient (Fig. 52-10) (Figure Not Available) . The elbow is flexed to 90° and held in the adducted position with the operator's hand closest to the patient. The other hand holds the patient's wrist and guides the arm into slow and gentle external rotation. The procedure may require several minutes, because each time the patient experiences pain, the procedure is momentarily halted. Although the report of Mirick and colleagues mentioned using the forearm as "a lever," [22] a later description clearly recommends allowing the forearm to "fall" under its own weight. [12] No additional force should be applied to the forearm and no traction is exerted on the arm.

The end point of the reduction may be difficult to identify, as reduction is frequently very subtle. It is therefore recommended to continue the external rotation until the forearm is near the coronal plane (lying on the bed, perpendicular to the body), a process that usually takes 5 to 10 minutes. [12] Reduction may occasionally be noted when the arm is rotated back internally. [23] The success rate of this technique in 3 series performed by emergency physicians was around 80%. One series reported that 36% of reductions could be performed without analgesia.

**Milch technique.**

There are many reports in the literature on the use of this method with praise for its gentle nature, high success rate, lack of complications, and tolerance by patients. [19] [25] [26] It can be described as "reaching up to pull an apple from a tree." The basic steps of this technique are abduction, external rotation, and gentle traction of the affected arm. Finally, if needed, the humeral head is pushed into the glenoid fossa with the thumb or fingers (Fig. 52-11) .

Milch, in describing this technique, wrote that the fully abducted arm was in a natural position in which there was little tension on the muscles of the shoulder girdle. [27] He postulated that this was related to our ancestral "arboreal brachiation" (swinging from trees). [27] The primary step in this technique is to have the affected arm abducted to an overhead position. Russell and coworkers had their patients raise the arm and put the hand behind the head as a first step. [19] Although this seems odd, patients can usually do this quite readily with little assistance and be quite comfortable in this position. Alternatively, the operator may abduct the arm by grasping the patient's arm at the elbow or the wrist. Lacey and Crawford found that the prone position, with the patient's shoulder close to the end of the bed, facilitated this step. [25]

Once the arm is fully abducted, gentle longitudinal traction is applied with slight external rotation. If reduction does not occur quickly, the humeral head can be pushed upward into the glenoid fossa using the thumb or fingers of the other hand. Beattie and associates reported a success rate of 70% with the Milch technique, [4] but others report success rates of 90%. [19] [26]

**Traction-countertraction.**

This method is commonly used in the ED, largely out of tradition, as it has a high rate of success and many emergency physicians are unfamiliar with other methods. Familiarity

is an advantage of this technique, but it requires more than one operator, some degree of force, and, occasionally, endurance. This technique is usually quite uncomfortable for the patient, and premedication is recommended prior to any attempt.

With the patient supine, a sheet or strap is wrapped around the upper chest and under the axilla of the affected shoulder (Fig. 52-12) (Figure Not Available) . An assistant holds this sheet so as to apply the countertraction. The operator's foot should *not* be used in the axilla to provide countertraction. Traction may then be applied to the extended arm, but this generally results in operator fatigue, especially if the operator relies on biceps strength to provide continuous traction. Preferably, the elbow of the affected side is flexed to 90° and a sheet or strap is wrapped around the proximal forearm and then around the operator's back. The bed should be elevated to a point at which the sheet can sit at the level of the operator's ischial tuberosities. This allows the operator to comfortably lean back and use the body weight to supply the force of traction, eliminating the possibility of operator fatigue. The portion of the sheet that is positioned on the patient's forearm has a tendency to ride up; flexion of the elbow beyond 90° will minimize this problem. Alternatively, the operator merely leans backward with the arms fully extended, using the continuous weight of the body rather than the strength of the biceps to provide constant traction.

Once traction is applied, the operator must be patient, as the procedure may take a number of minutes to be successful. Inadequate premedication is noted by the patient who resists the procedure or is notably uncomfortable during the reduction attempt. The operator should not hesitate to order supplementary medications. Gentle limited external rotation is sometimes useful to speed reduction. [5] Applying traction to an arm that is slightly abducted from the patient's body is often successful, but some operators prefer to slowly bring the arm medial to the patient's midline while maintaining traction, or have an assistant apply a gentle lateral force to the midhumerus to direct the humeral head laterally. Successful reduction is usually presaged by slight lengthening of the arm as relaxation occurs, and a noticeable "clunk" may occur at the point of reduction. A brief fasciculation wave in the deltoid may also be seen at the time of reduction.

**Other methods.**

Poulsen reported a method termed the *Eskimo technique*, which may be performed in field settings. [28] In this technique, the patient lies on the unaffected side and is lifted a short distance off the ground by grasping the abducted arm of the injured side. The patient's body weight acts to effect the reduction. Poulsen's success rate was 74% in a series of 23 patients, all of whom were premedicated. [28] Poulsen also postulated that this technique could place undue stress on the brachial plexus or axillary vessels. [28] Use of this technique, when other options are available, should probably be reserved until a larger experience is reported.

Noordeen and associates reported a simple method in which the patient sits sideways in a chair, with the affected arm draped over the backrest. [29] The operator holds the arm with the wrist supinated, and the patient is instructed to stand up. The success rate was 72% in 32 patients treated in this manner. [29] A variation of the chair technique, which was successful in 97% of 188 anterior shoulder dislocations, involves operator-applied

traction to the patient's flexed elbow by means of a cloth loop (e.g., stockinette). [30] While standing beside the patient, the operator supports the involved elbow, holding the cloth loop in 90° of flexion, while stepping down on the cloth loop. The patient sits in the chair, and an assistant may help support the patient by applying countertraction under the involved arm.

Waldron described a technique, without detailing the success rate, that is essentially a reverse of the Stimson method. [31] The patient is placed supine, the affected arm is forward flexed to 90°, and upward traction is applied at the distal humerus with the support of the epicondyles. The elbow is allowed to passively flex, and gentle internal and external rotation is applied through an arc of 20° total. [31]

**Postreduction Care**

After an attempt at reduction, the neurovascular status of the affected extremity should be rechecked and the results documented on the patient record. Indirect evidence that the reduction has been successful includes an immediate reduction in pain, restoration of the round shoulder contour, and increased passive mobility of the shoulder. No harm is done by putting the joint through a limited range of motion. If the patient can tolerate placement of the palm from the injured arm on the opposite shoulder, it is quite likely that the shoulder reduction was successful (Fig. 52-13) .

Postreduction radiographs are recommended, with a careful search for new fractures. Although most greater tuberosity fractures do not alter patient management, patients with greater tuberosity fractures displaced >1 cm after closed reduction should receive prompt orthopedic consultation, as they may require operative repair. [5]

It is important to prevent further external rotation or abduction of the reduced shoulder; adequate immobilization can be obtained by a commercially available shoulder immobilizer. Orthopedic follow-up is recommended for all anterior shoulder dislocations. The incidence of rotator cuff injury is as high as 38% [32] and may complicate restoration of normal function. Younger patients will generally be immobilized for at least 3 weeks and can be instructed to follow up within a week or so of the event. The older the patient, the shorter the time of immobilization. [5] Those older than 60 years should have early follow-up to allow for early mobilization and avoidance of shoulder joint stiffness.

It is appropriate to prescribe oral analgesics at the time of disposition and to instruct the patient to return for any worsening of the clinical condition. Periodically one may encounter a return visit from a successfully treated patient who is in severe pain from a hemarthrosis. Trimmings reported excellent relief of pain by aspiration of the hemarthrosis 24 to 48 hours after shoulder reduction in a series of patients older than 60 years. [33] This can be accomplished using the technique of arthrocentesis described in Chapter 57 . Intra-articular instillation of 10 to 20 mL of 1% lidocaine as has been recommended for shoulder reduction [2] may be helpful for further pain relief.

## Posterior Shoulder Dislocations

Posterior shoulder dislocations account for <5% of all shoulder dislocations. [7] Although uncommon, posterior dislocations are easily overlooked and the emergency physician must be knowledgeable about these injuries to avoid a misdiagnosis. Delays in diagnosis for weeks to months have been reported with posterior dislocations. The mechanism of injury is almost always indirect, with a combination of internal rotation, adduction, and flexion. [5] The precipitating events include seizure, electrical shock, and falls. The patient may also present at a point well past the original event. [35]

**Clinical Assessment**

While they are clinically less obvious than anterior dislocations, posterior shoulder dislocations do present in a typical, recognizable manner. Mistakes are made when the operator is overly reliant on the AP radiographs, which are potentially misleading. [5] The injury may be misdiagnosed as a soft tissue contusion or acromioclavicular strain. The principal signs of posterior dislocation are an arm that is somewhat fixed in adduction and internal rotation. Abduction and external rotation are limited, and attempts to perform these movements can elicit pain. [5] [7] Inspection and palpation reveal a loss of the normal anterior contour of the shoulder and a prominent coracoid and acromion. The shoulder is flattened anteriorly and rounded posteriorly, where the humeral head may be palpable.

Comparison to the opposite shoulder should be undertaken with the understanding that this injury may occasionally occur bilaterally. Neurovascular assessment is performed in the standard manner, although such complications are unusual with posterior dislocations.

**Radiologic Examination**

The key point regarding radiographs for posterior shoulder dislocations is the subtle nature of this dislocation on a single AP radiograph (Fig. 52-14 (Figure Not Available) *A* and *B*) and the diagnostic value of the scapular Y view (see Fig. 52-5 (Figure Not Available) *C*) or the axillary view (Fig. 52-14 (Figure Not Available) *C*). The diagnosis of posterior shoulder dislocation using the axillary view is quite easy, whereas the routine AP and lateral views are difficult to interpret in around half of cases. [35] The axillary view is generally available in the radiology department and can be obtained with as little as 20° to 30° of abduction, with the plate placed on the shoulder. [35] In addition to easy visualization of the posteriorly situated humeral head, the axillary view often reveals an impression fracture of the humeral head (Fig. 52-14 (Figure Not Available) *D*).

Whereas the axillary view is diagnostic, clues to posterior dislocation exist on the AP film. The internally rotated humeral head appears symmetrical on the AP film in the shape of a light bulb as opposed to the normal club-shaped appearance created by the greater tuberosity. [36] With posterior dislocation, the space between the articular surface of the humeral head and the anterior glenoid rim is widened, and there is a decrease in the half-moon-shaped overlap of the head and the fossa (Figs. 52-15 (Figure Not Available) and 52-16) (Figure Not Available) . [34] [36] There may also be a compression fracture of the medial aspect of the humeral head, indicated by a dense line. This is

known as the "trough" sign. [36] A fracture of the lesser tuberosity (see Fig. 52-16) (Figure Not Available) should always prompt a search for the presence of a posterior shoulder dislocation. [34]

### Reduction Technique

An acute posterior dislocation may be reduced by traction on the internally rotated and adducted arm combined with posterior pressure on the humeral head. [5] [35] Premedication is generally indicated and countertraction may be applied with a sheet looped in the affected axilla much as described for anterior dislocations. Neer and Rockwood recommend applying lateral traction on the upper humerus if reduction is delayed. [5] Hawkins and coworkers suggest that posterior dislocations with an impression defect of the humeral head that is >20% of the articular surface require open reduction. [35] Posterior dislocations that have been diagnosed late are difficult to reduce in a closed manner, but an attempt with adequate premedication is generally indicated. [35]

### Postreduction Care

As with anterior dislocations, a repeat neurovascular examination and radiographs are obtained after reduction attempts. As before, the patient's ability to place the palm of the injured arm on the opposite shoulder is suggestive of a successful reduction. Given the rarity of these injuries, orthopedic consultation is often sought early in the care of these patients. Certainly in a training environment, involvement of an orthopedic resident benefits his or her education and should be considered early on. If a successful reduction is unstable, immobilization with application of external rotation, often via a spica cast, will be needed.

## Unusual Shoulder Dislocations

Inferior dislocations of the shoulder, known as *luxatio erecta*, are quite rare, but also quite obvious. The patient presents with the arm locked in marked abduction with the flexed forearm lying on or behind the head. [5] Occasionally, the humerus may have less abduction, thus potentially obscuring the diagnosis. [37] The humeral head can be palpated along the lateral chest wall. Neurovascular compression may be present, but this is usually reversed once reduction is accomplished. [5] Overhead traction (generally with the arm in full abduction) is applied in the longitudinal direction of the arm and cephalad pressure can be exerted over the humeral head much as in the Milch technique. [5] [37] Countertraction toward the patient's feet can be applied using a sheet placed over the injured shoulder. After reduction, the abducted arm is brought into adduction against the body and the forearm supinated. [38]

Scapular dislocation or "locked scapula" is a rare condition that presents with an obvious protrusion of the lateral border of the scapula and significant swelling of the medial border due to tearing of the musculature. [39] Reduction is accomplished by traction on the abducted arm and medial pressure on the scapula.

# ACROMIOCLAVICULAR SUBLUXATION AND DISLOCATIONS

The acromioclavicular (AC) joint is a true diarthrodial joint with a synovial cavity surrounded by a relatively lax capsule and the weak acromioclavicular ligament. This structure allows for the necessary gliding motion for shoulder movement. [40] The major stability of the AC joint comes from the coracoclavicular ligament, which has posterior (conoid) and anterior (trapezoid) components. The mechanism of injury is generally from a direct force such as a fall on the point of the shoulder. [5] There are 4 grades of injury to the AC joint; they are classified by degree or type (I through IV) (Fig. 52-17)

## First degree (type I).

This injury consists of a minor tear in the AC ligament. The coracoclavicular ligament is intact. The clinical findings are limited to tenderness in the area of the AC joint. Radiographs show little if any change in the position of the clavicle in relation to the acromion. [40] The management of this condition consists of a sling for comfort, ice, and mild analgesics. The sling can usually be discontinued after 7 to 10 days. [5] Orthopedic referral is generally not necessary unless return to normal function is delayed beyond 2 weeks.

## Second degree (type II).

In addition to a complete tear of the AC ligament, the coracoclavicular ligament in this injury is stretched or incompletely torn. [40] The patient generally supports the injured arm and has slight swelling and definite tenderness over the AC joint. Radiographs demonstrate a definite change in the relationship of the distal clavicle to the acromion. The inferior edge of the clavicle should not be higher than the top of the acromion in this injury. [40] Others use the radiographic criteria that the coracoclavicular distance is within 5 mm of the uninjured side. [5] This injury is usually treated in a closed fashion with a sling. [5] Orthopedic referral is recommended, and some will use a sling-strap device that elevates the arm and depresses the clavicle for these injuries. [41]

## Third degree (type III).

In this injury, the distal end of the clavicle is essentially free floating, as both the AC and coracoclavicular ligament are completely disrupted. [40] The arm is supported by an uncomfortable patient and the distal clavicle is usually seen to be riding high above the acromion. The diagnosis is generally obvious, and radiographs are mainly used to rule out an associated fracture. Radiographic criteria for this degree of injury include an inferior border of the clavicle above the acromion [40] or a difference of 5 mm in the coracoclavicular distance as compared with the normal side. [5] These injuries require orthopedic referral, and a fair bit of controversy exists regarding the subsequent management of these injuries. [40] Larsen and colleagues conducted the only prospective, randomized trial of conservative vs operative management for significant AC separations and concluded that conservative management was generally better, with possible exceptions made for patients with significant cosmetic deformity and for

those who frequently keep the arm at 90° of abduction. [42]

**Fourth degree (type IV).**

In this injury, the distal clavicle is free floating and posteriorly displaced into the mass of the trapezius muscle. Orthopedic referral is required.

### Radiographic Examination

The diagnosis is usually made clinically, with pain and local tenderness at the AC joint in the absence of other findings. Radiographs are generally indicated to rule out associated fractures and to aid in assessing the degree of injury. In patients with minor clinical findings clearly suggestive of a first-degree injury, radiographs may not be necessary. A single radiograph of the injured shoulder usually suffices, but some clinicians prefer to obtain comparison views of the opposite shoulder. The value of comparison views remains uncertain. It has been traditionally recommended that "weighted" films be obtained in suspected type I or II injuries. [5] Weighted films are superfluous in clinically obvious type III injuries. Weighted films after "unweighted" routine radiographs are obtained by strapping about 4.5 to 7.0 kg (10 to 15 lb) of weight to the patient's wrists and repeating the radiographs. It is important that the patient keep the shoulders as relaxed as possible during this study. As expected, this study may cause significant discomfort for the patient.

Bossart and others examined the routine use of "weighted" studies of the AC joints and recommended abandoning their use in the ED. [43] In a prospective study of 70 type I or II injuries, the use of weights was associated with less evident separation in 7 cases. Only 3 injuries were re-categorized as type III after the performance of weighted films. [43] This yield is not necessarily inconsequential if subsequent management would entail a change in therapy for these 3 patients. However, Bossart and colleagues noted that surgery is often not recommended with type III injuries. [43] It is probably best to discuss the merit of weighted films with the consultant orthopedists and to obtain the study only in the selected cases in which open treatment would be dictated by a type III injury.

## STERNOCLAVICULAR DISLOCATIONS

Despite the fact that the sternoclavicular joint is the least stable joint in the body, sternoclavicular dislocations are rare. [5] The primary supports of this joint are the sternoclavicular and costoclavicular ligaments. [41] Anterior dislocations are much more common and are usually the result of an indirect mechanism involving a blow to the anterior shoulder. [41] Posterior dislocations also usually result from a blow to the shoulder but can also be the result of a direct superior sternal or medial clavicular blow. [5] Posterior sternoclavicular dislocation is potentially life-threatening, as injury to the great vessels or compression of the airway may occur. [5] [44] Any suggestion of these complications should prompt immediate surgical consultation.

The presentation of these injuries is usually straightforward, with pain, swelling, tenderness, and deformity of the joint. Plain radiographs of this joint are difficult to

interpret and generally include an apical lordotic-type view with the radiographic tube angled at 45° cephalad. Confirmation of the diagnosis is best made using a thoracic computed tomographic (CT) scan. [45] Children may have epiphyseal disruption with retrosternal displacement of the medial clavicle. [46]

Closed reduction of both types of sternoclavicular dislocation involves placing a rolled blanket or a sandbag between the scapula and applying traction to the 90° abducted arm in line with the clavicle. [5] The clavicle can also be pushed (anterior) or lifted (posterior) back into position. [5] Posterior dislocations may be difficult to reduce and to maintain reduced in a closed manner [44] and some recommend general anesthesia for all of these. [5] Given the rarity of this injury and the potential for major underlying complications, early consultation is recommended in suspected posterior sternoclavicular dislocations

# ELBOW DISLOCATIONS

The elbow is second only to the shoulder as a site for major joint dislocations in adults, and it is the most commonly dislocated joint in children. Anatomically, the principle articulation of the humerus and ulna is a stable hinge joint with the intercondylar groove of the distal humerus nestled in the olecranon fossa. Due to the stability of the elbow, any dislocation is expected to be accompanied by significant soft tissue damage, and associated fractures are common. Elbow dislocations are often simply divided into posterior and anterior dislocations (Fig. 52-18) (Figure Not Available) . However, there are actually several different types of elbow dislocations, including the two just mentioned as well as medial, lateral, divergent, and isolated dislocations of the radius. [47] In the rare divergent dislocations, the radius and ulna are dislocated in opposite directions, either anterior and posterior or medial and lateral. [47]

The most feared complication of elbow dislocation is injury to the brachial artery. This complication can occur with any type of elbow dislocation and is a frequent occurrence in open dislocations. [48] Vascular compromise can be delayed in onset either from unsuspected arterial injury or from progressive soft tissue swelling. The circulatory status of the arm must be carefully monitored even after successful reduction. [47] Although not an absolute, patients with these injuries are frequently admitted to the hospital for observation, and orthopedic consultation should be sought prior to disposition. [47]

Injury to the median and ulnar nerves may be the result of stretch, severance, or entrapment. It is difficult to clinically distinguish these etiologies, and management of nerve problems is frequently expectant. [47] It is imperative to conduct a careful neurologic examination before and after reduction, as any increase in findings would indicate entrapment and the need for surgical intervention. [47] Myositis ossificans is also a potential complication of this injury, which underscores the advisability of orthopedic consultation early in the course of care.

**Posterior Dislocations**

Posterior dislocations make up the vast majority of elbow dislocations [49] and most often are actually posterolateral dislocations. [47] The usual mechanism is a fall on the outstretched hand, with the arm in extension. The clinical examination is usually diagnostic unless severe soft tissue swelling is present. The patient presents with a shortened forearm that is held in flexion, and the olecranon is prominent posteriorly. The normally tight triangular relationship of the olecranon and the epicondyles of the distal humerus is disturbed in a posterior dislocation. A defect may also be palpated above the prominence of the olecranon. [47]

**Radiologic Examination**

Two radiographic views, preferably an AP and a true lateral view, are obtained. The diagnosis is obvious with proper radiographs. A careful search for fractures is undertaken, as they occur commonly in this injury. In one series of 60 elbow dislocations, 58 of which were posterior, 39% of patients had an associated fracture. [49] In children younger than 14 years, the fracture is usually a medial epicondyle separation, as the epiphyseal plate gives way before the medial collateral ligament of the elbow. [49] Postreduction radiographs are also necessary.

**Reduction Techniques and Postreduction Care**

Although, as with shoulder reduction, many authors claim that their method of reduction is virtually painless, this has not been objectively documented. In general, patients with posterior elbow dislocations are quite uncomfortable, and it is beneficial to administer IV analgesics early in the course of care, preferably prior to positioning for radiographs.

In addition to, or in lieu of, parenteral analgesia, some clinicians inject the elbow joint with a local anesthetic (e.g., 3 to 5 mL of 2% plain lidocaine) prior to attempting reduction. This should be done using strict sterile technique, with a previously unopened anesthetic vial. It may require 10 to 15 minutes for the anesthesia to take effect. The technique is similar to the technique used for aspiration of the elbow joint (see Chapter 57) . Prior to injection, the joint should be aspirated to remove blood.

**Traditional traction method.**

The traditional method  of reducing a posterior dislocation is to place the patient in the supine position and have an assistant stabilize the humerus with both hands (Fig. 52-19) (Figure Not Available) . The operator then grasps the wrist and applies slow and steady in-line traction. The elbow is slightly flexed to keep the triceps mechanism loose, and the wrist is held supinated as traction is applied. Reduction is usually signified by a "clunk" that is heard or felt. If this method is not successful after a reasonable period of traction (10 minutes), the forearm may be gently flexed to try and effect reduction. Alternatively, downward pressure on the proximal volar surface of the forearm may help free up the coronoid process.

Several authors have described variations of a prone method of reduction that is reportedly well tolerated by patients. [21] [50] [51] The patient is positioned with the arm hanging over the padded back of a chair or over the edge of the bed. Minford and Beattie simply applied pressure to the prominent posterior aspect of the olecranon in this position for successful reduction. [51] Lavine applied traction with the elbow flexed over the edge of a chair by pulling down on the hand while using the thumb to guide the olecranon into place (Fig. 52-20 *A*). [50] Parvin positioned the patient as for the Stimson method of shoulder relocation and applied gentle downward traction to the wrist. [21] When the olecranon was felt to ride distally on the humerus, the reduction was completed by lifting the humerus.

**Recommended initial approach.**

A prone technique is advantageous, as patients tolerate this position quite well. The elbow is allowed to hang flexed over the edge of the bed, and an assistant is positioned with the back toward the patient such that the humerus can be encircled with both hands and pressure applied with the thumbs to the posterior aspect of the olecranon. This pressure on the olecranon is intended to lift it up and away from the humerus. The operator applies longitudinal traction to the arm with the elbow in slight flexion. If traction is not succeeding, an attempt may be made to flex the elbow or the assistant can be instructed to lift the humerus (Fig. 52-20 *B*). Reduction is generally noted by a definite "clunk."

**Postreduction care.**

Once reduction is achieved, the elbow should immediately be put through a gentle range of motion to ensure that the reduction is stable and that there is no mechanical block to movement. [47] An inability to move the elbow through a smooth range of motion after reduction is often caused by a trapped medial epicondyle fracture that requires operative intervention. [47] The elbow is generally immobilized in at least 90° of flexion with a long-arm posterior splint. A complete recheck of the neurovascular status is performed along with postreduction radiographs.

Any delayed vascular compromise in the reduced elbow is first addressed by loosening the splint and decreasing the degree of flexion. This usually restores the pulse. [47] The risk of vascular compromise is a reason to consider in-hospital observation. Some operators observe the patient in the ED for 2 to 3 hours postreduction, evaluating for delayed neurovascular compromise prior to consideration of release to home.

## Anterior Dislocations

Anterior dislocations of the elbow are quite rare; they usually result from a direct posterior blow to the olecranon with the elbow flexed. [47] On physical examination, the arm is extended and there is anterior tenting of the proximal forearm with prominence of

the epicondyles posteriorly and an absent olecranon. [47] These injuries are the result of a great deal of force; they are frequently open and accompanied by significant neurovascular injury. An avulsion of the triceps mechanism may also occur.

Reduction of an anterior dislocation of the elbow involves in-line traction and backward pressure on the proximal forearm (Fig. 52-21) (Figure Not Available) . An assistant provides countertraction by grasping the humerus with 2 hands. Given the infrequent nature of anterior dislocations and the high probability of a severe associated injury, the emergency physician should consider early orthopedic consultation in such dislocations.

## Radial Head Subluxation (Nursemaid's Elbow)

Radial head subluxation is a common pediatric presentation generally occurring between the ages of 1 and 3 years. The mean age of presentation is just over 2 years, but this entity has been reported in infants younger than 6 months [52] [53] and in older children up to the preteen years. [54] There is a slight predilection for this injury to occur in girls and in the left arm. [53] [54] The classic mechanism of injury is longitudinal traction on the arm with the wrist in pronation, as occurs when the child is lifted up by the wrist. [53] There is no support for the common assumption that a relatively small head of the radius as compared to the neck of the radius predisposes the young to this injury. [55] The pathologic lesion is generally a tear in the attachment of the annular ligament to the periosteum of the radial neck, with the detached portion becoming trapped between the head of the radius and the capitellum. [55]

### Clinical Assessment

The history offered by the caretaker may not be that of the classic pulling type mechanism. Schunk, in a series of 83 patients, reported that only 51% described such a mechanism, whereas 22% reported a fall. [53] In patients younger than 6 months, the mechanism in the majority is simply rolling over in bed. [52] It is important to remember this and not to proceed with a child abuse investigation unless other suggestive features are present. The typical patient with a nursemaid's elbow presents in no distress with the arm held slightly flexed and pronated at the side (Fig. 52-22) (Figure Not Available) . This has been termed the *nursemaid's position*. [56] The exact area of pain is often difficult to locate. The child will refuse to use the arm, and this may be the chief complaint. [54] The older child will usually point to the dorsal aspect of the distal forearm when asked where it hurts. This may mislead one to suspect a buckle fracture of the distal radius.

Although tenderness about the elbow has been reported occasionally, [53] there is often little tenderness or swelling of the elbow region. [53] [54] In the cooperative child, the arm and shoulder are carefully palpated to discern any tenderness. Areas of focus on palpation should include the clavicle and the distal radius, as these are common sites of pediatric fractures. When patient anxiety interferes with a reliable assessment of tenderness in a child whose arm is in the classic nursemaid's position, the examiner can stand at a distance and have the parent or caretaker palpate the extremity to ascertain tenderness. This may also be done in the cooperative patient to reassure the doubtful parent regarding the absence of a fracture. If no tenderness is noted by palpation, it is

appropriate to attempt a reduction without prior radiographs. Although resistance to or pain with supination is a frequent finding in such patients, [53] one need not test for this finding until the time of reduction.

**Radiographic Examination**

Radiographs are generally not needed in a child presenting with an arm in the nursemaid's position that is nontender (or minimally tender in the radial head area) on palpation, regardless of the history. Radiographs are generally normal when obtained and, if obtained, the positioning of the child's arm by the x-ray technician for these studies often effects reduction. [53] Frumkin described 3 cases of nursemaid's elbow in which a line drawn through the longitudinal axis of the radius did not normally bisect the capitellum on prereduction radiographs, but did so after reduction. [55] Others recommend performing radiographs if the child is not moving the arm normally 15 minutes after reduction. [56] However, this time frame may be too short, as reuse can be delayed for >30 minutes. Quan and Marcuse recommend an approach in which no radiographs are obtained on the first visit, including in those children released from the ED prior to full use of the arm. At the time of a 24-hour follow-up visit, Quan and Marcuse perform radiographs only if repeat attempts at manipulation are not successful. [54]

While this condition does not generally require x-rays, they can be valuable in atypical presentations if external signs of trauma are present (e.g., swelling, abrasions, ecchymoses), or if the child does not use the arm normally after the subluxation is considered reduced. Other less common conditions that can present with similar findings are fractures, joint infections, tumors, or osteomyelitis.

**Reduction Technique**

Reduction of a nursemaid's elbow (Fig. 52-23) (Figure Not Available) is generally performed without premedication. It is important to explain to the caretaker that the reduction will likely cause the child discomfort, but that this is transient and a clue to the diagnosis. The child is positioned seated on the lap of an assistant who stabilizes the arm by holding the humerus adducted to the side. The operator then grasps the elbow with one hand placing the thumb over the region of the radial head. Although it has been stated that the thumb can apply pressure to the radial head, this positioning is mainly useful for palpation of the reduction "click." The other hand grasps the wrist and is then used to supinate the extended forearm in a steady, deliberate manner. Slight traction prior to supination is generally recommended, but it is unclear whether this actually adds to the supination maneuver. Once supinated, the arm can be flexed or extended; however, flexion is the most common maneuver and may actually be somewhat more successful than extension. [53] An audible or palpable click signifies successful reduction, but it is not always noted. Once the reduction has been performed, the child usually cries for a few minutes. Generally the operator should leave the room and then return in 10 to 15 minutes to do a repeat examination.

If a click is detected, the child will generally regain use of the arm quickly (almost always by 30 minutes). [54] Therefore, if a definite click is detected, it is reasonable to observe

the child for up to 30 minutes prior to further intervention. If there is still no use at 30 minutes, the operator may try to determine if supination is still painful, which would suggest the need for a repeat attempt. In those in whom a click is not detected, the majority will not use the arm by 30 minutes. [54] If a click was not detected, it is suggested to repeat the attempt after 10 to 15 minutes of nonuse. Two or more attempts are required to produce the click in up to 30% of patients. [54]

If the child has not regained the use of the arm after a few attempts and a reasonable period of time, radiographs can be obtained. [56] X-ray films also may help relieve parental anxiety. Alternatively, instructions should be given for 24-hour follow-up if normal function is not restored, with consideration for radiographs at the time of follow-up. [54] In 2 series of patients with nursemaid's elbow, [53] [54] of 10 patients released without normal arm use, 6 had spontaneous restoration of function, and the other 4 required remanipulation, which successfully restored function. The use of a posterior splint to protect the elbow of the child who refuses to use the arm after a presumed reduction is of uncertain value. Some form of immobilization (e.g., splint, sling, or both) may be valuable in the child with significant residual discomfort following a prolonged period of subluxation or in whom recurrent subluxations have occurred. On occasion, a successful reduction painfully resubluxates with movement; in this case, immobilization and referral may be necessary. [55] If reduction has been achieved clinically and maintained in the ED, analgesics or a follow-up visit are unnecessary. Because other pathology can *rarely* mimic this condition (e.g., occult fractures, osteomyelitis, joint infection, and tumors), full, unrestricted, and painless use of the arm must be documented at either the initial ED visit or at a follow-up visit within 24 hours.

## HAND INJURIES

The hand is an extremely common site of injury due to the demands placed on it and the exposed nature of this region. Proper motion and function of the hand are intimately related to normal anatomic alignment. [57] The emergency physician must therefore be skilled in the diagnosis and management of dislocations about the hand. An improperly managed hand injury can result in significant disability that the patient is reminded of on a daily basis.

Anatomically, the joints of the digits are quite similar and consist of a hinge joint with a tongue-in-groove type arrangement. [57] The soft tissue support includes 2 collateral ligaments that are attached to a volar plate (Fig. 52-24) (Figure Not Available) . The volar plate is dense fibrous connective tissue that is thickened at its distal attachment and thinner at its proximal attachment, to allow for folding with joint flexion.  Dorsal dislocation of a digit requires failure of the volar plate, whereas lateral dislocation disrupts a collateral ligament and induces at least a partial tear in the volar plate (see Fig. 52-24) (Figure Not Available) .

Radiographic examination of all hand injuries is relatively straightforward, including at least 2 views of the injured area. The most important radiographic error is failing to get a true lateral view of the injured joint. [58] This may lead to missing a fracture or a loose body in the joint.

Anesthesia is generally required for the proper management of dislocations about the hand. This is most often accomplished by finger or wrist block, although a more proximal regional or Bier block may be used on occasion (Chapters 32 and 34) . Getting a secure grip on the digits may be difficult and may complicate the reduction. Wearing rubber gloves or wrapping gauze around the fingers may be useful.

## Thumb Dislocations

The opposable thumb is an essential structure for countless activities. Despite its strong ligamentous and capsular support, the exposed positioning of the thumb makes it a frequent site of dislocations and subluxations. The metacarpophalangeal (MCP) joint is similar to those of the fingers but has a stronger volar plate and collateral ligaments.

### Interphalangeal (IP) Joint Dislocation of the Thumb

The single interphalangeal (IP) joint of the thumb has strong cutaneous-periosteal attachments, and dislocations of this type are therefore frequently open. [58] Dislocations are generally dorsal and can be reduced in a manner similar to IP dislocations of the finger (Fig. 52-25) (Figure Not Available) . The mechanism of injury is recreated by longitudinal traction and hyperextension to distract the phalanges. Reduction is accomplished by flexing the finger with continued traction and by applying direct pressure to the base of the distal phalanx. [58]

Following reduction, the range of motion is tested and the stability of the reduction is ascertained. An adequate reduction that is documented on postreduction films is then splinted in slight flexion for 3 weeks. [58] Orthopedic referral is advisable.

### Metacarpophalangeal Joint Injury of the Thumb

#### Dorsal dislocation.

The MCP joint of the thumb can be dorsally dislocated by a hyperextension injury. The proximal phalanx will come to rest in a position dorsal to the first metacarpal (Fig. 52-26) (Figure Not Available) . There are two basic types of MCP dislocations (this applies to the fingers also): simple and complex. The simple type is amenable to closed reduction, whereas the complex requires operative reduction due to interposed soft tissue. Additionally, a simple MCP dislocation can be converted into a complex one during reduction. [57] In a complex MCP dislocation, the volar plate becomes entrapped dorsal to the metacarpal head (Fig. 52-27) (Figure Not Available) with the flexor tendons and lumbricals acting to complete the trapping of the metacarpal head. [58]

Clinical features that suggest a complex MCP dislocation include a proximal phalanx that is less acutely angulated than with a simple dislocation (i.e., <60°). [58] There may also be dimpling on the palmar skin due to pressure from the entrapped metacarpal head. This will be seen over the thenar eminence of complex thumb MCP dislocations. [57] On radiographic studies of simple dislocations, the joint surfaces are in close contact,

whereas they are separated in complex dislocations. The presence of a sesamoid bone in the joint space is diagnostic of a complex MCP dislocation (Fig. 52-28) (Figure Not Available) . [57]

Reduction of a simple MCP dislocation (Fig. 52-29) (Figure Not Available) involves hyperextension of the joint as far as possible with the wrist in flexion to relax the tendons. Once maximal hyperextension is achieved, the base of the proximal phalanx is pushed distally while the joint is brought back into flexion. [57] Applying simple traction alone as an initial maneuver risks trapping the volar plate and creating a complex dislocation. [57] After reduction, the stability of the reduction is tested by placing the joint through a range of motion, and the integrity of the collateral ligaments can be assessed with the MCP joint in flexion (see below). Simple MCP dislocation injuries generally require casting for 3 weeks with the joints in moderate flexion. [58]

**Ulnar collateral ligament rupture.**

Also known as *gamekeeper's* or *skier's thumb,* this injury results from a laterally directed force at the thumb MCP joint. A rupture of the ulnar collateral ligament of the MCP joint occurs (Fig. 52-30) (Figure Not Available) . The usual mechanisms include falling with a ski pole in hand or having the thumb alone draped over the steering wheel in an auto crash. These injuries most often present in the reduced state with just the complaint of pain in the area. It is essential to recognize this injury to prevent further disability in the patient, as this ligament is important for the grasping function of the thumb.

The diagnosis is generally made through stress testing of the MCP joint (Fig. 52-31) . Radiographs occasionally demonstrate an avulsion-type fracture. The exact positioning of the thumb for stress testing is debatable, but the metacarpal should be stabilized with the thumb and index finger of one hand and stress applied with the other hand. Louis and coworkers recommend testing this joint in full flexion, as virtually no lateral movement of the MCP joint should be noted in this position. [59] Instability in full flexion of >35° was found to be indicative of complete rupture. [59] Others suggest testing the MCP joint in 20° to 30° of flexion to lessen the stabilizing effects of the volar plate; the results should be compared with stability on the other side. [58]

Partial injures to the ulnar collateral ligament are generally casted for 3 weeks; complete rupture usually requires operative repair. [59] An associated non-displaced fracture may be treated closed; displacement is an indication for operative repair. [59]

**Carpometacarpal Dislocations of the Thumb**

Carpometacarpal dislocations of the thumb are uncommon; when present, they often occur with an associated fracture. Closed reduction is generally unstable, usually necessitating operative stabilization through the percutaneous placement of Kirschner wires. [58]

## Finger Dislocations

The basic anatomic structure of the fingers is similar to that of the thumb with the exception that there is more lateral support of the MCP joints, making collateral ligament injury here much less common than in the thumb. The treatment principles are also similar. It is advisable to order radiographs for a specific finger (not just "hand" films). Complete views of the finger will include an AP view, a true lateral view, and an oblique view. The true lateral view is extremely important for detection of subtle dislocations or small avulsion fractures on the volar surface (Fig. 52-32 (Figure Not Available) *A* and *B*).

**Proximal Interphalangeal Dislocations**

The proximal interphalangeal (PIP) joint is extremely important, and any loss of motion in this joint severely restricts normal function. [57] This joint is also prone to stiffness, so careful treatment of injuries to this area is essential. Injuries to the PIP joint are generally slow to heal and often result in an increase in joint size due to scar tissue formation. [57] Because of this propensity for a less-than-perfect outcome, it is advisable to refer PIP injuries after emergency care.

Proper examination of the PIP joint (Fig. 52-33) (Figure Not Available) includes ulnar and radial stress to test the integrity of the collateral ligaments and hyperextension to determine the integrity of the volar plate. The inability to actively extend the flexed PIP joint against resistance suggests a central slip rupture, which may progress to a boutonniere deformity. [57] Such an examination should be carried out after any successful joint reduction. This examination should also be conducted in the painful PIP joint that is radiographically normal to detect soft tissue injury in a spontaneously or field-reduced dislocation. This is extremely important in athletes, as coaches often reduce these injuries. [57]

**Dorsal PIP dislocations.**

These are one of the most common types of dislocations encountered in the ED. The mechanism is usually a blow to the end of the finger, such as from a thrown ball, which creates an axial load and hyperextends the finger. [58] The middle phalanx comes to rest dorsal to the proximal phalanx (Fig. 52-34) . There is always an associated disruption of the volar plate. [57] [58] The deformity is obvious on clinical examination, and radiographs clearly demonstrate the injury. An associated fracture of the volar lip may be detected. If this fracture affects >33% of the joint surface, a closed reduction will be unstable and operative repair will be necessary, as the collateral ligament is attached to the bony fragment. [58]

A dorsal PIP dislocation can be reduced after a finger block. The usual method (see Fig. 52-25 (Figure Not Available) *E-H*) is to exaggerate the injury by slight traction and hyperextension, thereby distracting the injury. One can then apply pressure to the base of the middle phalanx as the finger is brought into flexion. These injuries usually reduce fairly easily, and failure of routine attempts should raise the suspicion of interposed soft tissue, for which an orthopedic consultation should be sought.

After reduction is completed, the joint should be placed through a range of motion to ensure stability of the reduction. If stable, the joint is generally splinted in flexion of 20° and 30° for 3 weeks. [57] [58] As PIP injuries can be slow to heal and are complicated by stiffness, it is advisable to refer patients with these injuries for orthopedic follow-up.

**Volar PIP dislocations.**

These are uncommon injuries and virtually always are accompanied by an injury to the central slip of the extensor tendons, which can lead to a boutonniere deformity if improperly immobilized (see Chapter 51) . [57] It is generally best to seek early orthopedic consultation for these injuries, as many require operative repair. If closed reduction is accomplished by the emergency physician, splinting in extension should be undertaken for 3 weeks, with early orthopedic follow-up. [57]

**Lateral PIP dislocations.**

These injuries are fairly common and are often reduced in the field. The patient will often dramatically describe how the finger was pointing in an unnatural manner. The injury can be detected by ulnar and radial stress of the PIP joint. If still dislocated, reduction is usually easily accomplished by recreating the injury and applying longitudinal traction to the finger. Partial tears of the collateral ligaments can be treated by buddy taping the finger for 3 weeks. [57] The management of complete tears is controversial, with some using operative therapy for all such injuries. [57] Referral is suggested for all but the mildest of PIP collateral ligament injuries.

**Distal Interphalangeal Dislocations**

As in the thumb, the distal phalanx is attached firmly to skin and subcutaneous tissue by osteocutaneous fibers. For this reason, dislocations of the distal interphalangeal (DIP) joint are frequently open. [57] A DIP dislocation is usually dorsal, and the mechanism is a blow to the end of the finger. Despite the dislocation, the DIP joint may retain some range of motion, so it is important not to overlook these injuries. [60] Lateral radiographs are diagnostic.

Management of the dorsal DIP dislocation involves reduction in a fashion similar to that described for other IP joint injuries. The injury is distracted by traction and hyperextension and relocated by pressure on the base of the distal phalanx during flexion. [57] Subsequent management involves application of a dorsal splint with 5° to 10° of flexion for 3 weeks. [57]

An injury to the DIP joint that may be confused with a dislocation is the mallet finger (Fig. 52-35) . The injury is often caused by blunt trauma to the end of the finger (e.g., struck by a baseball). The patient presents with an inability to extend the fingertip. The joint appears normal on passive extension by the examiner. The injury is a rupture of the extensor tendon, with or without avulsion of a small piece of bone. Unless the injury is properly splinted or surgically immobilized, a permanent deformity will occur (see

**Metacarpophalangeal Dislocations**

The pathology and management of finger MCP dislocations are identical to those of the thumb, as discussed above. The same classification of simple and complex applies; the complex type requires operative repair. Dimpling on the palmar surface suggests the presence of a complex dislocation. It is important to remember that the application of traction alone for a simple MCP dislocation may convert it to a complex dislocation. After the wrist is flexed to relax the tendons, the initial maneuver in reduction should be hyperextension as far as possible. This is followed by pressure on the base of the proximal phalanx to effect reduction. [57] After reduction of a simple MCP dislocation, buddy taping is generally sufficient to secure the reduction. [57]

**Carpometacarpal Dislocations**

Carpometacarpal dislocations are rare injuries that are frequently misdiagnosed. The usual site of injury is the fifth carpometacarpal joint, which is dorsally dislocated. [58] The injury is usually the result of a high-energy mechanism, such as a motor vehicle crash or a fall. The diagnosis can be quite difficult, as it may be obscured even on the lateral radiograph. Associated fractures and other injuries are frequently present, and percutaneous fixation is usually required.

# HIP DISLOCATIONS

The hip is generally a stable ball-and-socket joint. The head of the femur is deeply situated in the acetabulum, and ligamentous and muscular support is very strong. Hip dislocations are therefore usually the result of significant forces, and a careful search for other limb- or life-threatening injuries must be undertaken. Conversely, in cases of severe multiple trauma in which the evaluation and treatment of other injuries take priority, a dislocated hip may be overlooked unless specifically sought after immediate life-threatening injuries have been addressed. Common mechanisms of hip dislocation include motorcycle crashes, car crashes, and falls.

Associated fractures are quite common with hip dislocations. In fact, up to 88% of hip dislocations present with an associated fracture. [62] When a fracture complicates the dislocation, orthopedic consultation is generally indicated. The emergency physician should be able to reduce type I hip dislocations, which are dislocations without an associated fracture or with a very minor fracture.   Hip dislocations may occasionally be missed in the setting of severe trauma, as other injuries garner more attention. A missed diagnosis can also occur when a femur fracture obscures the clinical picture of hip dislocation. [63] Sciatic nerve injuries are seen in 10 to 14% of posterior hip dislocations. One of the more disabling complications is avascular necrosis of the femoral head. Although it is generally stated that early reduction will reduce the frequency of this complication, evidence for this statement is hard to find. Dreinhofer and coworkers noted poor outcomes despite early (i.e., <6 hours) reduction of type I hip dislocations. [62] Yang and colleagues found that reduction beyond 24 hours was associated with a

worse prognosis, but they could not find a significant time factor for those reduced in <24 hours. [61] However, it is still advisable to reduce hip dislocations as soon as feasible, to decrease soft tissue distortion. If evidence of nerve injury exists, the dislocation should be treated as an emergency and should be reduced as early as possible.

## Radiographic Examination

Dislocation of the hip is generally obvious on the standard AP film that is often taken during trauma resuscitations as a pelvic film. The use of a lateral or oblique view may help clarify the type of dislocation, but this can usually be deduced through clinical examination.

## Analgesia and Anesthesia

The dislocation of a prosthetic hip can usually be managed with moderate amounts of IV premedication in the ED. Premedication recommendations for acute traumatic dislocations run the gamut from general anesthesia for all reductions [62] to IV sedation only. [64] Some IV premedication is recommended, and patients often require deep sedation if the procedure is to be successful in the ED. One should not hesitate to push for spinal or general anesthesia if a reasonable attempt at reduction fails in the ED.

## Posterior Hip Dislocations

A posterior hip dislocation is usually the result of a force on the flexed knee with the hip in varying degrees of flexion. The greater the amount of flexion of the hip at the time of the injury, the less the chance of an associated fracture. [63] The humeral head is forced out of the acetabulum and rests behind it (Fig. 52-36 (Figure Not Available) *A* and *B*). The sciatic nerve is located just behind the hip joint and may be injured with posterior hip dislocation. The clinical picture includes a shortened, internally rotated, and adducted leg.

### Reduction Techniques

Two basic methods for hip reduction have been reported in the literature. In the prone or gravity method of Stimson (Fig. 52-37) , the patient is placed so that the distal pelvis overhangs the edge of the stretcher. The hip, knee, and ankle are all flexed to 90°, and downward pressure is applied to the proximal posterior tibia. [63] The hip can be gently internally and externally rotated to facilitate reduction, and direct downward pressure may be applied to the femoral head by an assistant. An alternative and more comfortable way to provide downward pressure on the tibia is for the operator to grasp the patient's ankle and place his or her own knee on the patient's calf, applying the body weight for pressure. [64]

Other techniques involve placing the patient in a supine position with downward stabilization of the pelvis performed by an assistant. In the Allis technique (Fig. 52-38) , upward traction is exerted in line with the deformity, and the hip is flexed to 90°. The hip

can be gently rotated internally and externally until it is reduced. [63] Howard suggests modifying this technique by applying lateral traction to the flexed upper femur to disengage the head of the femur from the outer lip of the acetabulum. [65]

Once reduction is achieved, the legs are immobilized in slight abduction through the placement of pillows or another object between the knees. Reduction is confirmed by repeat radiographs, and the patient will require admission to the hospital.

## Anterior Hip Dislocation

Anterior hip dislocation is a less common injury than posterior dislocation, constituting 10 to 15% of all hip dislocations. There are three general types of anterior hip dislocations, which are defined by where the femoral head comes to rest (Fig. 52-39) (Figure Not Available) : the iliac or subspinous, the pubic, and the inferior or obturator dislocation. Anterior hip dislocations generally result from a forced abduction of the thigh, which may occur in a fall or motor vehicle crash. [63] The clinical picture varies with the type of dislocation. With the obturator (inferior) type, the leg is abducted and externally rotated with varying degrees of flexion. In the other types, the hip is usually extended and externally rotated. [63]

### Reduction Techniques

The Stimson gravity method may work for anterior hip dislocation, although it is not recommended for the pubic type. [63] Alternatively, the Allis maneuver is applied in a modified fashion (Fig. 52-40) . The patient is placed in a supine position and an assistant stabilizes the pelvis and applies lateral countertraction to the thigh. Traction by the operator is applied in the long axis of the femur with the hip slightly flexed. The leg is then gently adducted and internally rotated to effect reduction. As with posterior dislocations, admission to the hospital is required for patients with these injuries.

# KNEE (FEMUR/TIBIA) DISLOCATIONS

Although the knee is a simple hinge joint, dislocations are quite rare due to its strong ligamentous support. The major ligaments include the anterior and posterior cruciate and the collateral ligaments. The usual mechanism of a knee dislocation involves a great deal of force, such as a motor vehicle crash or a sporting injury. However, knee dislocation has been reported after minor mechanisms, such as stepping off a curb or into a hole. [66] There are five general types of knee dislocations, including anterior, posterior, medial, lateral, and rotatory (Fig. 52-41) (Figure Not Available) . Knee dislocations are described with respect to the position of the tibia in relation to the femur. [67]

## Clinical Assessment

Knee dislocations are usually clinically obvious; however, they may have been reduced at the scene. A grossly unstable knee is probably a reduced dislocation and carries the same risk of vascular and other complications as a dislocated knee. [68] The severely

unstable knee can be defined as one that has >30° recurvatum (hyperextension) [68] or one that has medial joint opening when stressed in full extension. [67]

An impressive effusion may not be present in knee dislocation, as the joint capsule is often disrupted and extravasation occurs into the surrounding tissue. [67] The most important part of the clinical assessment is the vascular status of the extremity (see below). Nerve injury is less common, but peroneal nerve injury is a recognized complication, particularly of a posterolateral dislocation. [69] Posterolateral dislocations may be irreducible, as the medial femoral condyle buttonholes through the joint capsule. [70] A clue to this injury is the presence of a dimple sign at the medial joint line. [70]

**Vascular Injury**

The most feared complication of a knee dislocation is severance of the popliteal artery. Vascular injury is frequent in knee dislocations due to the popliteal artery being relatively fixed both proximally and distally. [67] This complication can be seen with both anterior and posterior dislocations. [69] Varnell and others pointed out that vascular injury was as common in the severely unstable knee as in a dislocated knee. [68] The incidence of popliteal artery injury in a dislocated knee is around 20% in most series. The seriousness of this complication is largely due to the fact that collateral circulation about the knee is poor, [66] and amputation may be the end result of popliteal artery (or vein) injury.

It has been previously stated that popliteal artery disruption can occur with a full pulse. [70] Such statements have led to recommendations to perform arteriography or exploration in all knee dislocations. [67] Recent studies question that perspective. Varnell and coworkers reported a pulse deficit or absence in all patients with vascular injury. [68] Kendall and colleagues also reported clear clinical evidence for all popliteal artery injuries in knee dislocations. [71] This group recommended exploration for obvious ischemia, angiography for those with ischemia who have pulse restoration after relocation, and observation for all others. [71]

If vascular compromise is detected on clinical assessment, it is appropriate to reduce the knee dislocation without obtaining radiographs. [67] [69] The use of the Doppler flow meter for pulse checks and ankle-brachial pressure indices should also be considered in these injuries (see Chapter 70) .

## Reduction Technique

Premedication is dependent on the clinical situation, but it should be considered when possible. The basic initial approach for all types of knee dislocations is to apply traction to the extremity (Fig. 52-42) (Figure Not Available) . This alone is often all that is required for reduction. [70] For anterior dislocations the distal femur is lifted to effect reduction. For posterior dislocations the proximal tibia is lifted to complete the reduction. [67] For medial and lateral dislocations a similar approach is acceptable, with pressure being exerted as needed in the medial or lateral direction.

After reduction the extremity is splinted in 15° of flexion. The posterolateral dislocation may be irreducible, and operative intervention should be considered if reduction is not easily accomplished.

**Postreduction Care**

Appropriate aftercare in knee dislocations involves serial reassessment of the neurovascular status of the extremity. Postreduction radiographs are performed and the patient is admitted to the hospital. These injuries cause severe ligamentous and other derangements in the knee and generally require operative stabilization.

# DISLOCATIONS OF THE FIBULAR HEAD

The fibula can be dislocated at its proximal articulation in the knee joint. This is most commonly an anterior dislocation. [67] The fibular head is normally nestled in a stable manner behind the lateral tibial condyle with 2 supporting tibiofibular ligaments. [72] The tibiofibular joint has a separate synovial cavity, and therefore a typical knee joint effusion will not be seen with this dislocation. When the knee is flexed the stability of this joint is decreased due to relaxation of the fibular collateral ligament. [72] The typical mechanism of injury is a fall on the flexed, adducted leg, often combined with ankle inversion. This mechanism is seen in sports and parachute landings. [72] Posterior dislocations can occur from a direct blow to the area while the knee is flexed, such as in horseback riding. [67]

Anterior dislocation is accompanied by obvious prominence of the fibular head anteriorly; no associated neurovascular problems are noted. The more uncommon posterior dislocation often is accompanied by an injury to the peroneal nerve. [67] Patients present with varying degrees of disability, and some may walk on the leg with only mild discomfort. [72] On radiographic examination, the 3 cardinal signs of anterior dislocation are lateral displacement of the fibula on the AP film, a widened proximal interosseous space, and anterior displacement of the fibular head on the lateral view. [72]

**Reduction Technique**

The position for reduction of an anterior fibular head dislocation is to place the patient supine and flex the knee to 90° in order to relax the biceps femoris tendon. The foot can also be inverted to create further distraction at the site. [67] Direct pressure is then applied to the fibular head and reduction is usually signified by a snap. [72] The method for a posterior dislocation is the same except that the direct pressure is applied in forward manner.

# PATELLAR DISLOCATION

Patellar dislocations are fairly common, especially among adolescents. The usual mechanism is a powerful quadriceps contraction combined with a strong valgus and

external rotation component. [73] This may be seen in activities such as making a "cut" in sports or with dancing. The patella may also dislocate from a direct blow to the flexed knee. [67] Predisposing factors to patellar dislocation include genu valgum and femoral anteversion. [73] The patellar dislocation is described by the relation of the patella to the knee joint. Lateral dislocations are the most common by far. Other types include superior, medial, and intra-articular.

## Clinical Assessment

Lateral dislocation of the patella is generally clinically obvious (Fig. 52-43) . The knee is held in some degree of flexion and the patella can be easily seen and palpated on the lateral side of the knee. A tenting type action of the patella is often detectable unless significant soft tissue swelling is present.

The patella may be spontaneously reduced in the field with leg straightening. The patient will report that the leg "went out" and may describe actually seeing the lateral deformity caused by the displaced patella. Clinical clues to the spontaneously reduced patella include the presence of a knee effusion and tenderness along the medial edge of the patella. Fairbank's test or the patellar "apprehension" sign is elicited when the patella is pushed laterally and the patient grabs for the knee, indicating the sensation of repeat injury. [67]

## Radiographs

Prereduction films are difficult to obtain as the patient is usually in flexion. Some recommend prereduction films in all patients; [67] however, it is an easy matter to reduce these injuries prior to radiography. The diagnosis is usually obvious and there are no reports in the literature of complications from gentle reduction. Osteochondral fractures are detectable in about half of patients with patellar dislocations, but many of these are only visible on arthroscopy. [73] Postreduction radiographs are recommended, as are prereduction studies, when the diagnosis is uncertain. The clinical diagnosis of patellar dislocation in an older patient should be made with caution, as these are primarily injuries of the young.

## Reduction Technique and Postreduction Care

Reduction of a lateral patellar dislocation is usually quite simple. Premedication is often not required if the patient can be verbally reassured. If the patient is anxious or in great discomfort, premedication should be considered. The 2 basic maneuvers for patellar relocation are extension of the knee and gentle medial pressure applied to the patella, lifting the most lateral edge of the patella over the femoral condyle (Fig. 52-44) (Figure Not Available) . [67]

The leg is then immobilized in extension. This may be done by casting or application of a commercially available knee immobilizer. Orthopedic follow-up is necessary because of the need for physical therapy and the high rate of persistent instability. [73]

Patellar dislocations in other locations are often irreducible, and orthopedic consultation should be sought in these circumstances. Hospitalization is not required for routine lateral dislocations of the patella.

## ANKLE DISLOCATIONS

The ankle joint is a modified hinge-type joint in which the talus is nestled in the mortise formed by the distal tibia and fibula. [74] The ligamentous support of the ankle is quite strong, and pure dislocations are uncommon. Usually there are associated fractures of the ankle joint (Fig. 52-45) (Figure Not Available) . Ankle dislocations

are described by the relation of the talus to the tibia. Posterior dislocations of the ankle are more common than area anterior dislocations, and they usually result from a fall on a plantar flexed foot. Patients with posterior dislocations often have an associated fracture of the posterior tibial margin (Fig. 52-46) (Figure Not Available) . [74] The clinical picture is usually one of significant deformity and disability.

Anterior dislocations generally result from forced dorsiflexion or a posterior blow to the distal tibia while the foot is fixed. The talus is prominent anteriorly and the dorsalis pedis pulse may be lost secondary to pressure from the talus. [74] Superior dislocations are uncommon and result in diastasis of the tibiofibular joint. These injuries are usually the result of a significant axial force. Lateral dislocations of the ankle are always fracture dislocations.

### Radiographic Examination

Because of the high rate of associated fractures and the clinical difficulty in assessing for the presence or the nature of a dislocation, it is recommended that prereduction radiographs be obtained in all suspected ankle dislocations. An AP and lateral view usually suffice for emergency management, and other views can be ordered if necessary after the joint is relocated.

### Analgesia

Unless a strong contraindication is present, it is advisable to administer IV premedication to patients with ankle dislocation early in their care, preferably before conducting any manipulations or radiologic studies. Reduction is always painful, and sufficient premedication must be administered.

### Reduction Techniques

For posterior dislocations, the patient is placed supine and the knee is flexed to relax the Achilles tendon. This can be done by an assistant, or the patient can be brought to where the knee hangs over the end of the bed. The operator then grasps the foot with both hands, placing one hand on the heel and the other on the forefoot (Fig. 52-47)

(Figure Not Available) . The foot is flexed slightly plantar, and traction is applied to the foot. A second assistant can then apply downward pressure on the distal tibia as the operator moves the heel anteriorly to effect reduction. [75]

For anterior dislocations, the initial steps and positioning are the same as for posterior dislocation (Fig. 52-48) (Figure Not Available) . However, instead of plantar flexion, the foot is dorsiflexed to free up the talus. The second assistant applies upward pressure to the distal tibia while the operator pushes the foot in a posterior direction. [74]

Lateral dislocations are really fracture-dislocations, and orthopedic consultation is generally required. The emergency physician will often need to reduce these injuries due to the extreme lateral deformity and the occasional compromise of the dorsalis pedis artery by stretch. Open dislocations (in the absence of vascular compromise) may be better handled by cleaning in the operating room prior to attempts at reduction. If a lateral fracture-dislocation is to be reduced in the ED, the approach is quite similar to that for posterior ankle dislocation. However, instead of pressure in the AP direction, the foot is moved medially after application of traction.

### Postreduction Care

The ankle is splinted at 90° with a long-leg posterior splint; necessity for admission to the hospital will need to be determined in consultation with orthopedic surgeons. Many patients with these injuries have associated fractures that necessitate surgical intervention.

## DISLOCATIONS OF THE FOOT

The importance of the foot is recognized by anyone who has had to spend time ambulating with an injury to this area. For the purposes of discussion, injuries to the foot can be divided into those of the hindfoot and those of the forefoot.

### Hindfoot Injuries

Injuries to this area are uncommon and usually require high-energy transfer. The major dislocations are the subtalar and talar dislocations, and midtarsal fracture-dislocations (Lisfranc's injury). Lisfranc's injury is complex and is always a fracture-dislocation because of the rigid nature of the region. These injuries require orthopedic management and are not discussed.

#### Subtalar Dislocation

This uncommon injury generally occurs secondary to sports, falls from heights, or motor vehicle crashes. The calcaneus, navicular, and forefoot are displaced from the talus. [75] The primary process is severe inversion causing a medial dislocation, or severe eversion resulting in a lateral dislocation. It occurs so commonly during basketball that it has been termed *basketball foot.* [76] This is an injury usually seen in young adult males. Medial dislocations constitute the majority (85%) of these injuries, with lateral

dislocations making up the rest. [76]

The diagnosis is usually obvious, as the talus is prominent and often tents the skin of the proximal foot. The medial type has been termed an "acquired clubfoot," whereas the lateral appears as an "acquired flatfoot." [76]

Some authors recommend spinal or general anesthesia for all such injuries; however, it is commonly possible to reduce these injuries with IV premedication. The patient is positioned in a supine fashion and the knee is flexed much as in posterior dislocation of the ankle. One hand is placed on the forefoot and the other grasps the heel. Firm longitudinal traction is required to effect reduction, and dangling the leg over the end of the bed allows the operator to use his or her body weight to assist in traction. Once traction is applied, the deformity is initially increased (inversion for medial; eversion for lateral) and then reversed to effect reduction. [76]

### Dislocation of the Talus

In this extremely rare injury, the talus is essentially extruded from its normal position, coming to lie anteriorly. This injury is not amenable to closed reduction and virtually always progresses to avascular necrosis. [77] Talectomy is generally required, and orthopedic referral should be emergently undertaken if vascular compromise of the foot is present.

## Forefoot Dislocations

Much of what is pertinent to the diagnosis and management of forefoot dislocations has already been discussed in the management of dislocations of the fingers and hand MCP joints. Anatomically, the joints are quite similar.

### Metatarsophalangeal (MTP) Dislocations

These uncommon injuries are generally the result of hyperextension resulting in a dorsal dislocation of the MTP joint. [78] As with MCP dislocations, these can be simple or complex. Complex dislocations of the first toe can be suspected by the presence of sesamoid bones in the joint space in the prereduction radiographs. [76] Complex MTP dislocations are irreducible.

For simple MTP dislocations, reduction is accomplished by increasing the deformity through hyperextension and then applying traction while applying thumb pressure over the base of the dislocated proximal phalanx. Plantar flexion of the foot may be used to relax the flexor tendons. [75] Operative intervention is required after reduction if crepitus is present on motion, the joint is unstable, or an intra-articular loose body is noted on the postreduction radiographs. [76]

### Interphalangeal Dislocations

In the foot, IP dislocations result from an axial load to the toe, such as from kicking a

wall. These dislocations are generally dorsal and can be reduced as in the hand. Dislocations of the first toe interphalangeal joint are usually buddy taped to the second toe for 2 to 3 weeks, whereas those of lesser toes can be taped for 10 to 14 days.

## CONCLUSION

The following points are important regarding the assessment and management of dislocations:

1. A search for other more serious injuries should be undertaken when there is a high-energy mechanism of injury.
2. A neurovascular assessment should be performed early in the evaluation and appropriately documented.
3. Radiographs and IV premedication are generally indicated prior to reduction attempts.
4. Reduction attempts should involve the gentle, gradual application of forces and patience on the operator's part.
5. After completion of reduction, the operator should recheck the neurovascular status, request postreduction radiographs, and, in certain circumstances, assess the stability and the range of motion of the joint.

A definite percentage of dislocations are irreducible, and the need for multiple attempts should prompt orthopedic consultation.

# Chapter 53 - Splinting Techniques

**Carl R. Chudnofsky**

Splints are frequently used in the emergency department (ED) for temporary immobilization of fractures and dislocations and for definitive therapy of soft tissue injuries. Immobilization is the mainstay of fracture therapy, but it is difficult to find firm scientific data that support the use of splinting for soft tissue injuries. Although the general principle of immobilizing sprains and contusions is strongly supported by custom and personal preference, its exact influence on healing, number of complications, and ultimate return to normal activity is not known. In most studies of ankle sprains, for example, the function and pain of the injured joint are similar at 6 weeks' follow-up regardless of whether treatment consisted of ad lib walking, a simple elastic bandage, a posterior splint, or a formal cast.Patients with acute gouty arthritis of the wrist acknowledge reduced pain with short-term use of a short arm splint while medical therapy is initiated.

Most splinting techniques are handed down from housestaff or experienced physicians, but the procedure is often suboptimal and haphazard. [7] This chapter presents guidelines for the adequate immobilization of injuries that are commonly encountered by emergency physicians.

Patients routinely present to the ED with injuries that are amenable to splinting to relieve pain and to augment

healing (Table 53-1) . Emergency physicians have virtually abandoned the use of circumferential casts in favor of premade commercial immobilizing devices or splints made from plaster of Paris or fiberglass. The impetus for this change is primarily related to the complications occasionally associated with circumferential casts, liability issues, and ease of application brought about by new technology. In most instances, properly applied splints provide short-term immobilization equal to that of casts while allowing for continued swelling, thus reducing the risk of ischemic injury. Other obvious advantages of splints are that patients can take them off when immobilization is no longer needed or can remove them temporarily to bathe, exercise the injured part, or perform wound care.

## INDICATIONS

Theoretically, immobilization facilitates the healing process by decreasing pain and protecting the extremity from further injury. Other benefits of splinting are specific to the particular injury or the problem that is being treated. For example, in the treatment of fractures, splinting helps maintain bony alignment. Splinting deep lacerations that cross joints reduces tension on the wound and helps prevent wound dehiscence. Immobilizing tendon lacerations may facilitate the healing process by relieving stress on the repaired tendon. The discomfort of inflammatory disorders such as tenosynovitis or acute gout is greatly reduced by immobilization. Deep space infections of the hands or feet as well as cellulitis over any joint should similarly be immobilized for comfort. Limiting early motion also may reduce edema and theoretically improve the immune system's ability to

combat infection. Hence, selected puncture wounds and mammalian bites of the hands and feet may be immobilized until the risk of infection has passed. Splinting large abrasions that cross joint surfaces prevents movement of the injured extremity and reduces the pain that is produced when the injured skin is stretched. Finally, patients with multiple trauma should have fractures and reduced dislocations adequately splinted while other diagnostic and therapeutic procedures (e.g., peritoneal lavage, computed tomography scan) are completed. Immobilization decreases blood loss, minimizes the potential for further neurovascular injury, decreases the need for opioid analgesia, and may decrease the risk of fat emboli from long bone fractures.

| **TABLE 53-1** -- Conditions That Benefit from Immobilization |
| --- |
| Acute arthritis |
| Severe contusions and abrasions |
| Skin lacerations that cross joints |
| Tendon lacerations |
| Tenosynovitis |
| Puncture wounds to the hands, feet, and joints |
| Animal bites to the hands or feet |
| Deep space infections of the hands and feet |
| Joint infections |

# EQUIPMENT

## Support Materials

### Plaster of Paris

Plaster of Paris is the most widely used material for ED splinting. [8] Its name originated from the fact that it was first prepared from the gypsum of Paris, France. When gypsum is heated to approximately 128 °C, most of the water of crystallization is driven off, leaving behind a fine white powder--plaster of Paris. When water is added to plaster, the reaction is reversed, and the plaster recrystallizes or sets by incorporating water molecules into the crystalline lattice of the calcium sulfate dihydrate molecules.

Today, plaster is impregnated into strips or rolls (2-, 3-, 4-, or 6-in. widths) of a crinoline-type material. The crinoline allows for easy application, helps keep the plaster molded to the proper form during the setting process and adds support to the finished splint. Plaster rolls and sheets are available in a variety of setting times and widths. The distinct advantage of plaster over commercially available, premade splints is that plaster can be more easily molded and tailored to the individual's anatomy, negating the "one-size-fits-all" approach. Also, plaster is generally less expensive than premade splints.

### Prefabricated Splint Rolls

The use of plaster splints in the form of prefabricated splint rolls (OCL, Specialist J-Splint) are popular among emergency physicians. These splint rolls have 10 to 20 sheets of plaster enclosed between a thick layer of protective foam padding on one side, and a thin layer of cloth on the other side. Like custom constructed splints, they are secured to the extremity with an elastic bandage. The major advantage of prefabricated splint rolls is that significant time is saved because the splint and padding are ready to apply. In addition, prefabricated splint rolls are ideal for intermittent splinting and can be removed and reapplied by the patient as needed. However, prefabricated plaster splint rolls are more expensive than simple plaster rolls, and they lack some of the versatility and custom-fit qualities of self-made plaster splints. The application of premade splints is shown in Figure 53-1 (Figure Not Available) *A- F.*

Recently, prefabricated splint rolls using layers of fiberglass between polypropylene padding (Ortho-Glass) have been introduced. These splint rolls offer the same time-saving aspect of prefabricated plaster splint rolls. In addition, splints made from prefabricated fiberglass rolls cure more rapidly (20 minutes), have no messy residue (i.e., can be hydrated using a conventional sink without a special trap), can be washed and reapplied, and are stronger and lighter than splints constructed from prefabricated

plaster rolls. Another advantage is the polypropylene padding, which wicks moisture away from the skin better than polyester, nylon, or cotton padding. [9] However, like prefabricated plaster splint rolls, prefabricated fiberglass splints lack some of the versatility and custom-fit qualities of self-made plaster splints.

## Protective and Miscellaneous Equipment

### Stockinette

A single layer of stockinette is commonly used under circumferential casts and splints. It protects the skin and, when folded back over the ends of the plaster, creates a smooth, professional-looking, padded rim. Stockinette is available in 2-, 3-, 4-, 8-, 10-, and 12-in. widths.

### Padding

Padding under the splint protects the skin and bony prominences and allows for swelling of the injured extremity. In general, the older thin cotton padding known as sheet wadding has been replaced by newer materials such as Webril (Curity) or Specialist (Johnson & Johnson) cast padding. Webril is soft cotton with a much coarser weave than sheet wadding; consequently it has greater tensile strength, adheres better, and can be applied more evenly. Specialist padding uses micropleated cotton fibers that relax when moistened. This results in uniform, felt-like padding that conforms to the surface being wrapped. Felt (0.5-in. thick) also may be used to pad bony prominences.

### Elastic Bandages

Elastic bandages are used to secure the splint in place. Elastic bandages are available in 2-, 3-, 4-, and 6-in. widths.

### Adhesive Tape

Adhesive tape is used to prevent slippage of the elastic bandages, to line the cut edges of a bivalved cast, and to "buddy tape" digits.

### Utility Knife and Plaster Scissors

A utility knife, a No. 10 scalpel blade, or plaster scissors can be used to cut and shape dry plaster.

### Bucket

A large bucket (preferably stainless steel) is used for wetting plaster. Plaster should not be prepared in the sink because the residue quickly clogs the drain. A special drain is required to accept plaster residue.

**Protective Gear**

Gowns or sheets prevent soilage of the both the patient's and the physician's clothing. Gloves (vinyl or latex) and safety glasses are recommended to prevent skin or eye damage from plaster dust, wet plaster, or uncured fiberglass polymer. Wearing gloves also decreases cleanup time for the physician.

## GENERAL PROCEDURE OF CUSTOM SPLINT APPLICATION

The following section refers to the application of custom-made plaster splints (Fig. 53-2 *A- E*), unless otherwise stated. If periodic wound care is required, a more easily removable splint (e.g., an OCL, Ortho-Glass, or a Velcro-type splint) should be applied in lieu of the standard splint to be described. The issue of removability should be addressed before the splint is applied. In addition, use of Webril (Curity) cast padding is described, but other suitable cast padding may be substituted.

### Patient Preparation

If the clinical situation permits, the patient should be covered with a sheet or gown to protect the clothing and the surrounding area from water and plaster. Nursing and housekeeping staff also appreciate this courtesy. The involved extremity should be inspected carefully before splinting. All skin lesions and soft tissue injuries should be examined and documented clearly on the emergency department record. All wounds should be cleaned, repaired, and dressed in the usual manner. When immobilizing open fractures or joints, the soft tissue defect should be covered with saline-moistened sterile gauze.

### Padding

When the splint involves the digits, padding must be placed between the fingers and toes to prevent maceration of the skin. This can be done with pieces of Webril or gauze cut to the appropriate length.

Following placement of padding between the fingers and toes, stockinette is often used as the next protective layer in self-made splints (see Fig. 53-2 *A*). The stockinette should extend at least 10 to 15 cm beyond the area to be splinted at both ends of the extremity. Later, after plaster has been applied, the stockinette can be folded back over the ends of the splint to create smooth, padded rims. Folding back the stockinette can also help hold the splint in place when applying elastic bandages (see Fig. 53-2 *C*). Care is needed to avoid pressure damage from pulling the stockinette too tightly over bony prominences, such as the heel. Wrinkling over flexion creases should also be avoided by slitting and overlapping the stockinette at bony prominences. One may also use two separate pieces of stockinette (one at each end of the splint) to produce the smooth padded rims. As a general rule, 3-inch-wide stockinette is used for the upper extremity, whereas 4-inch-wide is used for the lower extremity.

After the stockinette has been properly positioned, Webril should be wrapped around the entire area that will be exposed to plaster. The Webril should be at least 2 to 3 layers thick and each turn should overlap the previous turn by 25 to 50% of its width (see Fig. 53-2 *B*). In addition, the Webril should extend 2.5 to 5.0 cm beyond the ends of the splint so it too can be folded back over the splint to help create smooth, well-padded edges (see Fig. 53-2 *C*). Extra padding should be placed over areas of bony prominence, such as the radial condyle or the malleoli (Table 53-2) . If significant swelling is anticipated, 3 to 4 layers of Webril should be applied as padding. Care should be taken to avoid wrinkling, because it can result in significant skin pressure when a tight splint is used for a long period. Wrinkles can be eliminated by proportionately stretching or even tearing the side of the Webril that must wrap around the bigger portion of an extremity. Joints that must be immobilized in a 90° position, such as the ankle, make continuous Webril wrapping difficult. To avoid wrinkles in the area of the ankle, the joint should be placed in the proper position before padding. Webril is then wrapped around the malleolar and midtarsal regions first. The bare calcaneal region can then be covered with overlapping vertical and horizontal Webril strips until the entire heel region is evenly padded. The same approach can be used in similar areas, such as the elbow. The width of Webril that should be used varies depending on the extremity to be splinted. In general, the 2-in. width should be used for hands and feet, the 3- to 4-in. width for the upper extremity, and the 4- to 6-in. width for the lower extremity.

A final caveat when using Webril is to be aware of the potential for ischemic injury. This rare complication is most likely to occur in an extremity that continues to have significant swelling after the patient is released from the emergency department. Ischemia may result because the concentrically placed Webril can become a constricting band. If this situation is anticipated, it can be prevented easily by cutting through the Webril along the side of the extremity opposite to the plaster splint. The splint is then secured to the extremity in the usual manner. Alternatively, 2 to 3 layers of Webril (the same diameter as the plaster) are placed directly over the wet plaster (Fig. 53-3) . The Webril-lined splint is then positioned over the area to be immobilized and secured with an elastic bandage.

**Plaster Preparation**

The choice of plaster setting time depends on the nature of the injury and the expertise of the physician. Extra-fast-setting plaster is typically used when rapid hardening is desired to help maintain alignment of an acutely reduced fracture. However, for the majority of ED splints, plaster with slower setting times (e.g., Specialist fast-drying) is recommended. [10] Plaster that sets more slowly is easier for some physicians to use, because the longer setting times allow more leeway in applying and molding the splint. Furthermore, plaster with a longer setting time produces less heat, thus reducing both patient discomfort and the risk of serious

burns. [11] Table 53-3 lists the setting times for commonly used plaster. These setting times are created by adding different substances to the plaster during the production process (Table 53-4) . Given plaster with equal setting times, the most important variable affecting the rate of crystallization is water temperature. *Warm water hardens a splint faster than cold water* and should be avoided when extra time is desired for splint

application.

The ideal length and width of plaster depends on the body part to be splinted and the amount of immobilization required. The best way to estimate length is to lay the dry splint next to the area to be splinted. It is best to use a generous length, because wet plaster shrinks slightly from its dry length. Also, if the wet splint is too long, the ends can be folded back easily. The plaster width varies according to the type of splint being made and the body part that is injured, but generally it should be slightly greater than the diameter of the limb to be splinted. Specific recommendations regarding splint length and width are made in sections describing individual splints.

The thickness of a splint depends on the size of the patient, the extremity that is injured, and the desired strength of the final product. An ankle splint may crack quickly and become useless if only 8 layers are used, but this thickness may be ideal for a wrist splint. In general, it is best to use the minimum number of layers necessary to achieve adequate strength. Thicker splints are heavier and more uncomfortable. It is important to note that plaster thickness is a major determinant of the amount of heat given off during the setting process. With more than 12 sheets of plaster, there is an increased risk of significant burns, especially when using extra-fast-drying plaster, using dipping water with a temperature

| **TABLE 53-3** -- Setting Times of Fast- and Extra-Fast-Drying Plaster | |
| --- | --- |
| **Plaster** | **Setting Time (min)** |
| Fast-drying | 5-8 |
| Extra-fast-drying | 2-4 |

greater than 24 °C, or placing a pillow under or around the extremity for support during the setting process (Table 53-5) . In an average-sized adult, upper extremities should be splinted with 8 sheets of plaster, whereas lower extremity injuries generally require 12 to 15 sheets. This layering usually gives the strength necessary for adequate immobilization while reducing the patient's discomfort and the risk of significant burns. In a 300-lb patient, however, up to 20 layers may be required to make a durable ankle splint.

The dipping water should be kept clean and fresh. The use of water that has been used

previously for wetting plaster increases the amount of heat given off during crystallization and causes plaster to set more quickly. As a rule of thumb, the temperature of the water should be kept around 24 °C. This temperature allows for a workable setting time and has not been associated with an increased risk of significant burns. As the temperature of the dipping water approaches 40 °C, the potential for serious burns increases, even at splint thicknesses of less than 12 plies. It is interesting to note that water temperature has been shown to be only a minor consideration in heat production in some studies (see Table 53-5) .

## Splint Application

The dry splint should be completely submerged in the water until bubbling stops. The splint is removed and excess water is gently squeezed out until the plaster has a wet and sloppy consistency. The splint is placed on a hard table or countertop (a protective covering is recommended to prevent water or plaster damage) and smoothed out to remove any wrinkles and to ensure uniform lamination of all layers. Lamination helps to increase the final strength of the splint. The splint is placed over the Webril and gently smoothed over the extremity. Plaster is usually somewhat adherent to Webril, but an assistant may be required to hold the splint in place. Once the splint has been properly positioned over

the extremity, folding back the underlying stockinette and Webril also helps hold it in place. The splint is secured with an appropriately sized elastic bandage by wrapping in a distal to proximal direction. Finally, the extremity is placed in the desired position and the wet plaster is molded to the contour of the extremity using only the palms of the hand. Finger indentations may cause a ridge that will produce a pressure point.

Molding the wet splint to conform to the body's anatomy is probably the most important yet the most frequently overlooked step to ensure adequate immobilization (see Fig. 53-2 *E*). The act of molding may cause some pain, and the patient should be forewarned. All manipulation of the wet plaster should be completed before it reaches a thick, creamy consistency. Any movement after this time, also known as the critical period, results in an imperfect crystalline network of calcium sulfate molecules and greatly weakens the ultimate strength of the splint. *While the plaster is setting*, a pillow or blanket should *NOT* be wrapped around the extremity for support (Fig. 53-4) . This leads to inadequate ventilation around the splint and greatly increases the amount of heat produced (see Table 53-5) .

If an elastic bandage is applied directly over wet plaster, the elastic bandage may be incorporated into the drying plaster, making subsequent removal of the bandage difficult. To make it easier for patients to remove and reapply the splint, a single layer of Webril or roll gauze can be wrapped around the wet plaster loosely before application of the elastic bandage. This prevents the wet plaster from becoming stuck to the elastic bandage. Only one layer of Webril should be used over the plaster because multiple layers have been associated with high drying temperatures.

Before the patient is released from the ED, the splint should be checked for adequate immobilization, and the patient should be observed for any evidence of vascular compromise or significant discomfort. If either occurs, the elastic bandage should be loosened. If the discomfort persists, additional padding should be placed over the painful areas. If this measure, too, is unsuccessful, a new splint should be made, and special attention should be paid to proper molding so that the wet plaster does not become indented. By resting tender tissue, splinting usually relieves discomfort quickly, and patients generally say that they feel better immediately after the splint has been applied. Never release a patient who complains of increased pain after a splint has been placed.

After a proper-fitting, comfortable splint has been applied, one may place 2 strips of tape along each side of the splint to prevent the elastic bandage from slipping. Tape should be applied over the metal fasteners used to secure the elastic bandages. Note that

these objects can be easily swallowed or aspirated by infants and small children. Finally, a sling should be provided for upper extremity injuries, and, if required, crutches should be dispensed (and instructions given for their proper use) for lower extremity injuries.

## Patient Instructions

Patients should receive verbal and written instructions on splint care and precautions. The importance of elevation in helping to decrease pain and swelling should be stressed and demonstrated (most patients do not understand the medical definition of elevation). *At night*, a pillow wrapped and secured around a hand or foot will help the patient keep the injured extremity satisfactorily elevated (see Fig. 53-4) . If the injury is less than 24 hours old, the application of ice bags or cold packs also should be encouraged. It is useless to apply cold packs over plaster, but it can be beneficial if it is applied over Webril and an elastic bandage or directly over an injury if the splint is removed. In theory, cold therapy stiffens collagen and thus reduces the tendency for ligaments and tendons to deform. Cold therapy also decreases muscle spasm and excitability, decreases blood flow (thus limiting hemorrhage and edema), increases the pain

threshold, and decreases inflammation. Because the thermal conductivity of subcutaneous tissue is poor, cold packs should be applied for at least 30 minutes at a time. This guideline is in contrast to the popular recommendation of "ice 20 minutes on, 20 minutes off," which does nothing more than cool the skin. Cold packs should not be applied for more than the first 24 to 48 hours because cold can interfere with long-term healing. The patient should be instructed not to stress the splint for at least 24 hours because plaster does not approach optimal strength until evaporation has reduced the water content of the plaster to approximately 21% of its initial hydrated level. This process of removing excess water by evaporation is called *curing,* and it generally takes several days to be completed. However, by 24 hours the water content of the plaster has usually been reduced enough to produce a strong resilient splint. In addition, because the chemical process involved in the formation of plaster is reversible, the patient should avoid getting the splint wet. However, if the injury permits, the splint can be removed for showering and then reapplied. Alternatively one or more plastic bags may be placed over a splint before showering.

Splints may crack, break, or disintegrate with wear, and a useless splint should be removed or replaced. Patients should be given general guidelines for length of immobilization and appropriate follow-up care. Long-term immobilization, particularly in the elderly, can produce permanent disability.

It is extremely important for the patient to continue to check for signs of vascular compromise. If the patient experiences a significant increase in pain, any numbness or tingling of the digits, pallor of the distal extremity, decreased capillary refill, or weakness, he or she should be instructed to return to the ED or to see the primary physician without delay. As with casting, increased pain after splinting is a warning sign that should prompt a return visit-- *not telephone advice*. Strong opioids should be avoided during the first 2 to 3 days after splinting to allow pain to prompt a follow-up visit.

# UPPER EXTREMITY SPLINTS

## Long Arm Splints

### Long Arm Posterior Splint

**Indications.**

The long arm posterior splint (Fig. 53-5 *A* and *B*) is used to immobilize injuries of the elbow and proximal forearm. It completely eliminates flexion and extension of the elbow, but it does not entirely prevent pronation and supination of the forearm. Therefore, it is not recommended for immobilization of complex or unstable distal forearm fractures unless used in conjunction with a long arm anterior splint. Alternatively, a double "sugar-tong" splint can be applied.

**Construction.**

The long arm posterior splint is constructed using 8 to 10 layers of 4- to 6-in. wide plaster. The splint starts on the posterior aspect of the proximal arm. It runs down the arm to the elbow and then continues along the ulnar aspect of the forearm and hand to the level of the metacarpophalangeal joints. The anterior splint is constructed in the same manner. It mirrors the posterior splint by running down the anterior aspect of the arm to the antecubital fossa, where it continues along the radial aspect of the forearm to the distal radius. The anterior splint is never used alone, but rather is used as an adjunct to the long arm posterior splint to improve immobilization by increasing stability and preventing pronation and supination of the forearm.

**Application.**

Stockinette and Webril are applied as described previously. A hole should be cut in the stockinette to expose the thumb, and extra padding should be placed over the olecranon to prevent pressure injury. The arm is positioned with the elbow flexed to 90°, the forearm neutral (thumb upward), and the wrist neutral or extended slightly (10° to 20°). It is helpful to have an assistant hold the wet splint in place, particularly when applying both a posterior and anterior splint. Once the splint has been properly positioned, the ends of the stockinette and Webril are folded back and the splint is secured in place using two 3- to 4-in. elastic bandages. Finally, the sides of the splint are folded up to create a gutter configuration, and the splint is carefully molded using the palms of the hand. The fingers and thumb should remain free to prevent stiffness from unnecessary immobilization.

### Double Sugar-Tong Splint

**Indications.**

Like the long arm posterior splint, the double sugar-tong splint (Fig. 53-6 is used to immobilize injuries of the elbow and forearm. However, because it prevents pronation and supination of the forearm, it is preferable for some fractures of the distal forearm and elbow.

**Construction.**

The splint consists of two separate pieces of plaster, a forearm splint and an arm splint. Each piece is constructed using 8 layers of 3- to 4-in. plaster. The forearm portion of the splint runs from the metacarpal heads on the dorsum of the hand, along the dorsal surface forearm around the elbow. It continues along the volar surface of the forearm to the palm of the hand, stopping at the level of the metacarpophalangeal joints. The arm portion of the splint begins on the anterior aspect of the proximal humerus. It runs down the arm over the forearm splint and around the elbow. It then continues up the posterior aspect of the arm, once again going over the forearm splint, until it reaches the starting point.

**Application.**

Use of stockinette and Webril and positioning are similar to those described for application of a long arm posterior splint. The two splints are secured in place using two 3- to 4-in. elastic bandages starting at the forearm splint at the hand. Once secure, the arm portion of the splint is wrapped beginning at the proximal end. The fingers and thumb should remain free to avoid stiffness.

## Forearm and Hand Splints

### Volar Splint

**Indications.**

The volar splint (Fig. 53-7 *A* and *B*) is used to immobilize a variety of soft tissue injuries of the hand and wrist. It is also used for temporary immobilization of triquetral fractures, lunate and perilunate dislocations, and second through fifth metacarpal head fractures. For these more serious injuries, some physicians prefer to add a dorsal splint to create a more stable bivalve effect (see Fig. 53-7 *B*). Because the volar splint does not completely eliminate pronation and supination of the forearm, it is not recommended for fractures of the distal radius and ulna.

**Construction.**

The splint is constructed using 8 to 10 layers of 3- to 4-in. wide plaster. The splint begins in the palm at the metacarpal heads and extends along the volar surface of the forearm to just proximal to the elbow. If there is an injury to any of the fingers, the splint

may be extended to incorporate the involved digit.

**Application.**

Stockinette and Webril should be applied as described previously. A hole should be cut in the stockinette to expose the thumb. In addition, Webril or gauze should also be placed between any digits that are going to be immobilized. The forearm is placed in the neutral position (thumb upward) with the wrist extended slightly (10° to 20°). Wrist flexion should be avoided. After the wet plaster has been properly positioned, the ends of the stockinette and Webril are folded back and a 3- or 4-in. elastic bandage is used to hold the splint in place. The sides of the splint are folded up, creating a gutter effect, and the plaster is carefully molded to conform to the contours of the palm and wrist. Some clinicians prefer to extend the splint to the fingertips and then fold the wet plaster back toward the palm, allowing the fingers to "grasp" the rounded distal end when at rest. In any event, the thumb and fingers should be free to move unless they are injured and are being intentionally immobilized by the splint.

## Sugar-Tong Splint

**Indications.**

The sugar-tong splint (Fig. 53-8 is used for fractures of the distal radius and ulna. The advantage of this splint over the volar splint is prevention of pronation and supination of the forearm. In addition, it immobilizes the elbow, which is desirable for the first few days following a distal forearm fracture.

**Construction and application.**

The splint is constructed and applied the same way as the forearm portion of the double sugar-tong splint, described above.

## Thumb Spica Splint

**Indications.**

The thumb spica splint (Fig. 53-9 is used to immobilize injuries to the scaphoid, lunate, and thumb and fractures of the first metacarpal. It is also used in the treatment of de Quervain tenosynovitis.

**Construction.**

The splint is constructed using 8 layers of 3-in. wide plaster. The splint extends from just distal to the interphalangeal joint of the thumb to the mid-forearm.

The forearm is placed in the neutral position with the wrist extended 25° and the thumb in the wine glass position (Fig. 53-10) . Stockinette and Webril are applied from the base of the palm to the mid-forearm. It may be difficult to place stockinette around the thumb. Instead, a hole can be cut in the stockinette to expose the thumb. The thumb is then padded with small vertical strips of Webril, or wrapped with 2-in. Webril. The dry plaster is then placed over the radial aspect of the forearm from just beyond the thumb interphalangeal joint to the mid-forearm. Once in position, the location of the first metacarpophalangeal joint is marked and a small (1 to 2 cm) perpendicular cut is made 1 cm distal to the mark on each edge of the plaster (see Fig. 53-9 inset). This will allow the splint to be molded around the thumb without creating a buckle in the plaster. The plaster is then dipped and secured in place with a 2- or 3-in. elastic bandage. It is important to carefully mold the wet plaster around the thumb and palm and to maintain the thumb in the wine glass position while the plaster is drying.

## Ulnar Gutter Splint

**Indications.**

The ulnar gutter splint (Fig. 53-11) is used to immobilize fractures and serious soft tissue injuries of the little and ring fingers and fractures of the neck, shaft, and base of the fourth and fifth metacarpals.

**Construction.**

The splint is made using 6 to 8 layers of 3- to 4-in. plaster. It incorporates both the little and ring fingers. It runs along the ulnar aspect of the forearm from just beyond the distal interphalangeal joint of the little finger to the mid-forearm.

**Application.**

Stockinette and Webril are applied as usual. Additional Webril or gauze should be placed between the little and ring fingers to prevent maceration of the skin. The forearm is in the neutral position with the wrist in slight extension (10° to 20°), the metacarpophalangeal joints in 50° of flexion, and the proximal and distal interphalangeal joints in slight (10° to 15°) flexion. When immobilizing a metacarpal neck fracture (i.e., boxer's fracture), the metacarpophalangeal joint should be flexed to 90°. Once in the proper position, the sides of the splint are folded up to form a gutter. The ends of the stockinette and Webril are then folded back to help hold the splint while it is secured in place with a 2- or 3-in. elastic bandage.

## Radial Gutter Splint

The radial gutter splint (Fig. 53-12 is used to immobilize fractures and serious soft tissue injuries of the index and long fingers and fractures of the neck, shaft, and base of the second and third metacarpals.

**Construction.**

The splint is made using 6 to 8 layers of 3- to 4-in. plaster. It runs along the radial aspect of the forearm from just beyond the distal interphalangeal joint of the index finger to the mid-forearm.

**Application.**

Stockinette (with a hole cut to expose the thumb) and Webril are applied as previously described. Additional Webril or gauze should be placed between the index and long fingers to prevent maceration of the skin. The forearm is in the neutral position with the wrist in slight extension (10° to 20°), the metacarpophalangeal joints in 50° of flexion, and the proximal and distal interphalangeal joints in slight (10° to 15°) flexion. When immobilizing a metacarpal neck fracture the metacarpophalangeal joint should be flexed to 90°. The dry plaster is placed over the extremity and the location of the thumb is marked. A hole is cut in the dry plaster to expose the thumb. The plaster is then dipped and positioned over the extremity. The ends of the stockinette and Webril are folded back to help hold the splint while it is secured in place with a 2- or 3-in. elastic bandage.

## Finger Splints

Fingers are splinted following sprains, fractures, tendon repair, or infection. Minor finger sprains can often be managed with dynamic splinting (e.g., buddy taping) (Fig. 53-13) or a commercially available foam splint with aluminum backing (one-surface splint) (Fig. 53-14) , but fractures, tendon repairs, and some soft tissue injuries benefit from formal splinting (e.g., thumb spica, ulnar and radial gutter splints). Specific conditions, such as mallet finger, require a specialized splint (Fig. 53-15) . When complete immobilization of a finger is required (e.g., unstable phalangeal fractures) an "outrigger" finger splint that incorporates the wrist may be used (Fig. 53-16) .

## Sling, Swathe and Sling, Shoulder Immobilizer

### Sling

The sling is used to maintain elevation and provide immobilization of the hand, forearm, and elbow. It is most often used in conjunction with a plaster splint or cast. There are a number of commercially available slings to choose from. Many of these are fairly economical and simple to use, whereas others are expensive and do not allow the versatility of a simple, inexpensive triangular muslin bandage. When applying a sling, it

is important to have adequate support of the wrist and hand (Fig. 53-17) . A sling that is too short will allow the wrist and hand to hang down (ulnar deviation) and can result in ulnar nerve injury.

### Swathe and Sling, Shoulder Immobilizer

The swathe and sling is the treatment of choice for most proximal humerus fractures and shoulder injuries, such as reduced dislocations. The sling supports the weight of the arm, and the swathe immobilizes the arm against the chest wall to minimize shoulder motion. In most EDs, the swathe and sling has been replaced by the commercially available shoulder immobilizer (Fig. 53-18) . Its advantage is that it may be removed for showering and range-of-motion exercises and it is easily reapplied by the patient (a desirable option in the care of a shoulder dislocation). If used for more than a few days, the axilla should be padded to absorb moisture and decrease skin chafing.

The Velpeau bandage is a sling-and-swathe device that positions the forearm diagonally rather than horizontally across the chest, with the hand elevated to the level of the shoulder. This offers no particular advantage over a standard sling and swathe, is difficult to apply, cannot be removed easily, and is not well tolerated for prolonged immobilization.

### Figure-of-8 Clavicle Strap

Clavicle fractures have been traditionally treated with an uncomfortable and complex figure-of-8 bandage. Despite its widespread use, this device has never been proved superior to a simple sling (in terms of cosmesis, functional outcome, or pain relief). [12] [13] Indeed, use of the figure-of-8 dressing should be discouraged because it may actually promote nonunion or increase the deformity at the fracture site; it is uncomfortable; it prohibits bathing, often causing chafing and discomfort in the axilla; and it may predispose to axillary vein thrombosis. Although some orthopedists continue to recommend the figure-of-8 bandage, a simple sling is sufficient to treat most clavicular fractures.

## Pitfalls of Upper Extremity Dressings

and Splints

The two most common problems with hand dressings are putting them on too tightly and leaving them on too long (Table 53-6) . One must be especially careful to avoid wrapping elastic bandages too snugly. The patient should be instructed to loosen an elastic bandage if it feels too tight. The patient should always have access to emergency follow-up care. It is often advisable to start patients on a regimen of early protected motion. This means that the patient removes the splint for a specified period, does a prescribed exercise, and then replaces the splint. A splint is not an all-or-none device, and the patient is generally weaned slowly from it before it is discarded entirely. A stiff hand is a nonfunctional one, and stiffness is often a consequence of prolonged immobilization. It is important for the patient to be made aware of his or her

responsibility for the injured hand.

# LOWER EXTREMITY SPLINTS

## Knee Splints

### Knee Immobilizer

**Indications.**

The knee immobilizer (Fig. 53-19) is commonly used for mild to moderate ligamentous and soft tissue injuries of the knee. It is removable and extremely easy to apply, making it popular among patients and physicians

| **TABLE 53-6** -- Useful Estimates of Splint Times for Various Hand Problems | | |
|---|---|---|
| **Injury** | **Splint Type** | **Immobilization Time** * |
| Mallet finger | FIN | 8 wk |

* These are average times only. Every patient is treated as an individual when a splint is used. Clinical judgment is critical.
Finger splint.
Digit-hand-wrist-forearm splint.
§ The diagnosis of a sprain should be made only after a thorough effort has been made to rule out a fracture or a dislocation. This is particularly true in the wrist.

alike. In many EDs it has almost totally replaced the more bulky plaster splint. Its use should be restricted to injuries that do not require immediate surgical intervention, traction, or casting. For these injuries, in which temporary but more complete immobilization is needed, a plaster knee splint can be used because it provides better stabilization and costs much less than a knee immobilizer. The exact scientific benefit of the knee immobilizer is poorly studied and difficult to document. However, it clearly helps relieve pain and, at least theoretically, hastens healing.

**Application.**

The knee immobilizer is available in small, medium, large, and extra-large sizes. To choose the appropriate size, the knee immobilizer is placed next to the injured leg so that the tapered end lies distal to the patient's knee; if present, the cutout patellar area on the anterior aspect of the splint lies adjacent to the knee. In this position, the splint should extend distally to within a few inches of the malleoli and proximally to just below the buttocks crease. To apply the knee immobilizer, the open splint is slid under the injured extremity and firmly secured in place using the Velcro straps. The knee immobilizer can be applied directly over clothing, obviating the need to remove or cut the patient's pants.

**Posterior Knee Splint**

**Indications.**

In many EDs, the knee immobilizer has virtually replaced the plaster knee splint for mild to moderate

injuries to the knee. However, the plaster knee splint can be particularly useful in patients whose extremities are too large for the knee immobilizer, in the treatment of angulated fractures, or for temporarily immobilizing other knee injuries that require immediate operative intervention or orthopedic referral. The posterior (gutter) knee splint (Fig. 53-20 *A* and *B*) is the type most commonly applied, but as an alternative, two

parallel splints can be placed along each side of the leg and foreleg, creating a bivalve effect (see Fig. 53-20 *B*), or a long leg sugar-tong splint can be applied (see below). The bilateral knee splint is slightly more difficult to apply than the posterior knee splint, but it may provide better immobilization of the lateral and medial collateral ligaments and can be used for injuries to these structures.

**Construction.**

The knee splint is made with 12 to 15 layers of 6-in. plaster. It should run from just below the buttocks crease to approximately 2 to 3 in. above the malleoli. The sides of the splint are folded upward to form a gutter configuration.

**Application.**

A stockinette should be placed in the usual manner, and the leg should be well padded with 4- to 6-in. Webril. If available, an assistant can help elevate the leg and hold the splint in place while it is being secured with 4- or 6-in. elastic bandages. If no aide is available, the patient can be placed in the prone position and the splint laid on the posterior surface of the extremity. The leg is then wrapped in the usual manner without need for special support of the applied plaster. Also, while in the prone position, the patient's toes can elevate the lower part of the leg off the bed, allowing sufficient room to wrap the Webril and elastic bandages around the injured extremity.

**Jones Compression Dressing**

**Indications.**

A Jones compression dressing is commonly used for short-term immobilization of soft tissue injuries of the knee. It immobilizes and compresses the knee, reducing both pain and swelling. However, because it does allow slight flexion and extension of the knee, it should not be used for injuries that require strict immobilization. In addition, it is difficult to maintain the splint for more than a few days.

**Construction.**

A Jones dressing is made using 6-inch Webril and elastic bandages.

**Application.**

To apply a Jones dressing, the patient is placed on a stretcher, lying supine. If available, an assistant can elevate the patient's leg to facilitate wrapping. If no help is available, a pillow placed under the patient's heel should suffice. Webril is then wrapped around the extremity from the groin to a few inches above the malleoli. Two or 3 layers of Webril can be used, and each turn should overlap the previous turn by 25 to 50%. The elastic bandages (2 are usually required) are then wrapped around the Webril. If more support is required, the process can be repeated with another 2 to 3 layers of Webril held in

place by a second elastic bandage.

## Ankle Splints

### Posterior Splint

**Indications.**

The posterior ankle splint (Fig. 53-21 *A-C*) is one of the most common splints applied in the ED. It is used primarily to immobilize severe ankle sprains, fractures of the distal fibula and tibia, and reduced ankle dislocations. It can also be used for fractures of the tarsal and metatarsal bones or for other foot conditions that require immobilization. In particularly severe or unstable injuries, an additional anterior splint may be used to provide extra immobilization resembling that of a formal cast (Fig. 53-22) . For severe lateral or bilateral ligamentous injuries, a sugar-tong or stirrup splint (see below) may be added to the posterior splint for increased immobilization. With minor soft tissue injuries, patients may have partial weight bearing on ankle splints after 24 hours. If the patient will be bearing weight, a cast shoe worn over the splint makes it easier to walk. In addition, a cast shoe increases the longevity of the splint because walking on an unprotected splint quickly destroys the device. Generally, walking on the splint is prohibited if immobilization for more than 2 or 3 days is desired.

**Construction.**

The posterior splint is made using 4- to 6-in.-wide plaster strips. It should extend from the plantar surface of the great toe or metatarsal heads along the posterior surface of the foreleg to the level of the fibular head. If it hurts to move the toes, they should be incorporated into the splint (after padding is placed between the digits). It is a common mistake to apply a posterior splint that does not extend far enough to support the ball of the foot. Fifteen to 20 layers should be used if partial weight bearing is allowed, because this splint frequently breaks or cracks when walked on. [14]

**Application.**

The easiest way to apply a posterior splint is to place the patient in the prone position with the knee and ankle flexed at a 90° angle (see Fig. 53-21 *B*). Failure to place the ankle in a 90° angle results in a plantar-flexed splint. The supine patient may help maintain the ankle at a 90° angle by pulling up on the foot with a wide stockinette stirrup. Flexing the knee to a 90° angle relaxes the gastrocnemius muscle and facilitates ankle motion. With the knee and ankle in the proper position, stockinette may be applied and the foot and leg padded with Webril as described earlier. Extra padding is used over bony prominences, particularly the malleoli. Again, Webril or gauze is placed between the toes if they are to be included in the splint. The wet plaster is then laid over the plantar surface of the foot and secured in place by folding back the ends of the stockinette and Webril and then wrapping with one or two 4-in.-wide elastic bandages. The wet plaster is carefully molded around the malleoli and instep to ensure maximum comfort and immobilization. The toes should be left partially exposed for later

examination of color and capillary refill.  Posterior ankle splints are probably one of the most commonly used splints in the ED, and one's splinting prowess is often judged by other physicians when the patient returns for follow-up evaluation in the office. It therefore behooves the emergency physician to avoid some of the common mistakes shown in Fig. 53-21 *C*.

**Anterior-Posterior Splint**

**Indications.**

The anterior splint is never used by itself, but it can augment a posterior splint, creating a bivalve effect (Fig. 53-22) . It is used for serious fractures and soft tissue injuries of the ankle.

**Construction.**

A piece of plaster should be cut several centimeters shorter than the one used for the posterior splint, but because this splint does not bear weight, only 8 to 10 layers are required.

**Application.**

The patient should be positioned and padded as for the posterior splint. After the wet posterior splint has been applied, the anterior splint is placed over the anterior aspect of the ankle and foreleg parallel to the posterior splint. The two are then held in place with elastic bandages as described earlier for the posterior splint alone. An assistant is needed to apply the anterior-posterior splint because it is extremely difficult to hold both splints in place while wrapping the elastic bandages. Once secured, both splints are carefully molded over the instep and ankle joint.

**Sugar-Tong (Stirrup) Splint**

**Indications.**

The sugar-tong or stirrup splint (Fig. 53-23) is used primarily for injuries to the ankle. It functions like the posterior splint, and either of the two provides satisfactory ankle immobilization. In one study that compared these splints in normal volunteers, the sugar-tong splint allowed less plantar flexion and broke less often with plantar flexion than the posterior splint. [14] Also, because it actually covers the malleoli, the sugar-tong splint may protect the medial and lateral ligamentous area from further injury better than the posterior splint.

**Construction.**

The sugar-tong splint is made using 4- or 6-in.-wide plaster strips. The splint passes under the plantar surface of the foot from the calcaneus to the metatarsal heads and

extends up the medial and lateral sides of the foreleg to just below the level of the fibular head.

**Application.**

The patient is positioned, and the extremity is padded as described for the posterior splint. If both posterior and sugar-tong splints are used, the posterior splint is applied first. The wet plaster is laid across the plantar surface of the foot between the calcaneus and metatarsal heads with the sides extending up the lateral and medial aspects of the foreleg. The plaster is secured in place with 4-in. elastic bandages. The elastic bandage should be wrapped around the extremity starting at the metatarsal heads and continuing around the ankle using a figure-of-8 configuration. Once the ankle has been wrapped, another 4- or 6-in. elastic bandage can be used to secure the remainder of the splint in place. The splint should be carefully molded around the malleoli. The plaster may overlap on the anterior aspect of the ankle; this overlap does not interfere with the splint's ability to accommodate further swelling.

**Semirigid Orthosis**

**Indications.**

In patients with sprains of the lateral ankle associated with a stable joint, the use of a functional brace with early mobilization is frequently more comfortable and results in an earlier return to normal function than complete immobilization in a plaster splint or cast. Consequently, functional bracing with early mobilization has become the standard of care. However, it should be pointed out that there is no documented difference in long-term outcome between the two methods of treatment.

**Application.**

Most functional ankle braces resemble a sugar-tong splint with air bladders (Aircast, Inc., Summit, NJ) or foam padding (DeRoyal Inc., Powell, Tenn) for cushioning the malleoli. The braces are secured about the ankle by Velcro straps. The device is worn within the patient's shoe over a sock and appears to eliminate ankle instability.

**Hard Shoe (Cast or Reese Shoe)**

**Indications.**

A hard shoe can help reduce the pain associated with ambulation in patients with fractures or soft tissue injuries to the foot. This device can also be used over a splint or cast to allow partial weight bearing.

**Application.**

If the cast shoe is going to be used by a patient with a fractured toe, the injured digit

should first be buddy taped to the adjacent toe. After this is done, the patient merely slips on the hard shoe like a sandal or loafer. The shoe is then fastened with ties or Velcro straps.

**Soft Cast**

**Indications.**

A "soft cast" is basically a modified Jones compression dressing. It is useful for minor ligamentous and soft tissue injuries of the foot and ankle that do not require prolonged or complete immobilization. A soft cast can help reduce the pain and swelling often associated with mild ankle sprains and gives support for early weight bearing.

**Construction.**

A soft cast is made using 3- or 4-in. Webril and elastic bandages.

**Application.**

A soft cast is as simple to apply as the Jones compression dressing. To begin, the patient is placed in a supine position with the foot and ankle extending off the end of the stretcher. Alternatively, the leg can be elevated by an assistant or by placing pillows under the knee and foreleg. The ankle and foot are then wrapped with 2 to 3 layers of Webril, starting at the metatarsal heads and continuing around the ankle in a figure-of-8 configuration. The Webril should extend 5 to 7 cm above the malleoli and, as discussed earlier, should overlap by 25 to 50% of its width. After the Webril is in place, an elastic bandage is wrapped around the foot and ankle in a similar fashion. Additional layers of Webril and elastic bandages are seldom required.

**Unna Boot Dressing**

Ligamentous injuries of the ankle may be treated with a cloth dressing impregnated with calamine gelatin-zinc oxide (Dome paste or Unna boot) (Fig. 53-24) . [22] This moist dressing is applied like that for a rolled cast in a figure-of-8 design, from the metatarsal heads to the distal foreleg. This dressing remains moist for a few days (it should be covered with a gauze roll or an elastic bandage) and dries to a leathery consistency. It requires minimal maintenance or patient compliance, is lightweight, can be worn under a shoe, and is associated with few complications. It is cut off with scissors by the patient after 5 to 10 days, depending on symptoms. This dressing is non-yielding; hence, evaluation for ischemia is essential in the edema-prone extremity.

# COMPLICATIONS OF SPLINTS

## Ischemia

A compartment syndrome leading to ischemic injury and ultimately to a Volkmann

ischemic contracture is the most worrisome complication of cylindrical casts. Although the risk of ischemia is drastically reduced with splinting, Webril or elastic bandages can cause significant constriction. To reduce the likelihood of this occurring, the elastic bandage should not be excessively tight. If the patient has a high-risk injury, the Webril may be cut lengthwise before the plaster is applied. Elevation, no weight bearing, and application of cold packs should be stressed to each patient. Furthermore, signs and symptoms of vascular compromise should be explained carefully, and all patients whose injuries have the potential for significant swelling or loss of vascular integrity should receive follow-up in the first 24 to 48 hours. *Complaints of increasing pain under a splint should not be ignored by the physician and should not be treated with a telephone prescription for opioid analgesics*.

### Heat Injury

Many physicians are unaware of the potential for drying plaster to produce second-degree burns. [23] Thermal injury can occur with both cylindrical casts and plaster splints. Some physicians have reported a higher incidence of burns with the use of plaster splints, although the reasons for this are unclear. Table 53-5 lists factors that can increase the amount of heat that is produced during plaster recrystallization. Their effects are additive, and this fact should be taken

into account when applying a splint. For example, if 15 sheets of plaster are needed for strength in a particular splint, one should not increase the heat production further by using extra-fast-drying plaster or by reusing warm dip water. To avoid plaster burns it is prudent to use only 8 to 12 sheets of plaster when possible, to use fresh dip water with a temperature near 24 °C, and to never to wrap the extremity in a sheet or pillow during the setting process. Peak temperatures usually occur between 5 and 15 minutes after plaster wetting.

The patient should be warned that the hardening process produces warmth. The heat of drying may produce pain in patients with hemophilia-related hemarthroses. Splinting these patients may require that the plaster splint only be placed long enough to verify a proper fit; the splint is then reapplied after setting (and cooling) of the plaster. *If any patient complains of significant burning sensation while the plaster is drying, do not ignore this complaint!* Immediately remove the splint, and promptly cool the area with cold packs or cool water. Patients with vascular insufficiency or sensory deficits (e.g., diabetic neuropathy, stroke) are at high risk for plaster burns and require close observation during the drying process.

### Pressure Sores

Pressure sores are an uncommon complication of short-term splinting. [25] They can result from stockinette wrinkles, irregular wadding of Webril, incorrectly padded or unpadded bony prominences, irregular splint ends, plaster ridges, or indentations produced from using the fingers rather than the palms to smooth and mold the wet plaster. Attention to detail during padding and splinting reduces the incidence of pressure sores. However, whenever a patient complains of a persistent pain or a burning sensation under any part of a splint, the splint should be removed and the

symptomatic area inspected closely.

### Infection

Bacterial and fungal infections can occur under a splint. [26] [27] Infection is more common in the presence of an open wound but may occur with intact skin. The moist, warm, and dark environment created by the splint is an excellent nidus for infection. Also, it has been shown that bacteria can multiply in slowly drying plaster. To avoid infection, all wounds should be cleaned and debrided before splint application, and clean, fresh tap water should be used for plaster wetting. In some instances, it is preferable to apply a removable splint that allows for periodic wound inspection or local wound care.

### Dermatitis

Occasionally patients develop a rash under a cast or splint. Allergy to plaster is exceedingly rare, but there have been several reports of contact dermatitis when formaldehyde and melamine resins are added to the plaster. [30] [31] The rash is usually pruritic, with weeping papular or vesicular lesions. Because these resins are unnecessary for ED splints, their use should be avoided whenever possible.

### Joint Stiffness

Some degree of joint stiffness is an invariable consequence of immobilization. It can range in severity from mild to incapacitating and can result in transient, prolonged, or, in some cases, permanent loss of function. Stiffness appears to be worse with prolonged periods of immobilization, in elderly patients, and in patients with preexisting joint diseases such as rheumatoid arthritis or osteoarthritis. Thus splints should be left on only for the period of time necessary for adequate healing. Table 53-7 lists several injuries that commonly require splinting, along with some suggestions for length of immobilization. Fractures, dislocations, or other conditions that require prolonged immobilization (more than 7 days) should have orthopedic follow-up. Patients must be told that a splint is only a short-term device and that prolonged immobilization can be detrimental. For minor injuries, the physician can suggest that the patient use his or her own judgment about when to remove the splint, but a definite end point should be set.

## CAST PAIN

Cast-related pain is a common complaint that brings patients to the ED. Because of the potential for ischemia with circumferential casts, all complaints should be fully investigated, and vascular compromise must be ruled out. A detailed history and physical examination should be performed on all such patients. The nature and onset of the pain is of particular importance. A dull, nonspecific pain that has worsened gradually since the time of injury may be the only clue to an early compartment syndrome (see Chapter 58) . The sudden onset of throbbing pain associated with swelling and redness suggests a possible deep venous thrombosis. In both of these cases, rapid intervention is the key to decreasing morbidity and mortality. The physical examination should pay particular attention to the areas of tenderness and the effect of active and passive

movement of the involved muscle group on the severity of pain.

With a *compartment syndrome*, tenderness over the involved compartment is a common finding; stretching or

| TABLE 53-7 -- Suggested Length of Immobilization for Conditions That Frequently Require Splinting | |
|---|---|
| **Condition** | **Length of Immobilization (Days)** |
| Contusions | 1-3 |
| Abrasions | 1-3 |
| Soft tissue lacerations | 5-7 |
| Tendon lacerations | Variable * |
| Tendonitis | 5-7 |
| Puncture wounds and bites | 3-4 |
| Deep space infections and cellulitis | 3-5 |
| Mild sprains | 5-7 |

| Fractures and severe sprains | Variable |
|---|---|

* There is considerable controversy surrounding the length of immobilization for tendon lacerations, and duration therefore is best left to the orthopedic or plastic surgeon.
Usually requires prolonged immobilization; best determined by an orthopedic surgeon

contracting ischemic muscle also elicits significant pain. The examination should also evaluate the presence and quality of distal pulses, amount of edema fluid present, distal sensation, capillary refill, and color and temperature of the digits. The finding of pain, pallor, paresthesias, paralysis, and pulselessness (the five Ps) are said to be pathognomonic for ischemia. Unfortunately, they seldom occur simultaneously, and their presence together is usually a late finding that carries a poor prognosis. Hence, the emergency physician must maintain a high index of suspicion for possible ischemia and remove the cast if any possibility of vascular compromise exists. Almost any cast can be bivalved and reapplied after inspection without significant loss of short-term immobilization.

To loosen a cast, an oscillating cast saw is used to cut along the medial and lateral aspects of the cast (Fig. 53-25 *A* and *B*). This is called *bivalving* the cast, and it allows the halves to be spread and reapplied in a less constricting manner while still maintaining proper immobilization. To use the oscillating power saw, proceed with a series of downward cutting movements facilitated by wrist supination, removing the blade between cuts. The blade is removed between cuts to prevent it from getting hot enough to burn the skin. This is particularly important if synthetic materials have been used in the cast. Also, the blade should not be allowed to slide along the skin, and the saw should not be used on unpadded plaster. In the apprehensive patient, the physician can demonstrate that the cast saw blade only vibrates (it does not turn) and that it does not cut the skin. After completely cutting through the medial and lateral sides of the cast, the two halves are separated using a cast spreader, and the padding is cut lengthwise with scissors. This may be sufficient to relieve early ischemia if the problem is simple post-injury swelling, but both the padding and cast can be removed totally to inspect the injured area if necessary. If ischemia cannot be ruled out, compartment pressures should be measured, and an orthopedic consultation should be obtained. If vascular integrity is established and no other problems are found, the bivalved cast can be replaced. The extremity should first be padded in the usual manner using fresh Webril. The cut ends of the bivalved cast are then lined with white adhesive tape, and the cast is replaced around the extremity. Finally, the cast is secured in place using elastic bandages.

If plaster sores are the cause of the patient's discomfort, the physician who placed the cast should be consulted. In some cases, additional padding is all that is needed, but in others a window should be cut out over the problem area. Because pressure sores can lead to significant tissue necrosis, the patient should receive follow-up care within 24 hours.

If the patient's problem is plaster (or more likely, resin) dermatitis, treatment generally

consists of topical or oral steroids and antihistamines. Therapy should be done in concert with an orthopedic surgeon because the patient may require admission for other forms of immobilization until the cast can be replaced. With mild cases, changing the cast or splint and using antihistamines for symptomatic relief may suffice. All of these patients should receive close follow-up, and if the condition does not improve, the cast must be removed.

## CONCLUSION

Splinting represents an important means of temporary fracture immobilization and provides protection and comfort for a variety of soft tissue injuries. The clinician should be aware of potential complications including ischemia, thermal injury, and pressure sores, which can occur with improper splint application. Proper technique should minimize the risk of these adverse outcomes. The emergency physician also should be facile in the release of circumferential cast and splint materials when ischemia is suspected.

# Chapter 54 - Podiatric Procedures

**Lancing P. Malusky**

A painful foot frequently motivates a person to seek professional medical care more readily than other limited musculoskeletal conditions, because mobility is compromised. This chapter addresses some common presentations of and procedures for the painful foot. A number of procedures (e.g., local and regional anesthesia, foreign body removal, soft tissue injections) are addressed in detail elsewhere in the text. These procedures also are discussed here in a limited fashion when they are relevant to the unique anatomy or function of the foot. The management of a paronychia, felon, and subungual hematoma is discussed in Chapter 40 . Joint aspiration for synovial fluid analysis is discussed in Chapter 57 . Lower extremity splinting techniques are discussed in Chapter 53 . Joint reduction techniques for digital and ankle dislocations are discussed in Chapter 52 .

## LOCAL AND REGIONAL ANESTHESIA

Most invasive podiatric procedures require local or regional anesthesia. A digital or metatarsal block is administered in the same fashion as that for anesthesia of the hand (see Chapter 32) . Because the digital arteries are end arteries, anesthetic agents without epinephrine are recommended. [1]

Although field blocks and local infiltration are generally adequate for anesthesia of the dorsal surface of the foot, regional nerve blocks at the ankle are preferred for anesthesia of the volar (plantar) surface (see Chapter 32) . The plantar surface is thickly calloused, but it is also exquisitely sensitive. Distention of the tissues by local infiltration on the plantar surface can be quite painful.

A device that has been used to facilitate placement of a skin wheal before deeper soft tissue infiltration is the MadaJet (Gill Podiatry Supply Company, Middleburg Heights, Ohio) (Fig. 54-1) (Figure Not Available) . The device mechanically injects a skin wheal using 0.1 mL of anesthetic without a needle. The device should be loaded daily with fresh anesthetic. After cocking the MadaJet, the aperture is placed about 1 cm from the skin site for anesthetic placement. The patient is warned about feeling a momentary sensation similar to a rubber band snap. The raised wheal area is instantly numbed, and injection of the remainder of the anesthetic using a standard needle and syringe technique can be begun immediately. The MadaJet is not recommended for the thicker adult plantar skin.

The physician who intends to use a jet injector should review and practice current disinfection recommendations. These devices have been linked with hepatitis B [2] and *Mycobacterium chelonei*[3] spread.

An alternative technique is to use a vapocoolant (e.g., fluorimethane or ethyl chloride) to numb the overlying skin prior to initiating needle puncture. The liquid is sprayed from a distance so that it begins to vaporize shortly after making skin contact rather than

running down the skin surface prior to vaporizing. Once the skin frosts, the superficial nerve endings have been deadened, and the operator can then numb the deeper tissues. If a plantar area is to be anesthetized and a tibial nerve block is not efficacious, this technique may minimize the pain of plantar injection. However, whenever possible, a less sensitive lateral, medial or dorsal approach site should be used.

## SHAVING OF PLANTAR LESIONS

The plantar skin is the thickest skin of the entire body and is especially designed to adapt to environmental influences in its effort to protect the foot's internal structures. Shearing forces and high pressure points will create hyperkeratoses on the plantar skin. These hyperkeratotic areas further focus weight-bearing forces in the foot, hence producing discomfort.

When the verruca virus is introduced to the plantar skin, its presence also frequently induces a hyperkeratotic response (i.e., wart). Unfortunately, *the definitive treatment methods for a wart are at odds with the appropriate regimen for a callus*. The wart should be treated with some form of epidermal eradication (see Curettage of Verruca and Porokeratosis), whereas the hyperkeratosis requires simple debridement with podiatric rebalancing of the weight-bearing surface.

Most hyperkeratoses occur directly over an area of focal friction or pressure, such as beneath a metatarsal head, on the ridge of the calcaneal skin, or adjacent to a digital bony prominence that is experiencing excessive shoe pressure. Verrucae may occur on any site in the plantar skin; they are less likely to occur on the digits and are rare on the dorsal skin.

Other, less common skin lesions can mimic the wart. A common error is to assume that a macerated lesion between two digits, especially at the crease between the fourth and fifth toes, is a verruca. This lesion is more likely a "soft corn" (heloma molle), discussed later. Another common misdiagnosis is porokeratosis plantaris discretia ("poro"), which is a small cyst-like lesion found in plantar locations and is histologically a sweat duct filled with a cone of keratin. This lesion often has been given the misnomer of "seed wart."

A "hard corn" (heloma durum, hammertoe, clavus) is a hyperkeratosis that occurs adjacent to a bony prominence on a digit. Hammertoes occur when the intrinsic (foot) muscles lose their stabilizing influence on the interphalangeal joints. The extrinsic (leg) muscles then overpower, producing flexion at the interphalangeal joints. Friction and pressure over the bony prominence, usually the proximal phalangeal head, cause a keratinization process that attempts to protect the dermis from penetration. The heloma durum may become macerated when it occurs between the toes, therefore becoming a heloma molle (soft corn) that may even perforate to the fascia. The heloma durum may become so chronically inflamed from recurrent friction or infection that a small sensitive neurovascular bundle (heloma milliare) may form amidst the keratosis.

Application of alcohol to the plantar lesion enhances skin line visibility. The skin lines of a hyperkeratosis should pass through the lesion or, in the case of severe pressure or

scarring, may flow into and disappear in the lesion. In contrast, the skin lines should pass around a verruca, which has a cystic capsule. A plantar verruca frequently has a coexistent surrounding hyperkeratosis, a response to the additional friction from the foreign mass. Differentiating a plantar verruca from a plantar hyperkeratosis also may be enhanced by observing the patient's response to pressure on the lesion. Direct pressure on a keratosis often elicits a more painful response than a squeezing maneuver of similar force. The reverse is true for a verruca.

## Indications

The lesion type may be more definitively determined by debriding the keratinized layers of skin. The clinician examines the shaved surface, seeking specific diagnostic signs of verrucae. Warts display the minicauliflower-like appearance of the papillomatous formation and the small capillary ends, which appear as black dots in the lesion. The process of debridement also affords a measure of temporary relief from the discomfort of the lesion. Should the shaving reveal a keratosis, more definitive shaving should be performed. If a wart is found, definitive curettage or podiatric referral should be provided.

## Equipment

Although a No. 10 or 15 Bard Parker scalpel blade on a handle may be used for debridement, these instruments are frequently difficult to handle when trying to debride thin layers of tissue from an oblique angle. Safer, more convenient instruments are the Beaver miniblades and the Gill chisel blade No. 312 and 313 with appropriate handles (Gill Podiatry Supply Company, Middleburg Heights, Ohio) (Fig. 54-2) (Figure Not Available) . When these instruments are held like a pencil, the physician can achieve a cutting angle more parallel to the skin.

## Technique

After the hyperkeratotic area is softened in warm tap water for 10 to 15 minutes, the patient is placed in a chair, and the foot is elevated to a comfortable eye level for the clinician. Heel lesions are often debrided with the patient in the prone position. After appropriate anesthesia for very sensitive lesions, the lesions are shaved under a bright examination light. A fresh, sharp blade is used for each patient.

The lesion is further moistened with an alcohol swab, and the skin is grasped above the area to be debrided using the fingers and below the area with the thumb of the nondominant hand. With the skin under traction, the Beaver blade handle is held like a pencil and placed at a 10° to 40° angle to the skin surface. The clinician rests or presses the knuckles or fingers of the dominant hand on the patient's foot and begins debridement tangential to the area of skin traction (Fig. 54-3) (Figure Not Available) . The rhomboid-shaped blade is held so that the end of the cutting edge distal to the clinician is wider than the proximal edge. Short, superficial strokes toward the clinician are used until a feel for the tissue and a feel for the patient's reactions are established. This hand placement technique provides a safety buffer for the patient, because if the

patient jumps, all materials move with him or her.

The skin surface to be pared should buckle outward to some extent. Using only the middle two thirds of the cutting edge, the layers are pared, and the site is repeatedly examined. A fresh swipe of an alcohol swab aids inspection. The clear, plastic-like appearance of keratinized skin over or around the shaved area identifies the safe debridement zone. No nerves or capillaries should exist in this tissue. However, even an experienced clinician occasionally inadvertently opens an end capillary, which bleeds into the field and obscures the diagnosis. The topical astringent Lumicain, which contains aluminum chloride (Medical Products Laboratories, Philadelphia) seals these bleeders off, but its application may be momentarily uncomfortable for the patient who has not had the lesion anesthetized before shaving. After initial shaving, the lesion should be more easily identified.

Plantar skin that thickens beneath a palpably prominent metatarsal head or heads is termed a *callus*. When this occurs in combination with a discrete, centrally bruised plug of keratin, it is called an *intractable plantar keratosis*. These lesions may require periodic podiatric evaluation for debridement, protective padding, and balancing of the weight-bearing surface with orthotics.

The routine corn is treated with periodic debridement and felt corn pads with an aperture to transfer pressure to the surrounding healthy skin (Fig. 54-4) (Figure Not Available) . The perforated soft corn is frequently misdiagnosed as an interdigital verruca by visual inspection. After a regional block, the lesion should be debrided with a mini-Beaver knife and a No. 64 blade for clearer diagnosis and relief of pain. Subsequent home care for this lesion includes astringent boric acid soaks twice daily, antibiotic cream or ointment applied topically, and a small, opened gauze pad laid into the web crease. The toes should be separated during healing with a cotton ball placed appropriately distal or proximal to the lesion or a small gauze pad taped in place. The soft corn may later require a foam interdigital cushion. All of these hyperkeratotic lesions are candidates for podiatric referral for bony correction if conservative care does not relieve pain adequately.

Definitive management of verrucae and "poro" requires treatment by curettage, acid, or freezing. Considerable comfort can be obtained before podiatric referral, however, by debridement under regional anesthesia.

## CURETTAGE OF VERRUCA AND POROKERATOSIS

### Indications

The preferred treatment regimen for the common verruca plantaris (plantar wart) varies among physicians and specialties, but all procedures concentrate on separating the verruca and epidermis from the basement membrane. Salicylic acid lyses the tissue interface, liquid nitrogen blisters it with cold, and the hyfrecator and the low-dose $CO_2$ laser blister it with heat. The curette mechanically separates the 2 skin layers. When the pain of a wart is severe because of its prominence, curettement may provide definitive

therapy.

## Technique

After placement of a regional nerve block (i.e., posterior tibial nerve block), several sterile curettes (Fig. 54-5) (Figure Not Available) , tissue nippers, and a hyfrecator needle are readied. An oval curette with a more pointed end is initially chosen. The skin distal to the site of the verruca is stretched taut with the physician's nondominant hand, and the handle of the curette is rested in the palm of the dominant hand. The dominant hand index finger guides the curette in a sweeping motion, directed opposite to the skin-stretching vector of the stabilizing hand (Fig. 54-6) (Figure Not Available) .

If the skin surrounding the verruca is still thick, the curette may face too much resistance, and the clinician may wish to give the curette a head start by making a snip 2 or 3 mm deep in the skin, just distal to the lesion in normal epidermis, using tissue nippers (see Fig. 54-5 (Figure Not Available) *B*). Larger lesions may require larger curettes; choosing the right size curette initially will simplify the process. Warts are cystic in structure and generally separate easily from normal tissue once the lesion begins to break away (Fig. 54-7) (Figure Not Available) . The clinician will appreciate the basement membrane when the curette scrapes on the skin lines. This process may mimic a metallic chime when encountered. The basement membrane is the protective layer of the dermis, and by design, the normal curette does not penetrate this zone unless undue force is used.

Some clinicians hyfrecate the lesion first to blister the wart and make curettement through the epidermis easier. Once the verruca has been thoroughly curetted with the various curettes, the hyfrecator may be used to sweep the area to loosen or destroy adjacent skin and discourage regrowth. If any purulence is uncovered, the base of the lesion should be inspected for the existence of a foreign body, which may be the original source of the virus.

Postoperatively, the treated area looks and feels like a blister to the patient, and 2 to 4 weeks of topical antibiotics and a gauze pad are commonly prescribed. Periodic debridement of the eschar may be needed to assist wound drying and resist plug formation. The recurrence rate is about 25% for most verruca procedures, and the patient should be warned to watch for regrowth.

The *porokeratosis* curettement process is similar to the verruca curettement process, but a sharper, smaller curette is needed. Whereas the verruca provides a relatively mild, broad-based pressure on the basement membrane, the porokeratosis creates a narrower, deeper pressure that may depress, scar, or even obliterate the dermis. The porokeratosis excision is begun with the same hand motions, but the narrow, cone-shaped lesion is found and followed into the basement membrane. The base appears bruised, and no hyfrecation is needed. A recurrence rate of 30% to 40% is common, and recurrence is more likely if the lesion is over a weight-bearing metatarsal head. Many podiatrists use a $CO_2$ laser on this lesion, and reported recurrence rates are <15%. Postoperative care is similar to that for wart curettage, but postoperative

debridement of the eschar plug may be needed during follow-up care.

# FOOT PAD USE

Foot pads are used to redistribute pressure applied to a tender, inflamed area of the foot. The type of pad used and its placement are dependent on the underlying problem. A number of commercial aperture pads are available for protection of bony prominences (Fig. 54-8) . These pads are helpful for management of corns and hyperkeratoses secondary to hammertoe deformities (Figs. 54-4 (Figure Not Available) and 54-9) (Figure Not Available) . The use of these shields for management of bunions is discussed subsequently.

## Metatarsalgia

Firm palpation that elicits pain directly beneath the metatarsal head can be diagnosed as a metatarsal bruise or contusion if it involves 1 head, or metatarsalgia if it involves more than 1 head. The metatarsalgia patient complains of discomfort that comes on during walking, becomes progressively worse during the day, and is relieved only by rest. The patient can often identify the painful spot for the clinician. Frequently the pain is felt beneath the second or the second and third metatarsal heads.

The physician palpates each of the lesser metatarsal heads and identifies the site of pain under the metatarsal head or heads. A hyperkeratosis may be associated with this condition, either diffusely under the central lesser metatarsus or discretely beneath a metatarsal head. Debridement of the hyperkeratosis (as discussed earlier) is important for diagnosis and treatment. A discrete lesion may be the real origin for discomfort, and adequate debridement and podiatric follow-up to address the source of the hyperkeratotic reaction may be sufficient emergency department therapy.

### Therapy

Any hyperkeratosis should be cushioned with a pad (e.g., Spenco [Gill Podiatry Supply Company, Middleburg Heights, Ohio] or PPT [Langer Biomechanics Group, Inc., Wheeling, Ill.]). For discrete pain beneath the second metatarsal head, which may be a flexor hood capsulitis (see below), a sub-first metatarsal head raise is accomplished using a 1-cm-thick PPT pad placed beneath an innersole (Fig. 54-10) (Figure Not Available) . Nonsteroidal anti-inflammatory drugs and a quality athletic or walking shoe should also be recommended. Continued symptoms require podiatric follow-up.

## Hallux Valgus (Bunion)

The basis for a bunion is complex and represents a dynamic imbalance between the structures on the lateral side of the first metatarsophalangeal (MTP) joint and the medial side of the MTP joint (Fig. 54-11) (Figure Not Available) . [4] [5] When there is lateral displacement of the distal hallux, a bunion begins to form. A number of anatomic, hereditary, physiologic, and footwear elements contribute to bunion development.

The typical bunion deformity develops in a woman wearing heels occupationally. She may state she has numbness on the distal medial aspect of the hallux (from compression of the terminal branch of the medial dorsal cutaneous nerve). She may recall a time when the intermetatarsal space was tender or when the area of the sesamoid apparatus was tender for a short time. Other foot complaints, such as lesser metatarsalgia, intermetatarsal neuroma, hammertoes, ingrown toenails, and corns and callus, may be common. First MTP joint bursitis commonly occurs over the medial bunion bump. Finally, gout should be considered, even in women.

**Therapy**

Removal of the offending footwear is advised, or a hole may be cut in the shoe to allow the sensitive area freedom from pressure. A precut bunion shield (Figs. 54-8 *C* and *D* and 54-12 (Figure Not Available) ) may be dispensed or constructed from 1-cm-thick felt. Nonsteroidal anti-inflammatory drugs are also commonly used. When inflammation is severe, aspiration of the bursal fluid with a 20-ga needle followed by instillation of 0.5 mL of a local anesthetic and a short-acting steroid (e.g., 4 mg of dexamethasone) can be performed.

## Flexor Hood Capsulitis

This condition is a common overuse presentation that is sometimes mistaken for metatarsalgia. Direct palpation of the dorsal or lateral metatarsal head will *not* be painful, but tenderness will be elicited directly beneath the proximal phalangeal shaft. The MTP joint is similarly nonpainful when palpated from the dorsum or axially loaded, thus ruling out an arthritis.

The flexor hood mechanism is a thin retinacular band that holds the flexor digitorum longus/brevis tendon complex close to the digit's proximal phalanx. A poorly functioning bunion foot, with its ineffective medial column, may overuse the second and, rarely, the third digit. The toe may hammer, causing the flexor plate that normally articulates beneath the metatarsal head to be pulled distally. Edema of these tissues may cause the involved toe to abduct from the neighboring digit. Treatment is the same as for metatarsalgia (see Fig. 54-10) (Figure Not Available) ; in addition, reinjury should be reduced by using footwear that restricts digital dorsiflexion at the MTP joint. A well-cushioned, hard-soled Reese shoe is useful for this condition.

## Heel Pain Syndromes

In-depth discussion of the multiple causes of heel pain is beyond the scope of this text. The use of foot pads as adjunctive therapy for these conditions is addressed later. Other supportive therapies for most of the entities include modification of physical activity, use of nonsteroidal anti-inflammatory drugs, local injection of anesthetic and steroid agents, and use of orthotic footwear.

**Heel Spur Syndrome**

The patient presents with heel pain that gradually worsens over several months. Palpation elicits pain about the medial border of the calcaneus, possibly extending distally at the radiographic site of a bony spur ledge (Fig. 54-13) (Figure Not Available) . Supportive therapy is helpful, including a local steroid injection (e.g., 10 to 20 mg methylprednisolone). Injections are performed from the medial aspect of the calcaneal spur, thus avoiding the sensitive plantar area. The medication is distributed along both the medial calcaneal tubercle and the central plantar calcaneus beneath the spur fascia junction. Shoe support in the form of a heel raise of 1.25 cm bilaterally reduces heel weight bearing. A temporary donut-shaped heel cushion cut from 1-cm-thick PPT or a similar high-density foam rubber also suffices for this purpose. Podiatry follow-up, especially for the severely pronated or supinated foot, should be considered.

**Retrocalcaneal Bursitis**

With this condition, pain is present at the specific site of the Achilles tendon insertion. Either or both bursae may be sensitive, and the clinician can palpate for either (see Fig. 54-13) (Figure Not Available) by relaxing the Achilles tendon with plantar flexion of the foot. Tenderness when a squeezing force is applied anterior to the tendon in the depression above the calcaneus suggests inflammation of the retrocalcaneal bursae. Tenderness with thumb pressure on the back of the insertion of the tendon behind the calcaneus suggests inflammation of the postcalcaneal bursa. Treatment is identical to that for heel spur syndrome, with the exception that steroids, when used, are injected into the inflamed bursae. A small steroid dosage is recommended to reduce the risk of atrophy of the Achilles tendon insertion. A PPT heel pad lift or varus pad in the shoe is also helpful. All shoes worn at home and work by the patient should have a uniform heel height with a nylon cleat on the lateral side.

**Calcaneal Apophysitis (Sever Disease)**

This condition commonly occurs in active children between the ages of 8 and 14 years old. As a result of incomplete fusion, the apophysis at the plantar posterior aspect of the juvenile's heel is stressed at its cartilaginous connection by the Achilles tendon. Great tenderness is evident with palpation directly over the apophysis. There should be no significant tenderness of the Achilles tendon, and there is usually no edema. Treatment is identical to that for retrocalcaneal bursitis, with the exception that steroid injections are not recommended.

**Other Conditions**

A painful heel may be due to other conditions, including a partially ruptured Achilles tendon, gouty and psoriatic arthritis, and calcaneal stress fractures. These conditions are generally identified by history and physical examination; specific therapies for these entities are discussed in general emergency medicine and orthopedic references.

# TARSAL TUNNEL SYNDROME AND SINUS TARSITIS

## Tarsal Tunnel Syndrome

The tarsal tunnel syndrome (TTS) is similar to carpal tunnel syndrome in the upper extremity. TTS is caused by compression of the posterior tibial nerve in a restricted anatomic channel while traveling around the medial malleolus. The other structures in the tibiotalocalcaneal canal are the posterior tibial, flexor digitorum longus, and flexor hallucis longus tendons; the double posterior tibial veins; and the posterior tibial artery. Inflammation or disease of any of these structures may cause secondary inflammation of the nerve. These structures are held in place by a flexor retinaculum. The posterior tibial nerve trifurcates, sending off first the medial

calcaneal branch (this branch may become involved in the heel spur syndrome) and then splitting into the larger medial and lateral plantar nerves. These plantar nerves travel deep to the abductor hallucis muscle belly and into the deep fascia of the sole of the foot. There they serve motor, sensory, and proprioceptive functions.

TTS may present with a sensation of burning at the ball of the affected foot, usually in the second through fifth sub-metatarsal head areas. Percussion over the posterior nerve posteromedial to the medial malleolus may reveal a positive Tinel's sign. Because this condition may be due to a variety of causes, referral to an orthopedist or podiatrist is recommended. Emergency department management may include inversion position taping or Unna boot application to reduce nerve compression or use of nonsteroidal anti-inflammatory drugs. Severe cases may be treated with short-acting corticosteroids (e.g., 1.5 mL of dexamethasone acetate suspension [8 mg/mL]) and local anesthetic (e.g., 2 to 3 mL of 0.25% bupivacaine) injected into the canal at the level of the medial malleolus.

## Sinus Tarsitis

This condition, also known as *tarsal canal syndrome,* consists of inflammation within the subtalar (talocalcaneal) joint. This anatomic canal runs obliquely from proximal medial to distal lateral. The only intrinsic dorsal foot muscle, the extensor digitorum brevis, takes origin from the calcaneus here. Trauma, inflammation, or mass (e.g., ganglion) in the canal may produce a tight band sensation obliquely across the ankle below the level of the malleoli.

The diagnosis may be made by injecting a local anesthetic agent directly into the canal. The insertion point is palpated as a depression just anterior to the tip of the lateral malleolus. Injection of 3 mL of 2% plain lidocaine should be sufficient to resolve symptoms. Further therapy with a repository steroid, such as 2 to 8 mg of dexamethasone acetate, can be used. Consultant referral is recommended to differentiate this condition from a variety of disorders, including peroneal spastic flatfoot, tarsal coalitions, Charcot joint, and degenerative joint disease.

# INJECTION THERAPY FOR A NEUROMA

A forefoot neuroma, also known as a *Morton neuroma,* is a painful condition that is most likely to affect the female adult, especially if she wears heels occupationally. The neuroma is usually unilateral, but it may also occur bilaterally. This lesion frequently occurs in the third intermetatarsal space but may occur in the second interspace; it rarely occurs in the first or fourth interspace. Its preponderance for the third space is thought to be due to dual innervation of this interspace by the lateral plantar nerve and the medial plantar nerve and to the fact that the fourth metatarsal is the most mobile. An intermetatarsal ligament (deep plantar aponeurosis) connects each metatarsal head on its plantar aspect, and the sensory nerve passes beneath this ligament (Fig. 54-14) (Figure Not Available) .

In high heels, the sensory nerve is forced to bend around this ligament and is compressed against it during weight bearing. The perineural covering becomes fibrotic from chronic irritation. Although the normal sensory nerve is the size of a pencil lead, the neuroma is the size of a pencil. The damaged nerve trunk no longer conducts normal impulses, and a burning pain, numbness, or other paresthesia is reported in the third or fourth toes. A feeling of a lump, cord, or rolled up sock is often expressed. A classic diagnostic feature is when the patient states that he or she had to sit down on a curb and massage the foot for relief.

The condition is diagnosed using careful forefoot palpation to rule out arthritis, metatarsalgia, capsulitis, ganglion, or stress fracture. The space between and just distal to the metatarsal heads is squeezed, and the resultant pain suggests a neuroma. A tender spot may be noted in the depression just behind and between the involved metatarsal necks, where the nerve first encounters the intermetatarsal ligament. Pain produced with palpation distally in the intermetatarsal sulcus also suggests a neuroma. The pain is reproduced by squeezing the metatarsal heads together. The differential diagnosis includes ganglion, MTP joint capsulitis, and stress fracture. A common diagnostic maneuver is to instill 2 mL of 1% or 2% lidocaine in the intermetatarsal space, just proximal to the ligament and in the fascia just deep to the plantar skin. The injection is done from dorsal to plantar. If the pain is totally relieved on repeat palpation maneuvers, a Morton's neuroma is likely.

## Therapy

A serial treatment plan may include a reduction in heel height, a cushioned innersole such as PPT or Plastizote, sub-fourth metatarsal shaft raise (Fig. 54-15) (Figure Not Available) , and local injection. After skin preparation, the tender neuroma is injected with a 1- to 2-mL mixture of a long-acting local anesthetic (e.g., 0.5% bupivacaine) and steroid (e.g., 5 to 10 mg methylprednisolone). The injection is made either directly into the lesion or indirectly into its fascial plane, as described above. The previous local anesthetic diagnostic block will make this steroid injection more tolerable. The dorsal venous arch is frequently encountered when performing this injection; thus, careful aspiration prior to injection should be performed. The patient also should be warned that a harmless ecchymosis is common following this procedure. Podiatric follow-up for

additional care is warranted.

## ASPIRATION AND INJECTION OF A GANGLION

A ganglion is histologically similar to a synovial sheath and frequently contains synovial fluid. The ganglion is considered traumatic in origin and usually has a stalk traceable to a tendon sheath or joint capsule. Although the ganglion is easily diagnosed when it occurs over a tendon on the dorsum of the foot, it can be a challenging diagnosis when present among the compact forefoot structures. This lesion may mimic the neuroma or MTP joint capsulitis.

When the clinician finds edema in the forefoot, the location of this swelling is a key diagnostic consideration. A neuroma usually does not cause edema of the intermetatarsal space unless it is unusually large. An MTP joint capsulitis causes swelling at the MTP joint, perhaps brawny in nature, but careful palpation confirms its location. A small ganglion causes swelling directly beneath the flexor apparatus of the involved digit or perhaps directly beneath a metatarsal head or the tibial sesamoid. The larger ganglion grows in the path of least resistance, which is to an available intermetatarsal space. If painful, a ganglion associated with the lesser metatarsal structures will provide a localized stinging or burning sensation on palpation, whereas the neuroma's pain travels out into the involved toes. The ganglion should roll under the examiner's fingers. If the lesion is painless and nonmovable, other soft tissue neoplasms should be considered. An extremity coil magnetic resonance image enhanced by gadopentetate may aid in this diagnosis and help rule out or stage the rare malignancy.

### Therapy

When the clinician suspects that the lesion is a ganglion, the diagnosis may be confirmed and treatment begun by aspiration of synovial fluid. The physician, with local or regional anesthesia, blocks the tender area and anticipated skin penetration site. After skin preparation, a 20-ga needle is inserted, and under negative pressure, the suspected ganglionic structure is explored for fluid. When fluid is encountered, the lesion should be drained. The fluid should have a yellow, thick, gelatinous character. Further aspiration and exploration with rotation of the bevel of the needle should be performed. Upon needle withdrawal, the lesion may be further squeezed to drain the rest of the fluid. After fluid drainage, infiltration with a steroid solution and local anesthetic is appropriate to enhance resolution. Although a small volume (<0.5 mL) will reexpand the cyst somewhat, the medication is generally absorbed within 24 hours. Fluid is not always found, but if the clinician is certain of the diagnosis, steroid infiltration may still be entertained. The ganglion frequently remains deflated and asymptomatic, although recurrences are common and warrant specialist follow-up.

## SPLINTING TOE FRACTURES

Although many clinicians and laypersons shrug their shoulders at a fracture of a toe and state that nothing can be done, something can and should be done to relieve the pain

and encourage healing. As with any other fracture, attention should be paid to the possibility of breach of joint cartilage, hypermobility of fracture segments, and malposition and malunion of the fracture segments.

Aggressive fracture reduction is indicated for great toe proximal phalanx fractures, as it represents the main propulsive segment of the forefoot. A plaster cast is *insufficient* treatment *except* in cases of a simple nondisplaced fracture through the body of a great toe phalanx. Any displacement should raise concern regarding the possibility of an axial rotation or a deviation in the way the hallux interacts biomechanically within its own interphalangeal or MTP joint. In the acute setting, a non-weight-bearing ankle splint with attached plantar component extending beyond the great toe provides protection until the patient with a complicated great toe fracture can obtain follow-up. Open fractures obviously need immediate referral for debridement and continued antibiotic therapy.

A fracture of the first MTP joint *sesamoid* bone may result from a jump from a height. The great toe sesamoid bones lie in grooves on the bottom of the metatarsal head. Each bone lies within the tendon of its respective flexor hallucis brevis muscle belly. With a sesamoid bone fracture, there is localized pain on the plantar aspect of the first metatarsal head. Bipartite sesamoids (tibial more frequently than fibular) are common, and bilateral radiographs are helpful to clarify whether the radiographic changes represent a true fracture.

Fractures of the lesser toes usually result from jamming

the toe into a nightstand or bedpost while barefoot. Radiographs of the phalanges will confirm the clinical suspicion.

**Therapy**

For a tibial sesamoid injury, an aperture bunion-type pad, reinforced medially, of 0.5- to 0.75-cm-thick felt protects the sesamoid and transfers weight bearing to the surrounding structures (Fig. 54-16) (Figure Not Available) . A Reese shoe and nonsteroidal anti-inflammatory drugs are also helpful. Subsequent radiographs rarely show bony consolidation, but the fracture interface appears smoother.

The treatment for closed lesser phalangeal fractures is "immobilization" for 6 weeks. The patient is ideally put in a less restrictive, stiff-soled shoe or a Reese orthopedic shoe. As the fracture is reduced, the injured toe is secured against an adjacent noninjured toe. A soft corn pad is placed between the toes, and the toes are held together with an adherent wrap around both digits (Fig. 54-17) (Figure Not Available) . Thus, the normal toe splints the injured toe. The procedure is demonstrated to the patient or family and materials are dispensed so that the splint can be changed every 2 to 3 days at home.

# PLANTAR PUNCTURE WOUNDS

Plantar puncture wounds often present a diagnostic and therapeutic dilemma for the

clinician. [8] (See also Chapters 36 and 39.) Considerable controversy exists regarding the proper initial management of these wounds. Although up to 98% of such wounds are produced by nails, [9] various other objects have been reported as causing these wounds, including other metal objects, wood, and glass. The host response to the injury is dependent on the penetrating material, location of the wound, depth of penetration, footwear, time from injury until presentation, and underlying health. Because superficial puncture wounds generally do well, the depth of penetration may be a primary determinant of outcome. This may in part explain why distal wounds in the MTP joint area that are associated with increased weight bearing during ambulation are often more serious. [10]

Because most minor puncture wounds are not seen in the emergency department, the true risk of infection, and in particular osteomyelitis, remains speculative. One review of these wounds suggests that no more than 2% to 8% of puncture wounds become infected, and only a small percentage of these go on to develop osteomyelitis. [8] The retention of foreign material (e.g., a portion of a tennis shoe sole) in the wound is an important factor in persistent infection. One prospective series suggests that only the presence of symptoms (e.g., redness, tenderness, increased swelling) at 48 hours was associated with the risk of infection or potential retained foreign body. [11]

**Therapy**

The approach to the patient is dependent on several factors, including the time from wounding to presentation, the suspicion regarding a foreign body, and the presence of infection (Fig. 54-18) (Figure Not Available) .

Patients presenting within 24 hours and without signs of infection generally require only simple wound care. [11] Although irrigation of all exposed dermal tissue is recommended, high-pressure irrigation of deep tissues with distention of soft tissue is unlikely to be helpful.

The extent to which a foreign body workup is pursued depends on the history and physical findings. When a patient clearly states that the puncture was produced by a new nail that was removed intact, a radiographic series or local wound exploration for a retained metallic foreign body is not needed. When the wound is large and the patient was wearing rubber-soled shoes, however, local wound exploration may be warranted to exclude the possibility of a retained portion of the shoe. Exploration should be performed under a regional anesthetic block after an ellipse of tissue has been removed from around the puncture site. Blunt probes should be used. General management of suspected foreign bodies is discussed in further detail in Chapter 39 .

Patients who delay presentation for medical attention have an increased risk for a retained foreign body, since delayed presentation is often due to the development of inflammation. Unless the patient presents without infection or with a clearly superficial cellulitis expected to respond to simple oral antibiotics, local wound exploration is warranted, as discussed earlier. Recurrent infections, deep soft tissue tenderness, and increasing soft tissue swelling indicate the probability of a retained foreign body or deep space infection. Such patients require prompt specialty referral. Consideration of the

need for additional diagnostic studies (e.g., wound cultures, ultrasonography, or computed tomography of the puncture area) should be made.

# DIABETIC FOOT CARE

The diabetic patient is at special risk for serious cutaneous injury and infection as a result of microcirculatory insufficiency and neuropathic changes. The diabetic often does not appreciate the development of pathologic conditions such as hyperkeratotic lesions, corns, ingrown toenails, and ulcers. Often these conditions are exacerbated by the patient's choice of footwear and activities.

**Therapy**

In general, the diabetic patient with foot lesions is instructed not to stand for longer than 20 minutes at a time. The patient is also cautioned to avoid extreme temperatures when cleansing the feet.

A hole or slit may be cut in the shoe over any obvious non-weight-bearing prominence. Hyperkeratotic lesions should be shaved and shielded with an aperture pad (see Fig. 54-9) (Figure Not Available) . For a hammertoe lesion, the toe is covered with an aperture pad. For the bunion area, a large commercial adhesive bunion pad or bunion shield cut from felt may be applied.

Ingrown toenails and mycotic toenails can be managed as for nondiabetic patients. The only caveat is that these conditions can become serious lesions before the patient is aware of the problem. The diabetic with advanced disease who has an infected or progressive lesion also should have differential blood pressures checked in all four extremities to assess large artery patency (see Chapter 70) . Evidence of large artery insufficiency requires urgent vascular referral. The diabetic patient's metabolic status also should be closely monitored.

When ulcers develop, the necrotic rim should be debrided. Antibiotic ointments or biologic membranes as used for burn patients (see Chapter 41) are also helpful. These lesions should be shielded with aperture pads, and the patient should be followed closely. A radical reduction of walking, perhaps to total non-weight-bearing status, should be stressed for *plantar* ulcerations. A pillow placed under the patient's calf that allows the heel to overhang permits heel ulcers to repair (Fig. 54-19) (Figure Not Available) . A foot cradle keeps bedding pressure off the toes.

# MANAGEMENT OF FUNGUS TOENAILS (ONYCHOMYCOSIS)

The mycotic toenail can occur at any age but increases in frequency with increasing age. The condition is caused by the usual tineal fungi, most frequently members of the *Trichophyton* genus. Onychomycosis can also occur posttraumatically and is more often seen in the hallux and fifth toenails, where the greatest shoe friction occurs. Spontaneous resolution is rare and is less likely as the nail plate becomes more extensively involved and thickened. Occasionally a traumatic avulsion leaves an

individual free of the hypertrophic mycotic toenail temporarily, but the matrix retains its acquired predilection for growing a hypertrophied toenail. A new tinea subsequently colonizes the nail in most cases.

The tinea is contained in the nail plate, and the body usually maintains the integrity of the viable dermis of the nailbed (Fig. 54-20) (Figure Not Available) . The fungus feeds on the nail plate and deposits its waste products within the nail plate and on the nailbed. The dusty, brownish-yellow debris encountered in the mycotic nail consists of fungus spores and hyphae, desiccated toenail, and desquamated skin from above the nailbed. During the initial stages of the fungus infection, only the free edge or the surface of the nail plate is involved. As time proceeds, the fungus extends proximally and more deeply into the nail plate along longitudinal lines of stress. Once the entire free edge of the toenail is mycotic, the fungus works its way back to the central nailbed in a series of striations (see Fig. 54-20) (Figure Not Available) .

Any mechanical or shearing force causes microtrauma to the invaginated nailbed folds, and a resultant lysis of the nailbed-nail plate interface occurs. A local, transient, primary fungal infection of the nailbed may be followed by a secondary bacterial infection. Eventually the fungus reaches the nail matrix, which responds by growing a hypertrophic nail plate. The mycotic nail subsequently causes greater friction or pressure on the nailbed, and recurrent inflammation and infection may occur.

**Therapy**

When the fungal infection is limited to the distal nail, simple surface nail plate filing with topical anti-tinea therapy is often effective. When the involvement is more extensive, avulsion of the nail plate is performed, and an oral antifungal agent is prescribed for 1 month, along with local wound care. Topical antifungal therapy is applied twice daily as the new nail plate develops. Therapy for secondary bacterial infections should incorporate broad-spectrum antibiotics (e.g., second-generation cephalosporin agents).

Once the fungus reaches the level of the nail matrix as visualized by obliteration of the lunula, the hypertrophy becomes fixed, and the condition is usually irreversible. Surgical approaches to treatment of chronic onychomycosis include nail plate avulsion with nailbed debridement (with or without phenol nail matrix destruction, described later) and periodic limited debridement of the involved nail using a Dremel tool (Gill Podiatry Supply Company, Middleburg Heights, Ohio) and nail burs (Fig. 54-21)

## INGROWN TOENAIL (ONYCHOCRYPTOSIS)

The ingrown toenail represents a progressive nail curvature or static widening of the lateral sides of the toenail such that the nail impinges on the skin of the nail groove. Normally, the cuticle and periungual nail structures undergo a progressive maturation and sloughing process that permits the nail to slide forward easily as it grows anteriorly from the nail matrix. Additional frictional forces are present in the nail groove when the nail is severely incurvated or hypertrophic, when the patient habitually wears tight shoes, or when the patient has a digit that is axially rotated against an adjacent digit or

the bottom of the shoe. These frictional forces may stimulate a hyperkeratotic response in the nail groove.

The vast majority of ingrown toenails occur in the halluces. Discomfort occurs when the nail impingement causes hyperkeratosis of the nail groove with localized nerve irritation or when a foreign body reaction is generated. The foreign body response may be simply a mild erythema and edema of the nail fold, or it may progress to a purulent granulomatous formation. If the patient cuts the nails in a curved rather than transverse manner, there is also the potential for a spicule of nail to remain in the nail fold and impinge upon the hyperkeratosis (Fig. 54-22) (Figure Not Available) .

**Evaluation**

In the presence of predisposing nail changes, the decision to treat is primarily based on the subjective complaints of the patient. The offending margin in the nongranulomatous ingrown toenail must be examined closely for determination of the exact location of the problem. With this condition, the patient will complain of pain reproduced by fingertip pressure over the nail groove. The clinician also should apply pressure to the central portion of the nail plate, the proximal cuticle, and the opposite nail margin to rule out other potential sources of pain. Other causes for discomfort include a stress fracture of the distal phalanx and a subungual exostosis, a proximal bony bump on the dorsum of the distal phalanx that can produce central nailbed pain. Other considerations producing referred pain include diabetic neuropathy and shoe pressure-induced neuritis of the dorsal medial cutaneous nerve.

The clinician should continue diagnosis and treatment by cleaning the nail groove with an alcohol pad. Hyperkeratosis, mycotic debris, and impacted periungual debris can be visualized with this technique. The nail groove should be inspected with a mini-curette. The free edge of the nail should have a clear path to exit the nail groove. The clinician should curette the extraneous periungual debris with the mini-curette until the nail and nail groove are separate and visible. This debridement may be facilitated by a 5-minute topical application of a 1% phenol solution (made by adding distilled water to a 70% to 88% aqueous phenol solution in an 80:1 ratio [e.g., 80 mL distilled water to 1 mL of phenol]). The physician must be careful not to put a great amount of pressure directly on the nail groove with the sharp edge of the curette, because the area is quite sensitive. The blunt curve of the back of the mini-curette can be used for gentle probing of the nail groove to locate the hyperkeratotic plug. This plug will elicit tenderness and will be visible as yellowish to gray translucent tissue after being cleansed with alcohol.

Further treatment will generally require a digital block (see Chapter 32) . At this point, the clinician's options are (1) temporary removal of the presumed nail spicule and/or debridement of the periungual hyperkeratotic plug or (2) permanent correction of the toenail deformity using the phenol technique (see below). The decision is primarily based on the chronicity of the complaint, the degree of nail curvature, the subjective discomfort of the patient (without a concurrent desensitizing neuropathy), and the history of infection or current infection. Because this procedure can be time consuming, the clinician also will need to factor concurrent patient care demands in the emergency

department.

**Removal of Nail Spicule and Debridement of Hyperkeratosis**

This procedure is primarily reserved for those ingrown toenails with minimal inflammation, a small amount of incurvation, no concurrent infection, and limited discomfort. Spicule removal can also be used where the nail is loosely adherent to the nail groove and can be freed without causing any capillary bleeding.

Following a digital block, the toe is cleansed with a standard skin preparation. An oblique portion of the offending nail (about one third to two thirds of the way back to the posterior nail fold) is removed (Fig. 54-23) (Figure Not Available) . Ideally, an English anvil nail splitter or nail forceps is used (Fig. 54-24) (Figure Not Available) . If the nail is found to be spiculated more than two thirds of the way back, the clinician can switch to the permanent phenol correction technique described below.

Following removal of the oblique nail portion, the free edge of the remaining nail should be smoothed so that it will glide freely out of the nail groove as it grows. Loose keratinized debris exposed beneath the removed side of the nail plate can be curetted off the nailbed. Next, the keratotic plug in the nail groove is debrided (preferably with a mini-Beaver handle and blade No. 64 or 67). The blade should be sharp to facilitate debridement and reduce the risk of trauma and resultant scarring of the nail groove. The nondominant hand should firmly grasp the toe while the clinician's thumb or index finger plantarly rotates the nail groove open. The keratotic plug is debrided down to normal epidermis or dermis, which may be ecchymotic in character. The clinician should attempt to prevent patient bleeding during the procedure. Should bleeding occur, a digital tourniquet (see Chapter 36) or a commercial Tourni-cot (see below) can be used for maintaining a dry field during the procedure. The area is then dressed with antibiotic ointment, Adaptic (or similar nonadherent material), and a dry dressing. A dressing change should occur at 48 hours with nail fold reevaluation. Follow-up podiatric care with consideration for permanent correction should be advised.

**Technique of Partial Toenail Removal**

The decision to permanently remove a portion of a toenail is based on the following criteria. Ingrown toenails associated with chronic inflammation, severe pain, or infection (with the exception of simple paronychia [i.e., paronychia without a hyperkeratotic reaction]) should be considered for nail removal. Phenol is applied to the exposed nailbed to produce neurolysis of nerve endings and necrosis of the germinal matrix.

After a digital block on the involved hallux or toe (see Chapter 32) , the digit is squeezed or wrapped for exsanguination of the blood currently in the toe, and a digital tourniquet is applied (see Chapter 36) . One commercial tourniquet is the Tourni-cot (Mar-Med Company, Grand Rapids, Mich), which both exsanguinates as it is applied and provides excellent hemostasis. Hemostasis is mandatory for subsequent phenol application. The device is rolled onto the digit from the tip to the base of the toe. It is wise to leave the device's warning tag in place during surgery as a reminder that the device must be

removed at the completion of the procedure and prior to release of the patient.

While stabilizing the toe in the nondominant hand, one uses English nail nippers to clip the involved lateral quarter of the nail approximately one half to two thirds of the way back to the cuticle, following the longitudinal lines of the nail (Fig. 54-25) . Care must be used to avoid cutting or tearing the nail further because of the danger of phenol seepage onto the desired remaining portion of nail matrix. The clinician proceeds by splitting the nail the rest of the way back with a mini-Beaver No. 61 blade; a No. 11 or 15 scalpel blade on a handle can also be used but is less effective. An angulated nail splitter (or straight scissors, although these are less desirable) may be used for thicker toenails. The end of the chosen instrument is placed in the palm of the clinician's pronated dominant hand for stability. The blade is placed into the formerly created nail defect. The index finger of the dominant hand guides the blade as the palm forces it into the defect. Any residual blood pooled in the toe now appears in the wound; the blood should be removed by daubing with dried gauze. If minor hemorrhage persists, the toe tourniquet should be reapplied and tightened. The index finger of the dominant hand should press against the patient's toe or the clinician's opposite index finger to provide a stabilizing counterpressure as the blade is slowly forced into the nail and beneath the cuticle. One should gently rock the splitter to ease it proximally. The nail is cut until the sensation of resistance is gone after passing several millimeters beneath the posterior nail fold. Care must be taken to keep the blade directed slightly downward and perpendicular to the nail plate, or the cut may angle obliquely into the corner of the posterior nail fold. If this happens, a portion of toenail may remain directly over the unwanted matrix, thus blocking the phenol cautery and reducing the correction.

Once the nail is split, a blunt angulated nail splitter is then used to separate the unwanted toenail from the nail groove, nailbed, and posterior nail fold. The nail remnant is then grasped with a small straight hemostat and removed from the wound by rolling (twisting) the hemostat overhand toward the remaining nail plate. The clinician inspects the remnant to ensure that all of the desired nail is removed. The exposed nail groove is then inspected for the keratotic plug; the lateral nail groove is curetted to remove the plug. The cuticle that is tucked back under the exposed posterior nail fold also should be curetted with counterpressure on the skin above; this tissue may not initially yield to curettement until it has been exposed to phenol lysis, but removal should be attempted before dressing the operative site to prevent a possible foreign body reaction postoperatively. Some clinicians prefer to debride the lateral nail matrix prior to phenol treatment.

The wound must be freed of hemorrhage or pooled blood by daubing the area with gauze or a dry cotton-tipped applicator. Again, if even minor hemorrhage persists, the toe tourniquet must be tightened. When using a Tourni-Cot, a smaller diameter device may be required if seepage persists.

The wound is now ready for phenol cautery. A 70% to 88% aqueous phenol solution is applied by means of cotton-tipped applicators. If the cotton-tipped applicators are too bulky to fit into the nail defect, they should be debulked prior to use. Microtipped applicators also are commercially available (Gill Podiatry Supply Company, Middleburg Heights, Ohio). The applicators should be thoroughly moistened, but not saturated, with

phenol solution, and one should make three 30-second applications to the nail groove, concentrating on the matrix beneath the posterior nail fold. For small toes in children, a reduced dosage of three 20-second applications by means of a cotton wisp on a toothpick should be used. The applicator is twisted toward the top of the nail--that is, when facing the tip of the toe, the applicator is turned counterclockwise if the remaining nail is to the left of the applicator and clockwise if the remaining nail is to the right of the applicator (Fig. 54-25 *D*). One uses this technique to avoid forcing phenol under the remaining nail plate.

The chemical cautery should turn the nail groove tissue

to a brown-tinged grayish color. If fluid should drip from the wound or migrate along the posterior nail fold, it must be dabbed quickly with gauze to prevent it from lysing normal tissue. Upon completion of the third phenol application, the wound is lavaged with a small stream of sterile water. While the stream is flowing over the defect, the clinician rubs his or her latex-gloved finger over the wound until a greasy feeling is replaced by a squeaky friction sensation, indicating removal of the phenol. There should be no gross loss of nail groove tissue or matrix observed after the cautery; the tissue will merely appear gray and dry.

After chemical treatment, the area is inspected for any remaining cauterized cuticle or dead skin, which is snipped away with tissue scissors. The wound is dressed with an antibiotic ointment, Adaptic (or other nonadherent dressing), small gauze pads, and tape or Kling wrap. If a Tourni-cot or other tourniquet has been applied, it must be removed before or immediately after application of a dressing. The Tourni-cot device is released by cutting its narrowest groove. Some clinicians prefer to remove the tourniquet prior to application of a dressing, thus avoiding the potential for a tourniquet to be left in place under a dressing. Removing the tourniquet immediately after application of a dressing permits the dressing to be placed on a bloodless field. When significant underlying infection is present, a wound check is appropriate in 24 to 48 hours.

Postoperative care includes twice-daily scrubs, antibiotic ointment, and dry dressing changes for several weeks. Oral antibiotics generally are not required unless the patient is immunocompromised. The early wound will display red, moist granulation tissue. Wound drainage is often present for the first 2 weeks and appears clear and straw colored. A dry scab will remain in the wound of the uneventful phenol correction for 1 month and may need to be debrided if there is a complaint of tenderness persisting in the former ingrown corner of the nail fold.

This surgery is approximately 90% to 95% successful in preventing lateral nail regrowth after partial removal. In addition to nail regrowth, infection and postsurgical foreign body reaction to remaining cuticle or nail may occur. An inclusion cyst may also form around the nail remnants, and curettement of the nail groove and posterior nail fold may be necessary.

**Total Toenail Removal**

The entire nail is sometimes removed when there is extensive infection with medial and lateral symptoms. If infection has been present for >1 month, osteomyelitis should be considered and digit radiographs obtained. Periosteal abnormalities limited to the affected digit suggest concurrent osteomyelitis and warrant consultation with an orthopedist or podiatrist. The presence of osteomyelitis is not a contraindication to nail removal when removal is otherwise indicated. The patient should be warned that osteomyelitis is possible despite normal radiographs, especially if the toe still has a generalized ache or swelling after the nail has healed. With significant evidence of infection or in an immunocompromised patient, a wound culture should be obtained from the nail fold after nail removal and a sensitivity test performed.

The digit is prepared in a fashion similar to that used for partial nail removal. The Tourni-cot or digital tourniquet is applied. Rather than splitting the nail, the open arm of a small hemostat is placed under the nail with the toothed surface upward toward the nail. The hemostat is pushed straight back toward the proximal nail fold while elevating pressure is kept on the arm of the hemostat to avoid tearing the nail bed as the instrument is forced proximally. The hemostat is similarly inserted in bordering zones beneath the nail plate until the toenail is completely loosened from side to side. An alternative method is to insert a small straight hemostat sideways beneath the central nail plate and open the hemostat repeatedly. After the nail is removed, all debris is curetted, and the entire nail bed is treated with phenol as outlined above, concentrating on debriding the area beneath the posterior nail fold. The phenol solution is flushed from the wound after the third treatment, as previously discussed. Postoperative care and complications are similar to those for partial nail removal.

# Chapter 55 - Trigger Point Therapy

**Anders E. Sola**

Myofascial pain is probably the most common pain problem faced by physicians. [1] It may be the primary complaint or a crippling adjunct to other problems, and it is often accompanied by local or generalized fatigue. Unless it is properly diagnosed and treated, persistent symptoms haunt patients and often result in misdiagnoses, unnecessary pain, and debilitation.

Treatment of myofascial pain is an effective way of sorting out pain problems. Elimination or reduction of myofascial pain often unmasks other painful disorders and therefore is useful diagnostically. Myofascial pain is a common complaint in the emergency department, and affected patients often present with torticollis, headache, or lower back pain. Highly localized, exquisitely sensitive areas, usually found within or near the painful region, are recognized as a common feature of myofascial pain. Pressure on these areas, known as *trigger points* (TPs), causes local pain, referred pain, or both.

The local or referred pain associated with TPs may not follow segmental neurologic patterns and therefore may not occur with a well-defined dermatome distribution. Actions taken at TPs, such as application of heat or cold, electrical stimulation, injection with local anesthetic or saline, or simply stimulation of the sensitive point with a needle, have proved that TPs are, in many cases, the key to control of the painful experience. [5] A somewhat similar needling effect is associated with acupuncture points (many of which are located in areas in which TPs are commonly found). The exact mechanisms by which TPs are involved in and contribute to myofascial pain, as well as the response to intervention at TPs, indicate a continuous, cyclic relationship between TP activity and the pain phenomenon.

## BACKGROUND

### Mechanism

The TP phenomenon has its western origin in Germany, the Scandinavian countries, and Great Britain (the "rheumatic" countries). [10] [11] The Germans first reported on these painful muscular problems ("Muskel schmerzen") and "hard muscles" in the mid-19th century. Most of the investigations were directed at the microscopic findings of these hard nodules, or so-called *rheumatic lesions of muscle.* These sensitive areas in muscle caused local pain or tenderness on palpation with or without a predictable pain reference away from the local point of maximal tenderness. The British were unable to identify faulty microanatomy or pathophysiology with these elusive pain problems, commonly referred to as *fibrositis, myalgia,* or *nonarticular rheumatism.* Gower introduced the term *fibrositis,* [12] and it became fixed in the English literature when Llewellyn and Jones's massive text was published in 1915.

Travell described TPs caused by acute or chronic overload of a muscle as a palpable, firm, tense band in the muscle. The TP is characterized by a local twitch response to tapping of the muscle, restricted range of motion, weakness without atrophy, and no sensory deficit. Subjectively, patients complain of pain in a predictable pattern, stiffness and fatigue, and deep tenderness at the TP. [14]

In addition to muscular overload, a variety of stress-inducing stimuli--emotional or physical--may be implicated in the onset of myofascial pain (Fig. 55-1) (Figure Not Available) . The power of these stressors to induce pain in a particular individual is moderated by the genetics, personality, conditioning, and physiologic state of that individual. Recurrent injuries in a specific location may sensitize the tissue to development of a TP and discomfort out of proportion to the most recent insult. [15] This "injury pool" concept is consistent with current theories of pathophysiologic pain.  Once established, however, a painful event may sustain itself in spite of control or elimination of the initiating stimuli through a characteristic internal cyclic process of self-stimulus and response. Furthermore, the painful TP itself may become the stressor that involves other muscles in the event. Thus, TPs may act both as translators of stress to pain and, secondarily, as stressors that perpetuate pain.

While the exact physiologic mechanism of TPs is unknown, TPs may be "weak points" within the muscle or fascia that are particularly sensitive to stress-induced change. In the absence of stress, the TP may remain quiescent, only to become activated by a number of positive-feedback cycles that involve sensory motor reflexes, autonomic responses, vascular changes, and numerous other ill-defined events that ultimately lead to muscle tension, fatigue, and pain. [14] Hence, the resultant pain can be more intense, out of proportion, or of a longer duration than anticipated for the recent injury.

Both myofascial pain syndromes and fibromyalgia syndrome can be associated with painful TPs. While fibromyalgia is considered a form of nonarticular rheumatism and is associated with diffuse musculoskeletal involvement (multiple bilateral TPs), the myofascial pain syndrome is considered a regional pain syndrome associated with TPs. [20] While these conditions overlap somewhat and clinicians debate their definitions, most agree that TPs of recent onset associated with unilateral tenderness or referred pain are most amenable to therapy.

**Distribution**

A TP can occur in any muscle or muscle group in the body. Since the stresses involved in the onset of myofascial pain can commonly affect not only single muscles, but also entire muscle groups, TPs tend to cluster. In the upper trunk, a common TP cluster involves the muscles of the neck and the shoulder area--the trapezius, the levator scapulae, and the infraspinatus. In the lower trunk, an often-involved group of muscles consists of the quadratus lumborum, the gluteus medius, and the tensor fascia lata. As individuals age, there is an increase in the potential for nerve root irritation problems and subsequent pain, as suggested by Gunn.  Although nerve root irritation cannot be resolved by treatment of TPs, myofascial disturbances that may arise as a result of the

irritation may be reduced through such treatment. [22]

Painful TPs in a given muscle often affect all other muscles innervated from the same spinal segments. Therefore, the search for TPs and subsequent treatment is usually directed at those muscles innervated by *both* the *posterior* branch of the spinal nerves and the *anterior* spinal branch (Fig. 55-2) . Pain may be felt in a muscle innervated by an anterior spinal nerve, whereas little or no pain may be initially felt in the erector spinae muscles innervated by the posterior branch of the same spinal nerves. Palpation of the erector spinae muscles, however, may reveal evidence of active TPs: hypersensitive areas or, more importantly, a tight band-like local spasm plus hypersensitivity.

Although TP pain can be bilateral, it is frequently seen on 1 side. Besides pain in the muscles of the anterior and posterior branches of a specific segmental spinal nerve, there may be pain in the common musculature for several spinal segments above and below innervation of the major TP and in even more remote muscle groups. Thus, muscles in the erector group in the cervical area can be the source of noxious impulses that give rise to headaches (including migraine attacks) and can cause pain to be transmitted as far as the midthoracic area.

Common TPs abound in the lower trunk, gluteal muscles, abductors and adductors of the thigh. Their presence in the gluteal or lumbar muscles may often be related to hypersensitivity in the muscles of the upper trunk group. Therefore, a patient who is suffering muscle tension headaches on 1 side should be checked not only for TPs in the ipsilateral upper trunk muscles, but also for hypersensitive areas (TPs) in the gluteal and lumbar musculature (Fig. 55-3) . If TPs are found, they should be treated to reduce both the hyperactivity in the lower segment and the sensitivity of the upper muscle group. If hyperactive TPs are ignored in the lumbar and (especially) the gluteal region, treating only the cervical TPs can precipitate a painful low back

spasm. This may be severe enough to cause another trip to the emergency department.

**Therapy**

In 1937 Kraus published an innovative study on the use of ethyl chloride spray to relieve myofascial pain. [24] Travell and Rinzell subsequently identified common pain patterns and emphasized the use of procaine injections and the coolant spray Flouri-Methane (Gebaur Chemical Company, Cleveland, Ohio), instead of the more dangerous ethyl chloride.  Jaeger and Reeves quantitated clinical improvement with the "stretch and spray" technique. [26]

Travell and Rinzler also demonstrated that dry needling of the TP could bring relief. Sola and Williams discovered that normal saline injections could relieve myofacial pain. [27] In fact, Kibler found little difference in effect between type of anesthetic or amount and concentration of anesthetic injected into TPs. [28] Frost and colleagues, in a double-blind comparison of local anesthetic (mepivacaine) and saline injections, found that saline produced more consistent pain relief of longer duration. [29] However, Hameroff and colleagues found bupivacaine and etidocaine to be superior to saline

injection.  Interestingly, the immediate analgesia produced after TP injection can be reversed with IV naloxone.

Lewit postulated that injection therapy is most effective when an intense pain is produced at the exact site of maximal tenderness. [32] While sounding like torture, this brief "shot of pain" reduces TP pain in >80% of cases and provides persistent relief for months or even permanently in about 50% of cases.

## PATIENT PROFILE

All parts of the musculoskeletal system are susceptible to myofascial pain syndromes. The patient presents with localized or diffuse pain ranging from intense, burning, and debilitating to dull and bothersome. The affected areas are often described as stiff, heavy, or numb. The pain frequently affects a joint, and range of motion may be inhibited.

Many patients attribute their symptoms to overuse of muscles, sitting in drafts, or a "cold" in the muscle. Physical examination fails to elicit any sensory deficits or atrophy, although there may be some weakness of involved muscle groups. Thorough examination of the affected areas may reveal edema, coolness in an affected extremity, or exaggerated pilomotor reflexes.

In sedentary populations, TPs are common and are usually associated with chronic strain and stress. They tend to occur with great regularity in the same anatomic areas. In my clinical experience, TPs are less common in laborers and athletes and, when present, are usually the result of overuse or injury rather than chronic strain or stress. This suggests that regular exercise is of therapeutic value in prevention, as well as treatment, of myofascial syndromes, which start at an early age. Conversely, the presence of TPs inhibits the effectiveness of a well-designed exercise program.

Patients with prolonged or complicated myofascial pain syndromes may present to the emergency department after unsuccessful attempts to achieve relief from their symptoms. They may have consulted numerous physicians, chiropractors, or both; tried home remedies or vitamin therapy; or received treatment with a variety of muscle relaxants, anti-inflammatory medications, or potent analgesics. Their symptoms may have been diagnosed vaguely as overuse injuries, chronic bursitis, arthritis, or sciatica, or they may have been dismissed because there were no radiographic or laboratory confirmations of their complaints. Many patients labeled as "chronic complainers" have myofascial syndromes that, when treated, result in reduced symptomatology.

Younger patients are more responsive to TP injection than older individuals. In younger patients, TPs are more easily located and are less complicated in their pain referral patterns. As people age, muscle weakness and shortening and the effects of degenerative processes frequently confuse the pain referral pattern. Furthermore, patients seen in pain clinics tend to have more associated depression and less frequently have a medical explanation for their pain than patients seen in private

practice.

# EXAMINATION FOR TRIGGER POINTS

Any treatment of myofascial syndromes must be preceded by a history and physical examination to rule out other causes of apparent myofascial pain. Once this is accomplished, a systematic search for TPs is carried out, with special emphasis placed on the painful muscles and their segmental associates.

Suspected TP areas should be compared with their contralateral counterparts as a guide to their relative sensitivity. There are 4 general patterns of TPs [15] :

1. A single TP with minimal sympathetic involvement.
2. Clusters of TPs within a muscle group with segmental involvement (e.g., TPs isolated to cervical muscles).
3. Combined upper and lower trunk syndrome (e.g., ipsilateral TPs in both cervical and lumbar muscle groups).
4. Diffuse bilateral TPs--usually with extensive involvement of hyperanalgesic paraspinal skeletal muscle tissue. This pattern is often associated with "abnormal" or neuropathic pain. [22]

The most reliable method of locating TPs is by searching in the painful area with the tip of the finger. Pressure applied to the hypersensitive area in the muscle reproduces or accentuates the pain. This is usually accompanied by an involuntary "wince" by the patient. The hypersensitive area may feel rope-like, indurated, or tight, depending on which muscle is examined. The muscles should be examined in both relaxed and stretched positions. Although there may be a halo area or a surrounding zone of tenderness, one should search for the area of maximal tenderness or response.

It is helpful to mark the point of maximal tenderness with a pen and then repeat the search, varying the palpation. Variability in the site of maximal tenderness speaks against a true TP. If several areas of exquisite tenderness are found, it is important to treat the most sensitive point first.

Although the pain referral pattern may help to isolate the hypersensitive area, one should remember that the pattern differs according to severity and longevity of the TP injury, body build, state of health, gender, and degree of injury or weakness.

When searching for TPs, one should carefully examine the entire area of all muscles that may be involved. For

example, in treating torticollis, one should check the levator scapulae, trapezius, sternocleidomastoid, and posterior strap muscles (supplied by the posterior spinal ramus), especially the splenius and semispinalis muscles. The muscles are often innervated from many vertebral segments--for instance, innervation of the splenius starts at the C2 vertebral level and reaches to the midthoracic level. Thus, hypersensitivity at one level may readily involve other muscles with overlapping

segmental innervation. When treating neck pain problems, one must look for tender TPs along the entire spinal insertion of these muscles. The same principle of extended search is also important in the treatment of myofascial shoulder pain and headache pain. A common finding is an ipsilateral pattern involving cervical shoulder, lumbar, and gluteal muscles. The patient frequently complains of symptoms on 1 entire side of the body. When headache or neck pain is severe, often the patient is aware of stiffness, discomfort, or pain in the hip area.

## INDICATIONS AND CONTRAINDICATIONS

Local treatment of sensitive TPs is often quite effective for pain relief when the TP is the primary source of myofascial pain. Such treatment may reduce pain and speed recovery at sites of trauma in the same segment. Treatment of TPs that result from specific painful stimuli, such as nerve root lesions and nerve compression, is never more than moderately successful in relieving pain. Nonetheless, it is often difficult to ascertain the source of the stress that leads to the myofascial involvement until TP therapy has been tried. Therefore, in many cases the response to TP therapy may be valuable diagnostically.

The use of a vapocoolant for "stretch and spray" is contraindicated in the setting of cold hypersensitivity. Contraindications to injection treatment include the presence of a systemic illness (especially with fever), bleeding diathesis or anticoagulant therapy, cellulitis overlying the area of planned injection, high anxiety or emotional stress levels (including "needle" anxiety, manifestations of psychosis, and abuse of drugs or alcohol), and a history of hypersensitive or syncopal reactions to injections. If there is significant doubt concerning the diagnosis of myofascial pain caused by TP involvement, as opposed to such possible causes as a nerve root lesion, one should postpone injection therapy until other causes have been ruled out. Finally, injection of TPs should be avoided when malingering is suspected. Although the possibility of injection treatment may discourage some malingerers, it is less effective as a screening tool than acute observation of the "too-perfect" account of symptoms often given by such patients.

## EQUIPMENT

TPs may be treated with needling, injection therapy, or "stretch and spray" techniques. Little equipment is necessary for the injection procedure. A simple tray may contain a 5-mL syringe, a 25- or 27-ga needle, an antiseptic preparation, and a local anesthetic (1% lidocaine, 0.25% bupivacaine, or 1% procaine hydrochloride) or physiologic saline for injection. Some physicians use a repository corticosteroid preparation (e.g., 0.1 to 0.2 mg dexamethasone per 10 mL saline solution). [23] The stretch-and-spray technique uses a vapocoolant. Ethyl chloride (a volatile anesthetic agent) and fluorimethane spray have been used for this purpose.

## GENERAL PROCEDURE

**Injection Therapy**

Injection of the hypersensitive TP often provides dramatic pain relief. A body of evidence indicates that at least a portion of the benefit is derived from needle stimulation of the TP, regardless of the substance injected. [32] Although local anesthetics are often used, I have used normal physiologic saline for many years, with good results. [27]

Patients with marked pain and mild to moderate anxiety may benefit from an oral anxiolytic 30 to 60 minutes prior to therapy (e.g., 5 mg diazepam). When injection therapy is performed in the emergency department in patients with moderate to severe pain, the supplemental use of a local anesthetic may provide more immediate relief, although good results have been obtained, even in cases of severe pain, with saline injection alone. Some clinicians routinely inject small doses of a long-acting steroid preparation into painful TPs in conjunction with saline or a local anesthetic. Although steroids are of proven value in the treatment of inflammatory conditions, their role in TP therapy is unknown.

Prior to TP injection, the therapeutic plan and rationale should be explained to the patient. In particular, it is important to explain why the TP, rather than any site of pain referral, will be treated. It may be necessary to apply pressure over the TP to reinforce the need to treat the TP. It is wise to perform injection with the patient placed in a supine position to minimize vasomotor syncopal reactions. If the upper back, neck, or shoulder is being injected, a pillow is placed under the hips to rotate the trunk.

The hypersensitive point is located by palpation (with the affected muscle relaxed), and the area for injection is prepared in the usual manner. The point of entry should be in the area of maximal tenderness. One inserts the needle and aspirates to confirm a nonvascular site. If severe cramping pain or paresthesia occurs, suggesting nerve penetration, the needle should be repositioned. After proper positioning, inject 0.5 to 2 mL of fluid using a "fanning" technique, in which the needle is repeatedly withdrawn part of the way and redirected (Fig. 55-4) . This ensures maximal coverage of the area of the TP. Each TP is treated in this fashion. Generally, no more than 20 mL of saline total (for all sites combined) should be injected per day. Response to the injection should be observed within 10 minutes.

In most cases a short series of 2 to 5 injections of symptomatic TPs over a period of days to weeks is enough to treat myofascial pain caused by muscle strain or injury. After injection, a warm moist pack applied to the area relieves the temporary discomfort of the injection.

Follow-up treatment for patients with myofascial pain may include 1 or more of the following: repeated injection therapy; adjunctive physical therapy; and other special techniques, including intermittent cervical or lumbar traction, relaxation techniques, ultrasound, electrical stimulation, massage (especially deep friction), application of coolant sprays or ice packs, and, routinely, therapeutic exercise. Should the patient not respond to a brief course of TP therapy, suspicion for other structural phenomena should increase.

**Stretch-and-Spray Therapy**

The stretch-and-spray therapy technique [5] [34] seems most helpful for mild cases of myofascial pain syndromes. The patient is first informed of the therapeutic actions to be undertaken and informed as to why the therapy is directed to the TP rather than any pain referral zone. This can be reinforced by applying pressure to the TP. The expectation of some rebound pain exacerbation following treatment (see above) also can be discussed at this time.

The patient is placed in a comfortable position with the affected anatomy supported and the involved muscles relaxed. The vapocoolant is sprayed on the skin overlying the affected muscle TP, using a fine spray with the bottle approximately 45 cm from the skin. The spray is directed at an angle of 30° onto the skin overlying the TP. The spray is moved (in 1 direction) toward the zone to which any referred pain was previously noted. After a few initial sweeps of the spray over the referral zone, a warm moist compress is applied over the sprayed area to help relax the muscle. The affected muscle is then passively stretched with enough force to elicit pain and discomfort, followed by continued stretch with concurrent spray (Fig. 55-5) (Figure Not Available) .

As the spray is continuously applied over the muscle, progressive passive stretch is applied to the muscle. The spray is applied repeatedly in 1 direction, moving from the TP to the referral zone using slow, even, parallel sweeps over the entire muscle at a rate of about 10 cm/sec. This process is repeated 4 times, avoiding freezing of the overlying skin. After therapy, the patient is asked to perform a few sets of 5 repetitions demonstrating active range of motion with the treated area. The patient is given instructions for stretching and active range-of-motion exercises at home. Moist heat applications prior to these home activities may be helpful for some patients.

## COMPLICATIONS

Some patients are hyperreactors. These individuals may experience a vasomotor response with even a small injection of saline and may have an excessive flare-up of pain after treatment (generally within 24 hours, most commonly within 6 hours). Seated patients are more likely to faint than those kept supine. Those patients with an allergy history (e.g., allergies to foods and drugs and sensitivity to the sun), fair-skinned redheads, albinos, or blue-eyed blondes are more likely to faint. I monitor patients during injection therapy using the back of my hand, touching their skin to detect excessive sweating.

If complications occur, one should stop injecting. Some physicians inject as much as 5 to 10 mL of fluid at a given TP. I have found that this volume is excessive. The patient frequently develops a flu-like syndrome, characterized by malaise and myalgias, the next day. I have experienced few complications using saline with a normal pH. The use of local anesthetics, a standard procedure in emergency departments, slightly increases the risk of "-caine" allergies. However, the risks of excessive drug administration and IV

injections also are increased when local anesthetics are injected.

Particular care must be used when injecting the neck, the intercostal muscles, and the periscapular area, because these areas contain many large vessels and nerves, and the pleura is in close proximity to the injection sites. This risk is greatest if the patient is agitated or confused. Generally, TP injection should be avoided in the latter situations.

Ethyl chloride vapocoolant spray is highly volatile. Electrical sparks and flames should be avoided during its use. The agent also has general anesthetic properties and should be used in a well-ventilated room to avoid patient or operator toxicity.

# EMERGENCY DEPARTMENT TREATMENT OF COMMON PRESENTATIONS OF MYOFASCIAL PAIN

### Shoulder Disorders

A painful shoulder will frequently have TPs located in the posterior scapular muscles. Other muscles that are often involved include the supraspinatus, the infraspinatus, and the pectoralis major. Less commonly, the teres, the deltoid, and the triceps are involved. Some TPs in the splenius, the semispinalis, and the gluteal muscles also may contribute to shoulder pain and should be treated if found in conjunction with myofascial shoulder pain. Such pain often prompts the misdiagnosis of "bursitis." Patients may have had numerous prior unsuccessful treatments with muscle relaxants and potent anti-inflammatory medications.

When injecting the scapular and periscapular muscles, one should take extreme care to stabilize the scapula. The patient should lie on a bed with the arms along the sides and a pillow under the chest to round the shoulders and facilitate injection. A small pillow may be used to rest the forehead. The scapular boundaries (borders) should be noted before injection, and the patient should be warned not to move the shoulder. If the lower portion of the scapula moves, one can easily miss the muscle and pierce the pleura. Therefore, one should "fix the scapula" before injecting and should always double-check the anatomy. I frequently hook my thumb on the medial border while injecting TPs in the infraspinatus muscle. Myofascial pain is commonly associated with a number of muscles at the medial border of the scapula. These include the rhomboids; the serratus anterior; the subscapular muscles; and, at the superior edge, the levator scapulae muscle. It is best to inject the levator at an oblique angle to the muscle (nearly parallel to the thorax), because patients frequently flinch during injection, and the needle could puncture the pleura.

If the TPs are on the lower medial border, then the patient should place the hand behind the back. This causes a "winging" of the scapula, allowing easier and safer injection. A tangential laterally directed needle reaches much of the scapular undersurface (Fig. 55-6) . The rhomboids and the serratus anterior are easily treated with this maneuver. On occasion, the subscapularis muscle is involved, and the only complaint besides poorly localized scapular pain may be a sensation of "sleeping on a marble." When injecting along the lateral border (teres major and minor and latissimus dorsi), the

clinician should fix the scapula and warn the patient not to move.

## Headaches

Commonly, TPs contribute the muscle component of most headache syndromes. These TPs are usually found in the sternocleidomastoid, levator scapulae, and trapezius muscles and, not infrequently, in the scalp and facial muscles. In addition, the posterior strap muscles are often involved, particularly the semispinalis and splenius muscles (Fig. 55-7) (Figure Not Available) . When preparing to treat a patient with headache, one should carefully examine the entire back for hypersensitive areas, paying special attention to the thoracic paraspinal muscle group. These thoracic TPs are frequently associated with migraine as well as muscle tension headaches. As previously discussed, TPs located in the quadratus lumborum and the gluteus medius also may contribute to headache problems. These muscles seem to have particular significance if the headache is unilateral. When found, they should be treated concurrently.

## Back Pain

Unilateral back pain is usually responsive to TP injection. TPs are most commonly found in the quadratus lumborum, gluteus medius, and tensor fascia lata muscles. Hip pain caused by gluteal TPs may mimic trochanteric bursitis. Sciatica, by far the most frequently diagnosed back pain syndrome, is commonly caused by gluteal TPs (Fig. 55-8) (Figure Not Available) . In addition, ischial and sacral iliac syndromes may be seen.

The lumbosacral muscles are commonly involved in lower back pain. Here the TPs are frequently secondary to vertebral or nerve root irritation or spondylosis, which can cause neuropathic pain. Treatment of TPs may be of only temporary benefit. However, deep paraspinal (lumbar/thoracic) and hamstring muscle TPs are often overlooked. Nonetheless, if no better after a short course of TP treatment, affected patients should be referred for further evaluation and treatment of possible neuropathic pain. Back pain patients have many options other than TP therapy that should be considered before surgery. [35]

## Torticollis

Torticollis usually is a simple problem involving 1 to 3 muscles. The trapezius, sternocleidomastoid, and levator scapulae are the main offenders. A careful search of the posterior strap muscles, however, may reveal exquisite tenderness of the splenius and semispinalis muscles. If the trapezius is involved, particular care must be taken with the injection technique (Fig. 55-9) (Figure Not Available) .

The apical pleura in some individuals is much higher than normal. If there is a sudden upward flinch of the shoulder during injection, the pleura could be punctured. If possible, one should inject transversely, with the TP located between index finger and thumb.

**Somatic Visceral Reflex Phenomenon**

Skeletal muscle TPs may contribute to visceral pain by induction or continuation of spinal reflex arcs. Visceral sympathetic afferents converge on the same dorsal horn neurons as somatic nociceptive afferents. Reflex sympathetic efferent activity may result in spasm of visceral sphincters as well as of cutaneous nociceptors (leading in part to referred cutaneous pain). The rectus abdominis muscle is particularly prone to TP development in conjunction with visceral pain. Right upper quadrant TPs can be seen with gall bladder disease; left upper quadrant TPs can be seen with esophageal and ulcer disease, right lower quadrant TPs can be seen with dysmenorrhea, and left lower quadrant TPs can be seen with intestinal disorders.

While a full discussion of this phenomenon is beyond this text, treatment of abdominal wall muscle TPs can provide significant somatic and visceral pain relief in appropriate patients. Therapy for abdominal wall TPs should be considered when they are identified and when TP palpation or placing the muscle under tension (e.g., performing sit-ups) produces characteristic visceral discomfort. Painful abdominal TPs also are accompanied by TPs in the posterior paraspinal muscle segment. These TPs must be treated along with the abdominal muscle TPs. Esophageal spasm is often associated with TPs on the left posterior thorax at levels T3 through T6.

Visceral discomfort that persists following TP therapy warrants further diagnostic evaluation. Somatic and visceral pain differ in the following aspects:

> Somatic pain tends to be well localized and generally follows the distribution of somatic nerves, whereas visceral pain is more diffuse.

> Somatic pain is sharp and definite, whereas visceral pain may be dull and difficult to describe.

> Somatic pain is reproduced by external stimuli, whereas visceral pain is not, but may have associated referred pain or symptoms (e.g., nausea, vomiting or diaphoresis).

## SPECIFIC MUSCLE SYNDROMES

Some of the muscles that are commonly involved in pain problems are listed in the following paragraphs. Although the pain referral sites are fairly consistent, they may differ because of involvement of more than 1 muscle. Figures 55-7 (Figure Not Available) through 55-16 (Figure Not Available) demonstrate common TP sites and common pain referral zones (inserts).

**Infraspinatus**

Because of its multiple functions, this muscle is subject to earlier degeneration than

other muscles of the rotator cuff and therefore is more vulnerable to TPs in association with many types of shoulder lesions. The TPs in the infraspinatus invariably cause sympathetic hyperactivity and may be a major contributor to dystrophy-like syndromes of the upper extremity (Fig. 55-10) (Figure Not Available) . Careful palpation is necessary to locate TPs. It is useful to search the entire muscle along the length of the muscle bundles as well as across the "grain" of the muscle. Related pain is usually located on the posterior and lateral aspect of the shoulder and occasionally may return to the anterior chest. All of the scapular muscles are frequently involved, either singly or in concert with each other.

## Levator Scapulae

Painful sensitive foci may occur at the origin on the superior medial aspect of the scapula, along the entire flat muscle belly, or on the insertions on the transverse processes of the first 4 cervical vertebrae (Fig. 55-11) (Figure Not Available) . Invariably, the levator scapulae muscle is involved in chronic cervical conditions as well as in torticollis. The pain is usually referred to the posterior cervical region, the posterior scalp, and the area around the ear.

## Quadratus Lumborum

This muscle is a hip "hiker" and a lateral flexor of the spine; in addition, it assists respiratory function by anchoring the 12th rib for the pull of the diaphragm. It frequently signals its distress on deep inspiration with 12th-rib pain. Pain can be local or referred to the anterior abdominal wall. These TPs may accentuate postoperative pain or painful abdominal scars over the lower quadrant. TPs occur on the 12th rib, on the iliac crest, and along the lateral border of the entire muscle (Fig. 55-12) (Figure Not Available) .

## Gluteus Medius

TPs in the gluteus medius may well be the most critical TPs in the lower extremity. Like the infraspinatus, the gluteus medius is associated with sympathetic hyperactivity. Activity of these TPs often involves activation of TPs in the quadratus lumborum, the tensor fascia lata, and the other gluteal muscles, thus inducing widespread lower back discomfort (see Figs. 55-8 (Figure Not Available) and 55-12) (Figure Not Available) . There also is an interaction between the TPs of the gluteus medius and those in the cervical area, sometimes involving this remote muscle in cervical pain and headache. Although this muscle seldom causes pain without involving other muscles, the pain pattern most often attributed to the gluteus medius is along the iliac crest and into the posterior thigh and calf. It is a frequent cause of hip pain in the later stages of pregnancy and simulates sciatica. TPs most commonly are found along the iliac shelf, and with extensive involvement, the entire gluteal ridge (including also the gluteus minimus and maximus muscles from the sacroiliac joint to the anterior superior spine) may contain painful TPs. It is estimated that 10% of people have legs that differ in length by at least 1 cm. This difference can cause unilateral back pain and TPs of the gluteus, erector spinae, and quadratus lumborum muscles.

### Tensor Fascia Lata

This muscle is easy to examine, and it is also easy to locate the common TPs that are present in the muscle belly. Pain is usually referred to the lateral aspects of the thigh as far as the knee (see Fig. 55-8) (Figure Not Available) .

### Anterior Tibialis

Pain in the anterior ankle is usually experienced when the TPs of this muscle flare up, although in severe cases the entire muscle may be painful. These TPs are most commonly found in the upper one third of the muscle, and pain is referred to the anterior portion of the leg and into the dorsal portion of the ankle (Fig. 55-13) (Figure Not Available) .

### Gastrocnemius/Soleus

Myofascial pain related to this muscle group is felt behind the knee, over the muscle bellies, and along the Achilles tendon near the heel. The TPs are usually found on the medial and lateral margins of the muscle group and along the midline of the group. These TPs often flare up when a patient is experiencing vascular problems of the lower extremities. One report has suggested injecting these TPs for the relief of pain associated with intermittent claudication. [39] The pain is referred to the Achilles tendon and the heel (Fig. 55-14) (Figure Not Available) .

### Splenius Capitis/Semispinalis Capitis

Pain resulting from involvement of these muscles may be located over the muscles themselves. Both the splenius and the semispinalis can mediate pain to the head and the face, however, and both are commonly involved in headache. Occasionally, dizziness accompanies involvement of these muscles. Because TPs are difficult to pinpoint in these muscles, patient cooperation in pointing out positions of maximal tenderness is extremely helpful (see Fig. 55-7) (Figure Not Available) .

### Rectus Abdominis

These muscles are frequent sites of anterior abdominal wall pain. The TPs are best located with the patient in the supine position and with the head and neck flexed so that the abdominal rectus muscles are under tension. These TPs frequently flare up after abdominal surgery and can be one of the chief constituents of postoperative pain. The TPs are most commonly found in the upper 3 segments of abdominal rectus muscle, and the pain is usually localized over the muscle (Fig. 55-15) (Figure Not Available) . The lower segments also are associated with low back problems, and the posterior spinal segments L4-L5-S1 also must be treated.

**Pectoralis Major/Pectoralis Minor**

The pectoralis major muscles are a frequent site of myofascial pain in the area of the muscle insertion on the anterior medial shoulder. The inferior belly of the muscle is a common area of TPs; however, the entire muscle must be searched diligently. The clavicular portion of this muscle usually refers pain to the uppermost part of the muscle. On occasion, there is some referral into the arm (see Figs. 55-15 (Figure Not Available) and 55-16) (Figure Not Available) .

**Intercostals**

One should routinely examine the intercostals for chest pain by palpating the intercostal spaces with the fingers. The intercostals are frequently involved after any chest surgery or trauma. In treating chest pain when intercostal blocks are not successful, one must take care on injection to avoid entry into the pleural space. Pain from the exterior intercostal muscle is usually localized near the site of the TP and is emphasized during inspiration (see Fig. 55-16) (Figure Not Available) .

**Trapezius**

The trapezius is a frequent source of muscle pain and headache, especially at the angle of the neck or at the occipital insertions of the muscle, where TPs are most commonly located. When injecting TPs at the angle of the neck, one must take care to avoid the apical pleura (see Fig. 55-9) (Figure Not Available) .

**Sternocleidomastoid**

This muscle is often the source of neck pain and headache. In addition, dizziness and ipsilateral ptosis, lacrimation, and reddening of the conjunctiva have been reported in association with involvement of these muscles. [40] These TPs are most commonly located at occiput insertion in the upper two thirds of the muscle and frequently on its sternal and clavicular origins. The pain pattern may involve the muscle or may refer to the ear region, the face, or the frontal area (see Fig. 55-9) (Figure Not Available) .

## CONCLUSION

In summary, TPs may be involved in any painful event. They may play either a primary role (translating stress to pain) or a secondary role (supporting and intensifying a painful stimulus). They can complicate any type of pain and may mimic underlying visceral disorders. Obviously, interventions that directly affect the TP have a much greater chance for complete pain control if the TP is acting in the primary role of translator than if it is acting in the secondary role of pain intensifier. Even in the secondary role, however, there is the potential for benefit from properly administered treatment. The importance of TP therapy for differential diagnosis cannot be overemphasized.

Stretch-and-spray techniques, injections of local anesthetics, injection of saline solution, and dry needling are all useful in treating TP pain syndromes. However, use of local anesthetics is most appropriate when immediate reduction of severe pain is sought. Treatment considerations in addition to TP injection include administration of muscle relaxants, anesthetics, and analgesics; referral for physical therapy; reduction of stress; and prescription of therapeutic exercise following resolution of the event.

# Chapter 56 - Injection Therapy of Bursitis and Tendinitis

**David H. Neustadt**

*Bursitis* and *tendinitis* are terms frequently used to describe a variety of regional musculoskeletal conditions that are characterized chiefly by pain and disability at the involved site. Bursitis of the shoulder may be considered the prototypical disorder. All too often, in ill-defined regional soft tissue rheumatic problems, bursitis or tendinitis is used as a "wastebasket" diagnosis. For purposes of this chapter, in consideration of the accurate diagnosis that is necessary to institute appropriate therapy, the terms are reserved for well-defined, specific clinical entities.

## GENERAL ANATOMIC CONSIDERATIONS OF BURSAE AND TENDON SHEATHS

Bursae are potential spaces or sacs, subcutaneous (subcutaneous) or deep, that develop in relation to friction and facilitate the gliding motion of tendons and muscles. There are approximately 78 bursae on each side of the body. These were well described in the classic atlas of anatomy by Monro [1] in 1788 and were later elaborated in greater detail in the atlas of Spalteholz. [2]

The normal bursal wall is lined with a thin layer of synovial cells that appear to be similar to those of joint synovial membrane when examined by electron microscopy. [3] When a bursa becomes subacutely or chronically inflamed, the normally thin surface of sparse cells may thicken to 1 to 2 mm. The cause of bursitis may be trauma, infection, crystal deposition, chronic friction, or a systemic inflammatory arthropathy. In addition, so-called adventitial bursae may form in response to abnormal shearing stress at sites subjected to chronic pressure; an example is a bunion over the head of the metatarsal bone of the great toe.

Involvement of the synovial lining of bursae and tendon sheaths may also result from underlying systemic diseases, including rheumatoid arthritis, ankylosing spondylitis, psoriatic arthropathy, and gout. The most common bursal lesions in these systemic inflammatory arthropathies involve the olecranon at the elbow and the trochanter region of the hip. Smaller bursae, especially those around the Achilles tendon, also may be affected.

*Septic bursitis* usually affects the superficial bursae, such as the olecranon and the prepatellar regions. [4] Factors that predispose to infected bursae include trauma, steroid therapy, uremia, diabetes mellitus, and alcoholism. [5] Tuberculosis may affect any bursa but is rare, whereas other types of mycobacteria, such as *Mycobacterium kansasii*, are occasionally reported. [6] Another uncommon cause of involvement of superficial bursae and tendon sheaths is sporotrichosis, which can be contracted by gardeners and farmers. In addition, tendon sheaths at the hands, the wrists, and the ankles may be

affected by acute bacterial infections, such as gonorrhea.

*Tendinitis* and *tenosynovitis* are useful terms that describe inflammatory reactions in tendons and tendon sheaths. Tendon sheaths are relatively long and tubular, whereas bursae are round and flat. Except for their shape, however, the structures are similar. Common sites of tendinitis in the body are depicted in Figure 56-1 (Figure Not Available) .

Flexor tenosynovitis ("trigger," or "snapping," finger) is a frequent extra-articular manifestation of rheumatoid arthritis and occasionally may be the presenting symptom.

In *calcareous* (or calcific) tendinitis of the shoulder, there is a calcific deposit in and about one of the rotator cuff tendons (commonly the supraspinatus). The musculotendinous rotator cuff is composed of the supraspinatus, infraspinatus, teres minor, and subscapularis muscles, which insert as the conjoined tendon into the greater tuberosity of the humerus. The bursae in relation to the greater tuberosity and the subdeltoid (subacromial) bursa are the most common sites of calcific deposits. The nidus of the pathologic process is considered to be the calcific deposit (hydroxyapatite) within the substance of one or more of the involved tendons. The process has been likened to a chemical furuncle, or the so-called calcium boil. Calcific tendinitis may be hyperacute or acute, and release of the pressure from the inflammatory edema with rupture into the contiguous bursa (e.g., the subacromial bursae) provides prompt relief.

Bursitis and tendinitis embrace a variety of conditions that may be grouped together on a regional basis for the sake of a simple and convenient classification (Table 56-1)

## RATIONALE FOR STEROID INJECTIONS

The management of pain resulting from bursitis and tendinitis may be greatly enhanced by the proper selection and administration of local injections. Successful application of local injection and intrasynovial therapy requires an understanding of the diagnosis, accurate localization of the pathologic condition, and the appropriate choice of suitable injection techniques. Not infrequently, injections of lidocaine or corticosteroid preparations provide the additional aid that, alone or as an adjunct to the management program, overcomes the refractory pain.

Although local injection intrasynovial therapy is essentially palliative, it may provide striking and lasting relief. Restoration of function may follow a single injection, especially in a self-limited painful soft tissue condition. The precise mechanism of the lasting analgesia and the beneficial therapeutic effects have not been clarified. Explanations that have been considered include induction of local hyperemia, relaxation of reflex muscle spasm, generalized response from systemic absorption, pain relief allowing controlled activity or rest, favorable influence on local tissue metabolism, and mechanical benefit. The increased mobility permitted as a result of pain relief certainly accelerates recovery and restoration of function. Finally, the "power of suggestion" of the needle must not be underestimated (placebo therapy). Some observers believe the

pain relief may result from stimulation and release of the patient's endorphins.

Some physicians prefer to follow local injection with a short course of salicylates, oral corticosteroids, or nonsteroidal anti-inflammatory medications. Others prefer to prescribe simple analgesics and to evaluate the response to injection. In selected cases, short-term splinting or other forms of immobilization are beneficial. Cases must be individualized according to the specific pathologic condition and patient variables.

## INDICATIONS AND CONTRAINDICATIONS

Local injection therapy with corticosteroids or local anesthetics may provide valuable aid in a variety of acute or subacute bursitides and other painful soft tissue conditions. Abolition of symptoms confirms the localization of the involved site or structure, even if the response is not lasting. Visceral disease must be ruled out as a source of referred pain. Appropriate injection therapy is indicated when there are local accessible signs that are likely to respond to direct therapeutic infiltration. Acute localized bursitis or tendinitis warrants immediate direct injection for rapid relief.

Contraindications are relative and include infections, either local or in the vicinity of the site of involvement, and hypersensitivity to any preparation or substance that might be injected. The procedure is also contraindicated in patients receiving anticoagulants or those with any bleeding disorder. The patient with a pre-existing tendon injury may be subject to tendon rupture, which can inhibit full activity when the corticosteroid injection removes pain. Hence, partial tendon rupture is a relative contraindication. [9] Poorly motivated, "needle-shy," and severely neurotic patients obviously are considered poor subjects for this type of treatment. Active

herpes simplex infection and tuberculosis are generally considered contraindications.

## HAZARDS AND COMPLICATIONS

Local anesthetics are often mixed with a corticosteroid preparation to increase volume, decrease postinjection pain, and assess the accuracy of the injection. Local anesthetics may also be used before injection of the corticosteroid. The major hazards in the use of local anesthetics are hypersensitivity and accidental IV or intra-arterial introduction.

Serious (possibly even fatal) hypersensitivity to procaine and other regional anesthetic compounds is encountered very rarely; the possibility is usually suggested by a history of previous reactions. Lidocaine or one of the newer "caine" derivatives may be used to avoid sensitivity reactions to procaine. Bupivacaine is an excellent choice because of its safety and long duration of action. If a past history of a reaction is suggested, one should proceed cautiously and use small amounts of dilute anesthetic solutions. When there is a definite history of sensitivity, it is wise to avoid the use of anesthetic agents during injection therapy.

In the event of accidental IV injection of a "caine" drug or if symptoms of hypersensitivity arise from these compounds (e.g., a significant slowing of the pulse rate, or even a seizure, is an indication of a major reaction to IV administration), a benzodiazepine anticonvulsant, or rapidly acting barbiturates (e.g., sodium pentobarbital) should be readily available and should be given promptly in accordance with the reaction and response (see Chapter 31) . In addition, a clear airway should be maintained, and oxygen should be administered. Severe reactions from accidental vascular injection of these drugs in the doses usually given are very rare.

A repository corticosteroid given IV by accident has been reported. [10] No serious reaction to a depot corticosteroid preparation given IV has been reported. The possibility of an allergic reaction caused by corticosteroids is highly unlikely. However, an unusual skin rash following an intra-articular methylprednisolone injection has been reported that appears to be consistent with a delayed type of hypersensitivity. [11]

Minor reactions occasionally seen after injection of "caine" preparations include light-headedness or dizziness, pallor, weakness, sweating, nausea, and (rarely) fainting and tachycardia. These symptoms usually disappear within a few minutes after the injection and rarely require any treatment except reassurance and a cold compress to the forehead of the patient. Often it is difficult to decide whether the symptoms are the result of sensitivity to the drug or a fright reaction (vasovagal). *The patient should always be in a supine, prone, or reclining position during the injection to minimize the effect of any vasovagal reaction.*

The obvious ways to prevent entering a blood vessel are an awareness of the local anatomy and aspiration after every 1 to 2 mL of solution are injected. Penetration into or striking a nerve may cause sharp pain or paresthesias, and the patient should be warned of this possibility in advance.

Complications are listed in Table 56-2 . Although the possibility of introducing infection is the most serious potential complication, in a review of my extensive experience and that of others, I found that infections occurring as an aftermath of intrasynovial injections are extremely rare.  I do

---

**TABLE 56-2** -- Complications of Injection Therapy

not recommend routine prophylactic antibiotic administration unless the patient has had a significant recent systemic infection. Although the problem of infection is usually avoided with meticulous attention to aseptic technique, the patient should be cautioned to report the development of any significant pain, redness, or swelling after any local injection.

Local undesirable reactions are usually minor and reversible. A postinjection "flare," manifested as a significant increase in pain, may begin within a few hours after steroid injection and usually tends to subside spontaneously in up to 24 hours. Rarely, it can continue for as long as 72 hours. This transient increase in inflammation is considered to represent a true crystal-induced "synovitis" caused by precipitation of the microcrystalline steroid ester suspension. [16] Usually, the reaction is mild and can be adequately controlled with application of ice or cold compresses and analgesics as needed. Rarely, "afterpain" lasting for a few to several hours may occur following injections. Although the cause is obscure, this phenomenon may result from the trauma of needle insertion, penetration of inflamed tissue, or pressure on adjacent nerves from local swelling or bleeding. Afterpain usually is relieved by application of moist or dry heat and analgesics until the pain abates but is best handled by mixing a long-acting anesthetic, such as bupivacaine, with the steroid preparation.

Occasional subcutaneous bleeding at the site of injection may occur with penetration of

a venule, an arteriole, or a capillary. The patient should be warned that this may occur and should be reassured that the discoloration or hematoma will disappear spontaneously. Ice packs or cold compresses applied to the involved area for the first 24 hours are commonly advised.

Another relatively minor complication is localized subcutaneous or cutaneous atrophy at the site of the injection. [8] [17] This problem is chiefly of cosmetic concern and is recognized as a small depression in the skin frequently associated with depigmentation, transparency, and occasionally the formation of telangiectasia. These changes in the skin occur when injections are made near the surface and some of the injected steroid leaks back along the needle track. The skin depression usually recedes and the skin returns to normal with time, when the crystals of the steroid have been completely absorbed. Careful technique (avoiding any leaking of the steroid suspension to the skin surface) prevents this complication. A small amount of lidocaine or normal saline can be used to flush the needle of the suspension before removing it.

The potential danger of "spontaneous" tendon rupture (especially of Achilles tendons) following local corticosteroid injections in the Achilles bursal area must be given serious

consideration. Cautious administration with infiltrations around and beneath the tendons to keep any of the material from entering the substance of the tendon minimizes the occurrence of this complication. In general, *the injection of major stress-bearing tendons*, such as the Achilles and patellar tendons, *should be avoided in the emergency department*. Treatment with oral anti-inflammatory medications and splinting is preferred.

## AVAILABLE PREPARATIONS AND CHOICE OF COMPOUND

Hydrocortisone and a variety of available corticosteroid repository preparations are described in Table 56-3 . Local anesthetics, such as lidocaine or bupivacaine, can be mixed with the corticosteroid preparation in the same syringe. All corticosteroid suspensions, with the exception of cortisone and prednisone, can produce a significant and rapid anti-inflammatory effect (in synovial spaces). Unfortunately, soluble corticosteroids are absorbed and dispersed too rapidly, having only a brief duration of action locally. The tertiary butyl acetate (TBA) ester prolongs the duration of local tissue effect because of decreased solubility. The decreased solubility probably causes dissociation of the corticosteroid by enzymes to proceed at a delayed rate.

No single steroid agent has demonstrated a convincing margin of superiority, with the exception of triamcinolone hexacetonide. Prednisolone tebutate, however, simply by virtue of price advantage and long-term usage, is generally the drug of choice. Triamcinolone hexacetonide is the least water-soluble preparation currently available. Triamcinolone hexacetonide is 2.5 times less soluble in water than prednisolone tebutate, providing the longest duration of action. There is minimal systemic absorption, or "spillover," with this preparation, but because of its high potency and higher cost, it is usually reserved for use in conditions in which prednisolone tebutate or one of the other compounds has shown an inadequate response. Because of the long duration of action and its greater potential for subcutaneous atrophy, some authors use this preparation

only for intra-articular injections.

## DOSAGE AND ADMINISTRATION

The dose of any corticosteroid suspension used for intrasynovial injection must be arbitrarily selected. Factors that influence the dosage and expected response include the size of the affected area, the presence or absence of synovial fluid or edema, the severity and extent of any synovitis, and the steroid preparation selected for injection.

A useful guideline for estimating dosage follows: For relatively large spaces such as subacromial, olecranon, and trochanteric bursae, 20 to 30 mg of prednisolone tebutate or equivalent; for medium- or intermediate-sized bursae and ganglia formation at the wrists, knees, and heels, 10 to 20 mg; and for tendon sheaths, such as flexor tenosynovitis of digits and the abductor tendon of the thumb (de Quervain disease), 5 to 15 mg. Sometimes it may be necessary to give larger doses for optimal response. Intrabursal therapy of elbow (olecranon) or knee (prepatellar) bursae containing considerable fluid may require 30- to 40-mg doses.

Unlike intra-articular injections for synovitis in chronic joint disease, repeat infiltrations for soft tissue conditions such as bursitis and tendinitis frequently are not required. If only a partial response occurs or if recurrence develops, however, a single repeat injection can be given; the length of the interval between injections should not be a source of undue concern. In contrast with intra-articular injections, in which the hazard of "overworking" an injected joint is usually not a problem, following intrasynovial injection we recommend a reduction in activity with rest or splinting of the involved extremity. Limiting motion also delays somewhat the systemic absorption of the steroid. Anecdotal evidence suggests that those patients with inflammatory soft tissue lesions who follow a postinjection modified rest regimen obtain a more rapid and lasting resolution of the painful disorder. Frequency of injections is considered further in the discussion of techniques for the specific entities.

## PREPARATION OF THE SITE

Preparation of the site before injection requires meticulous adherence to aseptic technique. Anatomic landmarks are outlined with a black or red skin pencil. Tincture of iodine

Available as 3 mg acetate, 3 mg phosphate.

or thimerosal (Merthiolate) applied with a sterile swab can be used in place of the skin pencil. The point of entry is cleansed with povidone-iodine (Betadine) and alcohol. Sterile drapes are not generally considered necessary, especially after sufficient skill and experience with the procedure have been acquired. For operator protection, latex examination gloves (nonsterile) should be worn.

## TECHNIQUES

### General Considerations

Materials required for local injection procedures include needles, syringes, and items for

preparation of the injection site. Disposable needles and syringes are convenient and adequate for emergency department use. Special trays may also be stocked for this purpose. The usual sizes of needles for various approaches are as follows:

*Intradermal skin wheal:* 1.3 cm (0.5 inch), 25 ga

*Tendinitis in elbow and shoulder inflammation:* 3.9 to 5.0 cm (1.5 to 2.0 inch), 23 or 25 ga

*Digital tenosynovitis:* 2.2 cm (7/8 inch), 25 ga

*Bursitis with fluid:* 2.5 to 3.9 cm (1.0 to 1.5 inch), 23 to 25 ga

*Deep gluteal bursitis:* 7.6 to 10.2 cm (3.0 to 4.0 inch), 20 to 22 ga

Table 56-4 lists appropriately sized needles for various injection sites.

Once the point of entry has been determined and the site is prepared, either a superficial skin wheal is made with 1% lidocaine (Xylocaine) or 0.25% bupivacaine (Marcaine, Sensorcaine) or the skin is sprayed with a refrigerant such as dichlorotetrafluorethane (Frigiderm). Some physicians do not use a skin wheal when the steroid is mixed with a rapid-acting local anesthetic. Ordinarily, preanesthesia is not necessary, but occasionally, in highly nervous or agitated individuals, it may be advisable to give opioids or benzodiazepines IV or to administer a nitrous oxide-oxygen mixture before beginning the procedure. Thus, an anxiety-provoking injection can be carried out with patient cooperation.

Local injections can be administered with corticosteroids and local anesthetics mixed together in the same syringe. Because the steroid tends to precipitate or layer in the barrel of the syringe during the injection, the syringe should be agitated immediately prior to use to optimize its distribution. The local anesthetic can be given alone. Generally, when injecting synovial spaces, the steroid is introduced without anesthetic, but often syringes are changed, and lidocaine is used to flush out the needle, frequently causing injection and deposition of several milliliters of the local anesthetic. When injecting a painful soft tissue structure directly, it is best to administer a mixture of corticosteroid and anesthetic with the same syringe. This both relieves pain immediately and confirms the accuracy of the injection. The duration of action of lidocaine is approximately 100 minutes, whereas bupivacaine may last for a few hours. The patient should be cautioned that *the local anesthetic effect may "wear off" within a couple of hours* and that *the beneficial effects of the corticosteroid may be delayed*.

The most important aspect of a successful technique is accurate positioning of the needle. The needle must "hit the mark," or the results will be disappointing. Injecting an inflamed synovial space, such as a bursa-containing fluid, may be as simple as puncturing a balloon. Aspiration of the fluid confirms that the needle has correctly entered the sac. On the other hand, direct injection into a painful soft tissue lesion requires additional skill that can be acquired only with experience. When a bursa is

injected, as much fluid as possible is aspirated before instillation of the corticosteroid suspension to reduce the dilution factor. Sometimes it is advisable to reaspirate and reinject several times within the barrel of the syringe, so-called *barbotage*, to obtain heterogeneous mixing and maximal dispersion of the steroid throughout the synovial cavity.

While an accurate injection is desirable, using a generous

**TABLE 56-4** -- A Guide for Needle Size and Dosage for Injection of Common Regional Disorders

| Disorder or Injection Site | Needle Size | Usual Dosage of Prednisolone Tebutate |
|---|---|---|
| Bicipital tendinitis | 1.5-2.0 in., 22-25 ga | 20-30 mg |
| Calcareous tendinitis | 1.5-2.0 in., 22-25 ga | 20-40 mg |
| Subacromial bursitis | | |
| Radiohumeral bursitis | 1.5 in., 22-25 ga | 20-30 mg |
| Epicondylitis | | |
| Olecranon bursitis | 1.0-1.5 in., 20 ga | 15-30 mg |
| Ganglia on wrist | 1.0 in., 18-20 ga | 10-15 mg |
| de Quervain syndrome | 7/8 in., 22-25 ga | 10-20 mg |

| | | |
|---|---|---|
| Carpal tunnel syndrome | 1.0-1.5 in., 22-25 ga | 20-40 mg |
| Digital flexor tenosynovitis | 7/8 in., 22-25 ga | 5 mg |
| Trochanteric bursitis | 1.5-2.0 in., 22-25 ga | 20-40 mg |
| Prepatellar bursitis | 1.0-1.5 in., 22-25 ga | 15-20 mg |
| Anserine bursitis | 1.0-1.5 in., 22-25 ga | 20-40 mg |
| Bunion bursitis | 1.0 in., 22-25 ga | 5-10 mg |
| Calcaneal bursitis | 1.0 in., 22-25 ga | 10-20 mg |

volume of anesthetic (3 to 6 mL) to dilute and hence disperse the steroid can compensate for some less than perfect injections. As a general rule, one should allow the patient to localize the area of maximum tenderness; the injection should begin in that area. Limiting the patient to 1 finger to localize the area of maximum pain and tenderness is the best way to ensure the most accurate positioning of the needle. If pain persists despite the use of a local anesthetic, an additional injection may be required.

## Specific Regions and Clinical Entities

Table 56-1 and Figure 56-1 (Figure Not Available) list the areas of involvement by region. In addition, certain nonarticular disorders that may require local injection are included.

### Shoulder Region

Pain associated with disability may result from any of the intrinsic shoulder disorders, including bicipital tendinitis, calcareous tendinitis, and subacromial bursitis (Fig. 56-2) (Figure Not Available) . These areas are frequently injected because it is safe and easy to do so, one gets a consistently good response to therapy, and to avoid the danger of

an untreated persistent inflammation resulting in a "frozen shoulder."

**Bicipital tendinitis (tenosynovitis).**

This is a nonspecific low-grade inflammation or irritation of the long head of the biceps tendon sheath. [21] The tendon courses through the joint and along the bicipital (intertubercular) groove. Pain at the shoulder is accompanied by restricted motion and disturbed scapulohumeral rhythm. Efforts to elevate the shoulder, reach the hip pocket, or pull a back zipper all aggravate the symptoms. "Rolling" the bicipital tendon produces localized tenderness (Lipman test), and the Yergason test may be positive. The Yergason test elicits pain along the bicipital groove when the patient attempts supination of the forearm against resistance, holding the elbow flexed at a 90° angle against the side of the body (Fig. 56-3) (Figure Not Available) . Radiographs are normal.

**Approach.**

The point of maximal tenderness of the bicipital tendon is located. Entry is made with a 22- or 25-ga, 3.9- to 5.0-cm needle through a lidocaine skin wheal (Fig. 56-4) (Figure Not Available) . It is wise to *avoid an actual intratendinous injection,* which may cause weakening of the tendon and predispose the patient to tendon rupture. The needle is brought in along the side of the tendon, aimed at one border of the bicipital groove to give a *peritendinous infiltration*. One third of the injection is administered at this point. The needle is then withdrawn slightly but is kept subcutaneous. It is redirected upward approximately 2.5 cm for another one third of the injection, withdrawn again, and redirected downward, touching the bicipital border gently; the remainder of the drug is deposited at this point. Usually the corticosteroid suspension, 1 to 1.5 mL of prednisolone tebutate, is instilled at the maximum area of tenderness, and the lidocaine is injected along the upper and lower borders of the tendon. Two to 4 repeat injections may be required at 1- to 2-week intervals.

**Calcareous tendinitis, supraspinatus tendinitis, and subacromial bursitis.**

These inflammations are so clinically similar that their symptoms and signs are difficult to differentiate. The acute irritative inflammation of the bursa is a secondary reaction produced by the calcific tendinitis of the supraspinatus or one of the other rotator cuff tendons. After the calcific material ruptures into the subdeltoid bursa (Fig. 56-5) , spontaneous relief usually is obtained within a few days. During the acute or hyperacute stage, the patient holds the arm in a protective fashion against the chest wall. Pain may be incapacitating, and all ranges of motion are disturbed, with internal rotation markedly limited. Tenderness is often diffuse over the perihumeral region. Constitutional symptoms are rare, but sometimes in the hyperacute form, actual swelling may be visible, and even fever and an accelerated sedimentation rate may develop. When shoulder radiographs demonstrate a calcific deposit, the shadow appears "hazy," with lightening of the periphery caused by the pressure of inflammatory edema. Night pain may be intolerable, requiring opioids for control.

**Anterior approach.**

In calcific tendinitis or supraspinatus tendinitis without calcification, the injection is given by the anterior (subcoracoid) or lateral approach, below the acromion (Fig. 56-6) (Figure Not Available) . If the tenderness is not localized, a point is selected over the depression that is palpable between the anterolateral or anteromedial border of the acromion and the head of the humerus.

**Posterior approach.**

With the patient sitting and the lower part of the extremity resting on the lap, a lidocaine skin wheal is made at a posterolateral point under the acromion. A 3.9- to 5.0-cm, 22- or 25-ga needle is then directed toward the center of the head of the humerus and upward at an angle of approximately 10°. After the site has been penetrated 2 to 3 cm, aspiration is carried out for any fluid or calcific material. The syringe is then removed, leaving the needle in position. Another syringe containing 20 to 40 mg of prednisolone suspension or equivalent is attached, and the medication is instilled. This injection can be followed with 1 to 5 mL of 1% lidocaine (or a similar volume of 0.25% bupivacaine), or local anesthetic can be given combined with the steroid in the same syringe. One should be generous with the volume of local anesthetic to ensure adequate dispersion of the steroid. A single treatment relieves the majority of acute disorders, but occasionally it may have to be repeated once or twice.

Sometimes a painful reaction may follow when the analgesic has worn off. To avoid severe pain, the patient should be warned about this possibility and given appropriate analgesia. A sling may provide additional relief, and short-term use of opioids is appropriate.

**Acromioclavicular joint inflammation.**

Pain arising in the acromioclavicular joint is frequently an aftermath of an acute injury. With this injury, all ranges of motion of the shoulder cause pain, and the joint is tender but rarely swollen.

**Approach.**

Entry is made through a cutaneous lidocaine wheal over the interosseous groove at the point of greatest tenderness (Fig. 56-7) (Figure Not Available) . The joint line is relatively superficial, and a 2.2- to 2.5-cm, 22- or 25-ga needle is adequate. One to 2 mL of lidocaine and 5 to 10 mg of a prednisolone suspension are injected. It is not necessary to advance the needle beyond the proximal margin of the joint surface.

**Elbow Region**

The elbow is subject to frequently occurring characteristic extra-articular disorders.

These include radiohumeral bursitis, epicondylitis ("tennis elbow" and "golfer's elbow"), and olecranon bursitis ("barfly's elbow").

**Radiohumeral bursitis.**

This occurs at the juncture of the radial head and the lateral epicondyle of the elbow. Radiohumeral bursitis is commonly found in combination with lateral epicondylitis. The symptoms of the 2 adjacent problems are indistinguishable, but tenderness in bursitis overlies the site of the radiohumeral groove, whereas tenderness in tennis elbow occurs chiefly at the lateral epicondyle (Fig. 56-8) (Figure Not Available) . A clinical sign supporting the diagnosis of tennis elbow is the provocation of pain when the patient attempts elevation of the middle finger against resistance, with the wrist and the elbow held in extension.

**Approach.**

The entry site is the point of maximal tenderness, usually found at a point slightly distal to the lateral epicondyle. The radial head can be palpated and confirmed by rotation of the patient's forearm (Fig. 56-9) (Figure Not Available) . The injection is made through a skin wheal with a 3.9-cm, 22-ga needle, depositing 20 to 30 mg of prednisolone mixed with lidocaine. Alternatively, the steroid is followed with 1 to 3 mL of local anesthetic. Part of the repository preparation may be instilled into the radiohumeral bursa and part at the lateral epicondyle (Fig. 56-10) (Figure Not Available) . Generally, it is wise to limit repeat injection attempts to 2 or 3. In medial epicondylitis (golfer's elbow), a similar technique can be used, but it is important to remember to avoid the ulnar nerve, which lies in a groove behind the medial epicondyle.

**Olecranon bursitis.**

"Student's elbow", or "miner's beat elbow," is a common condition that is frequently idiopathic or provoked by minor trauma (Fig. 56-11 *A* and *B*). It is common for patients to present following some minor, often unrelated, trauma to the elbow region. The bursa also can be involved in rheumatoid arthritis and gout. Although most cases of olecranon bursitis are sterile, the olecranon bursa is the most frequent site of septic bursitis. The diagnosis of olecranon bursitis is obvious when the elbow is inspected and examined during flexion and extension. Radiographs are normal, but bony spurs (of questionable relationship) may be noted at the olecranon process, and amorphous calcific deposits may be seen. Occasionally in rheumatoid arthritis and gout, nodules, or tophi, may be readily palpated within the bursal sac. The olecranon bursa that is most commonly involved lies between the skin and the olecranon process. Motion at the elbow joint remains complete and painless unless there is also "true" elbow joint involvement.

Olecranon bursitis is bothersome to the patient but often does not cause discomfort and may resolve spontaneously unless there has been bleeding into the bursa or the effusion is extremely tense. When the bursa is large and subject to trauma or is tender and inflamed, provided that infection is excluded, aspiration and a steroid injection will expedite resolution (Fig. 56-11 *C-E*). Smith and associates demonstrated the superiority

of intrabursal methylprednisolone acetate over oral naproxen or placebo at 6 months, noting faster resolution and less reaccumulation of fluid with the steroid injection. [23] The addition of a nonsteroidal drug after steroid injection did not affect the outcome. Aspiration without injection is often followed by recurrence in a few days or weeks.

Fluid may be aspirated for analysis and culture to help distinguish a noninflammatory process from an inflammatory or septic bursitis. Clear or serosanguineous (and xanthochromic) fluid is seen with a sterile bursitis, whereas cloudy fluid should suggest a septic process. The sterile bursal fluid may demonstrate 50 to 4000 leukocytes/mL, predominantly macrophages and lymphocytes, and nonbirefringent cytoplasmic inclusion bodies can be seen. Glucose, protein, and complement ($C_3$ ) concentrations in bursal fluid range from 60% to 80% of respective serum values.

It is usually easy to detect a septic bursitis by physical examination (Fig. 56-12) . The bursal area is red, hot, swollen, and painful. Fever and systemic leukocytosis are not generally sensitive or specific findings. Smith and associates reported that the surface temperature of the skin overlying the olecranon bursa may be a very sensitive and specific indicator that can differentiate septic from nonseptic cases. [24] In their study, using an electronic temperature probe attached to the skin, the mean temperature difference uniformly between the affected and contralateral elbow was 3.7 °C in cases of septic olecranon bursitis versus 0.7 °C in nonseptic bursitis. A temperature difference of 2.2 °C (sensitivity, 100%; specificity, 94%) was more helpful than bursal fluid leukocyte count, cell differential, or Gram stain for differentiating septic from nonseptic bursitis. This study suggests a possible role for the recently developed infrared thermometer that detects surface temperatures.

Initial treatment of a septic bursitis includes aspiration of all fluid, appropriate culturing, and antibiotic therapy. Corticosteroid injections should not be used for cases of clinically apparent septic bursitis. [25] Antibiotics directed against penicillin-resistant *Staphylococcus aureus*--either oral or parenteral, depending on the extent of infection--are indicated. In frank septic bursitis, especially with thickening of the bursal wall or in cases resistant to antibiotic therapy, open incision with drainage may be required, with possible subsequent excision of the bursa. Rarely, acute gout or a cholesterol crystal synovitis develops, and this may mimic a suppurative bursitis.

**Approach.**

A 2.5- to 3.9-cm, 20-ga needle is introduced at a dependent aspect of the bursal sac through a lidocaine skin wheal; Frigiderm spray may be used, or the skin may remain unanesthetized. After *all* of the fluid is aspirated, 15 to 30 mg of prednisolone tebutate or an equivalent preparation is injected. The elbow is wrapped with an elastic compression bandage for 5 to 7 days following aspiration and injection. If infected or inspissated fluid is anticipated, a 16- to 18-ga needle may be necessary for aspiration of the viscous contents.

**Wrist and Hand Region**

**Ganglion cysts of wrist or hand.**

These are cystic swellings occurring frequently on the hands, especially on the dorsal aspect of the wrist. Ganglion cysts are common and make up approximately 60% of all soft tissue tumors affecting the wrist and hand. They usually develop spontaneously in adults between 20 and 50 years old, with a female-to-male ratio of 3:1.

The etiology of ganglia remains obscure. The word *ganglion* is derived from the Greek word meaning "cystic tumor." The cystic structures are attached to or may arise from tendon sheaths or near the joint capsule, and attachment is often by a pedicle. In 1971, Andr'en and Eiken [26] demonstrated that contrast material instilled into the wrist would pass into some ganglia, especially the volar wrist ganglion. However, the material injected into the ganglion did not flow into the joint. At times, the wall of the ganglion is distinct from that of the synovial membrane.

The wall of the ganglia is smooth, fibrous, and of variable thickness. The cyst is filled with a clear, gelatinous, sticky or mucoid fluid of great density. The viscous fluid in the cyst may sometimes represent almost pure hyaluronic acid.

The types of ganglia vary with their location. The most common ganglion is the dorsal wrist variety, which arises from the scapholunate joint and constitutes approximately 65% of ganglia. The volar wrist ganglion, which arises over the distal aspect of the radius, constitutes approximately 20% to 25% of ganglia (Fig. 56-13 *A* and *B*). Flexor tendon sheath ganglia make up the remaining 10% to 15% of ganglia found on the hand and wrist.

Another type of cystic ganglia on the dorsal wrist occurs not infrequently in patients with rheumatoid arthritis, but is easily recognized because of its soft, irregular appearance in association with other evidence of rheumatoid extensor synovitis.

Most ganglia are of no great clinical significance, and most do not require treatment. Spontaneous regression is common. However, if the appearance of the cyst is disturbing to the patient or if the ganglion is painful or tender (from soft tissue or nerve compression or bone erosion), then simple aspiration with or without injection of a corticosteroid suspension is usually an effective approach. Up to 3 aspirations may be required before the technique is termed a failure. A recent report of treatment by aspiration alone showed that 69% of 116 patients required only a single aspiration. [27] Two or 3 aspirations were required for 19%, and only 12% ultimately needed surgical excision. Certainly, aspiration with or without steroid injection is associated with considerable cost savings when compared with surgery. The "old" treatment of attempting to rupture the ganglion with a heavy book is not advised due to the potential for local injury. In the event of failure of nonsurgical treatment, surgical excision my be indicated. Reported recurrence rates after surgical removal range between 6% and 50%.

**Approach.**

Following instillation of 1% lidocaine for local anesthesia, a 2.5-cm, relatively large-bore needle (17 to 18 ga) is inserted into the center of the ganglion. The cyst is aspirated, with an attempt to achieve maximum evacuation of the contents. Usually 1 to 2 mL of mucinous fluid can be aspirated. Milking the contents of the cyst toward the aspiration needle can maximize the volume that is removed. When a steroid is administered, 10 to 15 mg of prednisolone tebutate (or equivalent) are injected. The use of steroids instilled into the cyst is a common procedure that has been proven to significantly augment the success of simple aspiration. [28] Following aspiration, a splint is usually not required, and activity need not be restricted. There is no proven role for routine nonsteroidal anti-inflammatory drug (NSAID) or oral steroid therapy.

**de Quervain disease.**

This relatively common disease is a stenosing tenosynovitis of the short extensor (extensor pollicis brevis) and long abductor tendon (abductor pollicis longus) of the thumb. Although occasionally associated with rheumatoid arthritis, the disorder more often occurs following repetitive use of the wrists, especially with a wringing motion. The syndrome has been called "washerwoman's sprain" but has been seen after repetitive hammering, and often no specific etiology is apparent. Tenderness and, occasionally, palpable crepitation is elicited just distal to the radial styloid process where both tendons come together in an osseofibrous tunnel. Patients usually present with wrist pain and often mistakenly attribute the discomfort to some distant, albeit irrelevant, trauma. The condition may be confused with first carpometacarpal arthrosis (osteoarthritis of the thumb). Radiographs will be normal in de Quervain disease but may be appropriate to rule out other pathologic abnormality.

A useful specific clinical finding that indicates de Quervain disease is the Finkelstein test (Fig. 56-14 *A*). This test is conducted by abducting the patient's thumb into the palm of the hand and folding the fingers over the thumb. Forcible ulnar deviation at the wrist is then carried out, with severe pain at the site of the affected tendon sheaths indicating a positive test. When examining for the Finkelstein test, one should also evaluate the tender area for palpable crepitus (see Fig. 56-14 *B*). If axial traction or compression (the "grind test") and rotation of the thumb produce pain, the condition is most likely due to degenerative changes of the carpometacarpal joint of the thumb rather than from de Quervain disease. It should be noted that gonococcal tenosynovitis of the wrist may mimic de Quervain disease, and one should inquire about other symptoms (e.g., sore throat, penile or vaginal discharge, or fever) and carefully look for the characteristic rash of this sexually transmitted disease (see Fig. 56-14 *C*).

Mild cases may be treated with NSAIDs and a splint, but less than a third will show any improvement. [29] Increasing evidence supports the effectiveness of local corticosteroid injections as the therapeutic preference for de Quervain tenosynovitis. In 1 report, 90% of 56 cases were effectively managed either with a single injection (58%) or with repeat injections (33%), with only 10% requiring surgical treatment. [30] These data support a previous report describing an 83% rate of successful response to injections in 63 wrists

with de Quervain tenosynovitis. [31] The striking favorable response of local injection suggests that surgery to release the tendon sheaths is seldom needed.

**Approach.**

A 2.2-cm, 25-ga needle is introduced at the most tender point (just distal to the radial styloid) through a skin wheal, and 10 to 20 mg of prednisolone suspension mixed with 4 to 5 mL of lidocaine 1% are deposited adjacent and parallel to the tendon sheath (peritendinous infiltration) (Fig. 56-15 (Figure Not Available) *A* and *B*). One should be generous with the injection volume, since a common reason for failure is the inability to get medication into both tendon sheaths. This may be partially overcome by increasing the volume of steroid-lidocaine injected in a more diffuse area. The injection may be repeated 1 or 2 times at 7- to 14-day intervals, if needed. A lightweight thumb or wrist splint for wrist support and protection may be used at night for several weeks after the injection, but routine splinting following injection is not required. [32] Oral NSAIDs may be prescribed as analgesics but will likely not effect a cure by themselves. There is no proven role for oral corticosteroids.

**Carpal tunnel syndrome.**

Carpal tunnel syndrome is a common nerve entrapment caused by median nerve compression. It is characterized by pain at the wrist that sometimes radiates upward into the forearm and is associated with tingling and paresthesias of the palmar side of the index and middle fingers and the radial half of the ring finger. Typically, the patient wakes during the night with burning or aching pain, numbness, and tingling and must shake the hand outside the bedclothes to obtain relief and restore sensation. Occasionally the discomfort is extremely severe, causing the patient to seek emergency aid. Clinical signs supporting the diagnosis include a positive Tinel sign, in which one reproduces the tingling and paresthesias by tapping (with a reflex hammer) over the median nerve at the volar crease of the wrist. [33] In addition, one can perform wrist flexion maneuvers (the Phalen sign) in an effort to provoke the symptoms in the median nerve distribution. [34] Severe muscle atrophy of the thenar eminence may develop in advanced or neglected cases. Causes of carpal tunnel syndrome include rheumatoid arthritis (sometimes as the presenting manifestation), pregnancy, hypothyroidism, diabetes, and acromegaly, but in many cases the disturbance is idiopathic, without a recognizable underlying cause.

**Approach.**

When injecting the carpal canal, one should insert the needle through a skin wheal at a site just medial or ulnar to the palmaris longus tendon and proximal to the distal crease at the wrist (Fig. 56-16) (Figure Not Available) . Injecting medial to the palmaris longus is preferred because it avoids direct injection of the median nerve and superficial veins. A 2.5- to 3.9-cm, 25-ga needle is directed at an angle of approximately 60° to the skin surface, pointing toward the palm. The needle is advanced 1 to 2 cm, and 20 to 40 mg of prednisolone suspension with or without lidocaine are injected along the track and into the tissue space. Up to 2 weeks may be required for symptoms to abate significantly. A lightweight wrist splint may hasten recovery. Repeat injections may be

given, but if response is not successful or lasting after 2 or 3 injections, decompressive surgery should be considered. Nerve compression should be confirmed by nerve conduction studies before surgery. [35]

**Digital flexor tenosynovitis (trigger finger).**

A "trigger" or "snapping" finger is characterized by a stenosed tendon sheath on the palmar surface over the base of the metacarpal head. The area of stenosis leads to intermittent catching of the tendon. Locking occurs when the involved digit is in flexion and is especially troublesome when the patient awakens in the morning. This can occur in any finger but is seen most frequently in the ring and middle fingers.

*Tendinitis* and *tenosynovitis* are terms useful for describing inflammatory reactions in tendons and tendon sheaths. The tendon sheaths are long and tubular, and the walls are lined with a thin layer of synovial cells. Symptoms develop when the tendon becomes trapped and is unable to glide within the tendon sheath (Fig. 56-17) (Figure Not Available) . A nodule or fibrinous deposit may form at a site in the tendon sheath, usually over or just distal to the metacarpal head. Carpal tunnel syndrome commonly coexists with trigger finger and may be caused by tenosynovitis. The common causes include trauma, diabetes mellitus, and rheumatoid arthritis.

Marks and Gunther [36] reported the results of treatment of a consecutive series of 74 patients, in whom 108 local injections of fingers were given, yielding an overall "cure rate" of 93% after 1 or 2 injections. In another study, [37] repeated corticosteroid injections for stenosing tenosynovitis were highly effective and without adverse effects in a similar consecutive series of 93 patients (104 fingers injected). Kraemer and colleagues [38] reviewed their treatment of 253 consecutive digits affected with stenosing flexor tenosynovitis (trigger fingers), comparing the results of steroid injection with those of surgical release. Analysis disclosed no significant difference in efficacy for injection versus surgery. Surgical treatment was associated with more complications and was more costly. The cost for an in-office steroid injection was 10% of the cost for in-hospital surgical release. A single steroid injection provided complete relief of symptoms in 110 digits (67%); 13% of these patients had a recurrence of symptoms. A series of as many as 3 injections provided complete, lasting relief of symptoms in 63% of all digits treated. Group analysis of all patients over the age of 10 years disclosed that 68% of the patients whose initial treatment was by steroid injections experienced complete relief of symptoms, whereas 73% of those whose initial treatment was by surgical release experienced complete relief of symptoms. Gray and colleagues, [39] in a retrospective study, reported resolution of 93% of 173 episodes of rheumatoid digital flexor tenosynovitis and 52 episodes of idiopathic flexor tenosynovitis. Other studies report success rates of 48% to 82% with follow-up of at least 1 year.

The precise mechanism for the lasting analgesia and the beneficial therapeutic effects is not fully understood. Explanations that have been considered include production of local hyperemia, relaxation of reflex muscle spasm, generalized response from some systemic absorption of the steroid suspension, a beneficial influence on local tissue metabolism, pain relief allowing increased rest and sleep, and mechanical improvement. The increased mobility resulting from pain relief undoubtedly accelerates recovery and

restoration of function. Finally, the "power of suggestion" of the needle (the placebo effect) must be given consideration in some cases. Some observers suggest that part of the pain relief may result from stimulation and release of the patient's endorphins.

Conservative treatment, including local rest or splinting, application of moist heat, and NSAID therapy, is the usual initial therapeutic approach for symptomatic tenosynovitis. If these simple measures fail to control symptoms, then corticosteroid injection, appropriately administered to the involved tendon sheath, is indicated. The procedure would be relatively contraindicated in patients receiving anticoagulants. The potential hazard of tendon rupture has been reported infrequently. This rare complication can be prevented by careful infiltration and by avoiding introduction of the corticosteroid into the substance of the tendon. Division of the first annular pulley and digital nerve injury are well-known complications of surgical release.

**Approach.**

Preparation of the site before the injection requires meticulous adherence to aseptic technique. Local anesthesia is usually provided by spraying with a skin refrigerant such as dichlorotetrafluoroethane (Frigiderm) to numb the skin before entry of the needle. The technique for injecting flexor tenosynovitis includes locating and marking the tendon point at the involved metacarpal base and instilling 0.25 to 0.35 mL of any corticosteroid suspension subcutaneous with a 2.2-cm, 25-ga needle into the involved tendon sheath (Fig 56-18) (Figure Not Available) . The needle enters the skin at an angle of approximately 30° and is inserted into the tendon sheath, parallel to the tendon fibers. Resistance should not be encountered on injecting. Similar injections can be administered to the base of the thumb metacarpal for a "snapping" thumb. Up to 4 repeat injections may be given at 6- to 8-week intervals. If relapses are frequent or the clinical response is not satisfactory, then surgical release is indicated.

**Hip Region**

**Trochanteric bursitis.**

Trochanteric bursitis may simulate hip joint disease and sciatica. [42] The principal bursa lies between the gluteus maximus and the posterolateral prominence of the greater trochanter, although other bursae of the hip are also commonly affected. Pain may be acute but is more often subacute or chronic; often patients have tried NSAIDs without success and have been given a number of incorrect diagnoses. The chief locus of the pathologic condition is in the abductor mechanism of the hip. Pain occurs near the greater trochanter and may radiate down the lateral or posterolateral aspect of the thigh. Pain is described as deep, dull, and aching, and it often interferes with sleep.

Pain is provoked by lying on the side of the hip, stepping from curbs, and descending steps. Tenderness may be elicited over and adjacent to the greater trochanter. In contrast with true hip involvement, the Patrick *fabere* sign ( *f*lexion, *ab*duction, *e*xternal *r*otation, and *e*xtension) may be negative, and complete passive range of motion is relatively painless. Active abduction when the patient lies on the opposite side typically

intensifies the discomfort, and sharp external rotation may accentuate the symptoms. Hip radiographs may demonstrate a calcific deposit adjacent to the trochanter. [42] Trochanteric bursitis is a fairly frequent complication in rheumatoid arthritis. [43]

**Approach.**

Intrabursal injection uses the site of maximum tenderness for the entry point. A 3.9- to 5.0-cm, 20- or 21-ga needle is advanced until the needle tip reaches the trochanter. The needle is then withdrawn slightly, and the site is infiltrated fairly widely with 3 to 10 mL of lidocaine and 20 to 40 mg of prednisolone tebutate or the equivalent. The condition usually improves following 1 or 2 local injections.

**Ischiogluteal bursitis.**

"Weaver's bottom" is a painful

disorder characterized by pain over the center of the buttocks with radiation down the back of the leg. [44] This condition is rarely initially diagnosed, often being mistaken for lumbosacral strain, a herniated disk, or spinal cord tumor. When it is recognized, a skillful intrabursal injection, coupled with a few days' rest, usually relieves the extreme pain. The bursa is adjacent to the ischial tuberosity and overlies the sciatic and posterior femoral cutaneous nerves. Pain is provoked by sitting on hard surfaces, bending forward, and standing on tiptoe. Tenderness is present over the ischial tuberosity.

**Approach.**

The usual technique for injection requires that the patient lie in a prone position. A 5.0-cm, 20- to 22-ga needle is inserted through a skin wheal and is advanced cautiously in an effort to avoid the sciatic nerve, which lies at a depth of approximately 6.5 to 7.5 cm. Paresthesias occur on striking the nerve, and if this occurs, the needle should be withdrawn from the nerve. Generally, 5 to 10 mL of lidocaine and 20 to 40 mg of prednisolone suspension are introduced into the bursa.

**Knee Region**

**Prepatellar bursitis.**

"Housemaid's knee," or "nun's knee" is characterized by swelling with effusion of the superficial bursa overlying the lower pole of the patella. Passive motion is fully preserved, and pain is generally mild, except during extreme knee flexion or direct pressure. Although the disorder is usually caused by pressure from repetitive kneeling on a firm surface ("rug cutter's knee"), rarely it can develop after direct trauma, and occasionally it is a manifestation of rheumatoid arthritis. The prepatellar bursa is also a common site of septic bursitis.

**Approach.**

Aspiration often yields a surprisingly scant amount of clear, serous fluid, owing to the fact that the prepatellar bursa is a multilocular structure rather than the usual single cavity. The instillation of 1 to 2 mL of lidocaine with 15 to 20 mg of a prednisolone suspension with a 2.5-cm, 20- to 21-ga needle is usually sufficient to cause the swelling to abate. In some cases the procedure may need to be repeated several times to obtain a lasting result. The provocative activity should be discontinued.

**Suprapatellar bursitis.**

Suprapatellar bursitis usually is associated with synovitis of the knees. On occasion the bursa is largely separated from the synovial cavity, with only a very minor communication, and the swelling and effusion are chiefly confined to the suprapatellar area. This may be traumatic in origin or an associated manifestation of an inflammatory arthropathy.

**Approach.**

The procedure for aspiration and injection of the suprapatellar area is similar to that for the knee (see Chapter 57) .

**Anserine bursitis.**

"Cavalryman's disease" now mainly occurs in heavy women with disproportionately large thighs in association with osteoarthritis of the knee. The bursa is on the anteromedial side of the knee, inferior to the joint line at the site of the insertion of the conjoined tendons of the sartorius, semitendinous, and gracilis and superficial to the medial collateral ligament. The entity is characterized by a relatively abrupt onset of knee pain, with localized tenderness and a puffy sensation in the vicinity of the anserine bursa.

**Approach.**

An injection of 2 to 4 mL of lidocaine with or followed by approximately 20 to 40 mg of a corticosteroid suspension is given at the point of greatest tenderness, using an anterior or medial approach with a 2.5- to 3.9-cm, 22-ga needle (Fig. 56-19) . Prompt symptomatic relief frequently is obtained, but the duration of benefit is variable and probably correlates with the patient's weight-bearing activities.

**Ankle, Foot, and Heel Region**

**Ankle tendinitis.**

This is a relatively uncommon condition. It may result from unusual repetitive activity or, rarely, from acute trauma. Crepitant swollen tendon sheaths commonly occur in rheumatoid arthritis. The disorder is differentiated from ankle joint involvement by the lack of pain or restricted motion during passive flexion and extension of the ankle. Active flexion and extension of the toes does produce pain. Local tenderness is elicited along the flexor and extensor tendons. Injection of the tendon sheaths is useful, producing considerable relief of symptoms.

**Approach.**

A 2.5- to 3.9-cm, 22- or 25-ga needle is used. One makes a tangential entry to the enlarged tendon sheath, distending the sheath with approximately 2 to 4 mL of a mixture of corticosteroid and lidocaine and instilling 20 to 40 mg of prednisolone tebutate. It may be necessary to repeat the injection after several months.

**Bunion bursitis.**

It is common for bunion bursitis to overlie the first metatarsophalangeal joint at its medial surface on the great toe. On occasion, tense swelling occurs, and decompression is required. Aspiration with culture of the fluid should be performed.

**Approach.**

If no infection is present, the bursa is injected with 5 to 10 mg of prednisolone suspension with a 2.5-cm, 20-ga needle. Special shoes or an orthopedic correction will be needed if the swelling recurs.

**Heel pain.**

"Talalgia" may be caused by Achilles tendinitis, calcaneal bursitis, or plantar fasciitis. The bursae of clinical significance around the heel include the space between the skin and the Achilles tendon, the retrocalcaneal bursa, and the subcalcaneal bursa. Achilles tendinitis or bursitis may be traumatic in origin but is more apt to be part of a systemic disease, such as rheumatoid or gouty arthritis. Although the normal Achilles tendon is thick and strong, when affected by an inflammatory arthropathy, it is predisposed to degeneration, and since the Achilles tendon is not invested by a full synovial sheath, it is more vulnerable to intratendon instillation. Because of the potential hazard of tendon rupture after local steroid injection, it is wise to avoid infiltration of steroids into this area. [45] It is preferable to treat Achilles tendinitis with rest, splinting, and oral medication. The major injectable condition in this region is calcaneal bursitis (plantar fasciitis), which is frequently associated with painful heel spurs ("policeman's heel" or "soldier's heel"). If orthopedic shoe corrections and aids are not effective, injection of the painful heel is sometimes beneficial.

**Approach.**

At the spot of maximal tenderness, a 2.5-cm, 22- to 24-ga needle enters the plantar surface at 90°, sliding into the space at the midpoint of the calcaneus. The tip of the needle lies in the aponeurosis of the attachment to the os calcis (Fig. 56-20) (Figure Not Available) . One milliliter of lidocaine and 10 to 20 mg of prednisolone tebutate are instilled. The injection may need to be repeated once or twice at an interval of 6 to 8 weeks.

## SEPTIC BURSITIS

Occasionally, bursitis may be caused by an acute bacterial infection of the bursal fluid and surrounding soft tissue. [5] [46] Septic bursitis is most common in the olecranon and prepatellar bursae, whereas infection of other bursae is exceedingly rare. [46] The infection is probably secondary to acute trauma resulting in direct penetration of the bursa by common skin pathogens, rather than by hematogenous spread. The patient frequently reports a history of minor trauma or is engaged in an occupation associated with sustained pressure on the knees or the elbows.

Septic bursitis is not associated with septic arthritis of the underlying joint, although rarely, adjacent bone may become involved. [47] Many patients have an underlying predisposition to infection (e.g., diabetes mellitus, alcoholism, uremia, or gout). Rarely, an infection may follow a bursal injection of corticosteroids.

In most cases the diagnosis of septic bursitis is obvious. The onset of pain and swelling may be quite rapid (over 8 to 24 hours), as compared with the more gradual onset of aseptic bursitis. The bursa is tense, swollen, and very painful. Pitting edema and classic cellulitis of the peribursal soft tissue may be present. In some cases it may be difficult to distinguish septic bursitis from trauma or other acute inflammatory disorders, such as acute gout or tenosynovitis. In questionable cases it is prudent to aspirate and culture the fluid and to treat with antibiotics and oral NSAIDs. Corticosteroid injection is withheld pending negative bacteriologic findings.

The diagnosis is confirmed by culturing bacteria from the bursal aspirate. Fluid is usually easily obtained from the tense bursa and (in the case of an established infection) is cloudy or grossly purulent. The white blood cell count of the fluid is 50,000 to 100,000 cells/mm3 or greater, and polymorphonuclear cells usually exceed 90%. Gram-positive organisms may be seen on Gram stain. The infecting organism is usually penicillin-resistant *S. aureus*, but streptococcal organisms may be isolated. Treatment of septic bursitis includes the use of antibiotics directed against penicillinase-producing *Staphylococcus,* splinting, hot soaks, and drainage of the bursa. Drainage may be adequately performed with one or more needle aspirations, but open incision and drainage may be required. Corticosteroid injections should not be performed in infected tissue. Outpatient therapy with oral antibiotics is generally acceptable.

## CONCLUSION

Local injection therapy for painful nonarticular rheumatic disorders is a relatively simple, safe, and effective form of treatment. The patient may experience rapid relief of pain and swelling and on occasion may return to work after a single injection. The response may be long lasting, as well as very gratifying. An additional benefit of injection therapy is that it may avoid surgical intervention in such soft tissue problems as carpal tunnel syndrome, digital tenosynovitis (de Quervain disease and trigger finger), and ganglia. [30]

The local introduction of a corticosteroid suspension should be carried out with due regard for any coexisting disease, such as diabetes mellitus and peptic ulcer. It is highly unlikely that these diseases would be provoked or aggravated after a single intrasynovial injection in usual therapeutic dosage. However, systemic "spill-over" and absorption may occur, depending on the size of the dose and the solubility of the preparation injected. Transient adrenal suppression may develop but rarely lasts longer than a few days.

# Chapter 57 - Arthrocentesis

**Georges C. Benjamin**

Arthrocentesis, the puncture and aspiration of a joint, is an acknowledged, useful procedure that is easily performed in the emergency department. It has been established as both a diagnostic and a therapeutic tool for a variety of clinical situations. Many physicians are wary of joint fluid aspiration because of a lack of experience and because of the fear of introducing infection. When performed properly, however, the procedure offers a wealth of clinical information and is associated with few complications. In the emergency department it is difficult to make an accurate assessment of an acutely painful, hot, and swollen joint without performing arthrocentesis.

## INDICATIONS AND CONTRAINDICATIONS

The indications for arthrocentesis include the following [1] :

1. Diagnosis of nontraumatic joint disease by synovial fluid analysis (septic joint or crystal-induced arthritis).
2. Diagnosis of ligamentous or bony injury by confirmation of the presence of blood in the joint. Arthrocentesis may be required to differentiate a traumatic joint effusion from an inflammatory process.
3. Establishment of the existence of an intra-articular fracture by the presence of blood with fat globules in the joint.
4. Relief of the pain of an acute hemarthrosis or a tense effusion. Although a minor hemarthrosis need not be drained, arthrocentesis not only reduces pain in large effusions, it also facilitates examination of an injured joint.
5. Local instillation of medications in acute and chronic inflammatory arthritides. Instillation of lidocaine into an injured joint also makes the initial examination of a traumatic injury much easier.
6. Obtaining fluid for culture, Gram staining, immunologic

   studies, and cell count in cases of suspected joint infection.

The most important contraindication to arthrocentesis is the presence of infection in the tissue overlying the site to be punctured (e.g., an abscess or a frank cellulitis). However, inflammation with warmth, swelling, and tenderness may overlie an acutely arthritic joint, and this condition may mimic a soft tissue infection. Once convinced that cellulitis does not exist, the clinician should not hesitate to obtain the necessary diagnostic joint fluid. A relative contraindication to joint puncture is the presence of a bacteremia. Not all joint infections following arthrocentesis are the result of poor antiseptic technique. The hematogenous spread of bacteria into the joint, with or without hemorrhage, in a bacteremic patient also may lead to infection.

Bleeding diatheses may at times be a relative contraindication, but arthrocentesis to relieve a tense hemarthrosis in bleeding disorders, such as hemophilia, is an accepted

practice following infusion of the appropriate clotting factors. Arthrocentesis is also relatively contraindicated in a patient receiving anticoagulants or in the presence of a joint prosthesis, unless the procedure is being performed to rule out infection.

## Articular Versus Periarticular Disease

Periarticular diseases such as tendinitis, bursitis, contusion, cellulitis, or phlebitis may mimic articular disease and suggest the need for arthrocentesis. Therefore, administration of the correct therapy for acute joint disease requires that the physician first determine whether the patient's constellation of signs and symptoms derives from the joint itself and not from some other musculoskeletal or periarticular structure.

If swelling is secondary to joint effusion or inflammation, then the entire articular capsule will be inflamed and distended, and fluid can often be palpated within the joint. In the knee, this condition must be differentiated from effusion into the prepatellar bursa, where swelling distends the bursa that lies mainly over the lower portion of the patella, between it and the skin. Effusion into the joint occurs posterior to the patella, whereas bursal swelling occurs anterior to it. When there is considerable articular effusion, the capsule of the joint is distended, and an inverted U-shaped swelling of the joint occurs. This characteristic shape occurs because the dense patellar ligament prevents distention of the capsule along its inferior border. Also, with the knee extended, a large effusion causes the patella to "float" or lift away from the femoral condyles. A sharp thrust of the fingers makes the patella click against the condyles, confirming the effusion. [2] Complete extension and flexion are often impossible because of the joint tension produced by the effusion.

Joint effusion causes limited movement of the joint in all directions with active and passive motion producing pain. The pain arising from a pathologic condition involving a joint may be diffuse or clearly localized to the joint, or it may radiate. Hip pain, for example, frequently radiates into the groin or down the front of the thigh into the knee. Shoulder joint pain also commonly radiates into the elbow or the neck. Because of this, complete examination of contiguous structures is essential for adequate diagnosis.

In contrast, pain from a periarticular process is often more localized, and tenderness can be elicited only with certain specific movements or at specific points around the joint. In periarticular inflammation, one can often passively lead a joint through a range of motion with minimal discomfort, yet pain is significant when the patient attempts active motion. Crepitus may be elicited in tendinitis, or the pain may be traced along the course of a specific tendon.

## Septic Arthritis

Acute monoarticular arthritis is a common problem in emergency medicine. Although there are many causes of acute monoarticular arthritis, the one most requiring urgent diagnosis and treatment is septic arthritis. Infectious arthritis is still relatively frequent, and suspicion of a septic process in the joint is the first step in appropriate management; confirmation requires arthrocentesis and synovial fluid culture. Although repeated arthrocentesis may be needed when treating a septic joint, such therapy is

usually performed on an inpatient basis.

Infection of a joint occurs by 1 of 4 mechanisms: hematogenous spread, spread from a contiguous source of infection, direct implantation, or postoperative contamination. The joint distribution of septic arthritis is typically monoarticular with a swollen, erythematous, and painful joint. Radiographically the differential diagnosis includes limited rheumatoid arthritis, gout, synovial osteochondromatosis, and pigmented villonodular synovitis. Early diagnosis is essential to prevent complications such as growth impairment, articular destruction with ankylosis, osteomyelitis, or soft tissue extension. [3]

Because an acutely swollen joint may be indicative of a number of disease entities, a thorough history and physical examination are the cornerstones of evaluation, followed by arthrocentesis. Laboratory findings can be useful in diagnosis, as can response to therapy (e.g., response to penicillin in gonococcal arthritis is often the only criterion for diagnosis, as the organism is difficult to culture). Patients with malignancy (especially leukemia) or who are immunosuppressed or otherwise debilitated are at particular risk for a septic etiology. Infectious arthritis should be the first potential cause looked for in these patients, as well as in patients with such preexisting joint diseases as rheumatoid arthritis. A swollen joint is usually not injected with corticosteroids until the possibility of infection has been eliminated. [4]

*Neisseria gonorrheoae*, *Staphylococcus,* and *Streptococcus* are the most frequently identified etiologic agents. [3] *N. gonorrheoae* is the most common organism causing septic arthritis among adolescents and young adults. [5] Patients >40 years old and those with other medical illnesses are more likely to have *Staphylococcus* joint infection, whereas infants aged 6 months to 2 years show a higher incidence of *Haemophilus influenzae*. In neonates, staphylococci and *Escherichia coli* predominate. [6] Intravenous drug abusers commonly develop staphylococcal or *Pseudomonas* infections.

Although precise incidences for nongonococcal septic arthritis have not been established, predisposing factors have been described. These include chronic debilitating disease; prior antibiotic or immunosuppressive medications; a previous history of joint damage, such as from rheumatoid arthritis or degenerative joint disease; and prosthetic joints. [7] [8] [9] In a study by Sharp and coworkers, 22 of 113 patients (19%) with septic arthritis had other arthritides, the most common being rheumatoid arthritis. [3] Elderly patients with a debilitating

arthritis and minor skin infections seem to be the most susceptible; the infection may be overlooked and the patient's findings thought to be an exacerbation of the rheumatoid arthritis. [10]

The simultaneous occurrence of gout and septic arthritis may be more common than generally recognized. One should not allow the establishment of a diagnosis of crystal-induced disease to stop a thorough search for infection. [11]

Because *N. gonorrhoeae* is the most common organism causing septic arthritis, gonococcal arthritis deserves special mention. The incidence in men is increasing, but

the majority of disseminated gonococcal infections occur in women with asymptomatic anogenital infections. Dissemination usually occurs during menstruation or pregnancy.

A useful context in which to view gonococcal arthritis was presented by Gelfand and coworkers. [14] Three sequential stages with associated clinical subgroups have been described, although in practice fewer than 50% of patients will fit classically into 1 of the 3 stages. Patients in the first group *(hematogenous phase)* have constitutional symptoms (high fever and chills), polyarthralgias-polyarthritis (but with little effusion), tenosynovitis, and dermatitis. They then enter a second stage *(transitional phase)* with skin lesions; positive blood cultures; and occasionally, positive joint fluid cultures in an early arthritis and effusion. Those in the third stage *(joint localization phase)* do not have systemic symptoms or skin lesions. The infection settles into 1 or 2 large joints, yielding a purulent arthritis.

Whereas *N. gonorrhoeae*-infected joint fluid is usually "septic" in character, the yield of positive synovial fluid cultures has ranged from 25% to 60%. [15] It is rare to simultaneously find positive joint fluid cultures and blood cultures. [5] A positive Gram stain is immediately diagnostic of septic arthritis. Gram staining is positive in only 65% of cases of septic arthritis, and therefore a negative Gram stain does not rule out an infectious process. A white blood cell count and a synovial fluid glucose reduction may give confirmatory data. Counterimmunoelectrophoresis and latex agglutination have been evaluated for early identification of infection.

**Hemarthrosis**

Isolated nontraumatic hemarthrosis may occasionally be seen by the emergency physician. An inflammatory reaction may follow an intracapsular bleed, and the proliferative reaction and the hyperplastic synovium formed may predispose the patient to recurrent hemorrhage in that joint, especially patients with bleeding diatheses. The knee is the most commonly affected joint (whether the cause is hemophilia or oral anticoagulants), followed by the foot and the ankle. [17]

The most common cause of intra-articular hemorrhage in the setting of no trauma or minor trauma is a hereditary clotting factor deficiency, as in hemophilia. Hemarthrosis is an infrequent complication of oral anticoagulant therapy but may occur even with prothrombin times within the normal range. [18] Chronic arthritis does not appear to be a long-term complication in patients with intra-articular bleeds from oral anticoagulant therapy. Hemarthrosis may also be a complication of sickle cell anemia, pseudogout, amyloidosis, pigmented villonodular synovitis, synovial hemangioma, rheumatoid arthritis, and infection. [17]

Management of acute hemarthrosis depends on the cause. Studies by Jaffer and Schmid and Wild and Zvaifler showed that the synovitis associated with oral anticoagulant therapy improves only after the oral anticoagulant is discontinued and the prothrombin time returns to normal. Hemarthrosis following trauma is a frequent occurrence. It is most common in the knee and often denotes significant internal damage.

Distention of the joint by effusion or hemorrhage causes considerable pain and disability. If the exudate or the blood is not removed, it is partly absorbed, but part of it may undergo organization, resulting in formation of adhesions or bands in the joint. This is one argument for drainage of the joint. [2] Some believe that in an otherwise healthy joint that is subjected to a single traumatic event, even a relatively large hemarthrosis will be spontaneously resorbed without significant sequelae and therefore presents no pressing need to drain. This remains an area of controversy.

Nonetheless, a large, tense traumatic effusion is quite painful, and its presence precludes proper evaluation of an injured joint. Therapeutic arthrocentesis to drain a symptomatic traumatic effusion is a well-accepted practice. [20] The source of blood following trauma is frequently (1) a tear in a ligamentous structure, knee capsule, or synovium or (2) a fracture. Cruciate (especially anterior) ligament injury is the most common cause of significant hemarthrosis following trauma to the knee. [21] A joint effusion that develops 1 to 5 days following trauma may be secondary to a slow hemorrhage or a reinjury, but the swelling is often caused by a nonhemorrhagic irritative synovial effusion.

Occasionally one will diagnose an occult fracture by the presence of fat globules in the arthrocentesis blood. This may be appreciated when the bloody effusion is placed in a clear container (e.g., test tube or specimen jar) and held to the light. If the history of trauma is vague, arthrocentesis may be required to differentiate hemorrhage from other causes of joint effusion. Following therapeutic arthrocentesis for a hemarthrosis, it may be desirable to inject 2 to 15 mL of a local anesthetic, depending on joint size, into the joint to facilitate examination or provide temporary symptomatic relief. [20]

**Intra-articular Corticosteroid Injections**

In 1951 Hollander and coworkers first demonstrated that intra-articular corticosteroid injections were useful for symptomatic relief in patients with severe rheumatoid arthritis. [22] The use of steroids has proved to be a dependable method for providing rapid relief from pain and swelling of inflamed joints, although it is strictly local, usually temporary, and rarely curative.

Corticosteroid injections are most helpful when only a few of a patient's joints are actively inflamed. The most frequently used corticosteroids for intra-articular injection are shown in Table 57-1 (Table Not Available) . [12] Diminution of joint pain, swelling, effusion, and warmth is usually evident within 6 to 12 hours after injection.

The most serious complication of this practice is intra-articular infection. Therefore, steroids should not be injected into a joint if there is suspicion of a joint space infection. Repeated injections into 1 joint carry the risk of necrosis of juxta-articular bone with subsequent joint destruction and instability. Other complications include local soft tissue atrophy and calcification, tendon rupture, intra-articular bleeding, and transient nerve palsy. [24] Deposition of steroid crystals on the synovium may give rise to a transient,

self-limited flare-up of a synovitis. [25]

It is always important to ascertain whether local corticosteroid therapy has been used previously, not only to consider the array of clinical conditions associated with steroid use, but also because crystalline corticosteroid material can hinder proper interpretation of crystals found in synovial fluid.

## EQUIPMENT

Necessary materials for arthrocentesis include skin preparation solutions (usually povidone-iodine followed by alcohol), sterile gloves and drapes, local or topical anesthetics, a syringe, and various-sized needles (Table 57-2) . Fluid for cell count should be collected in a lavender-topped tube with ethylenediaminetetra-acetic acid (EDTA) anticoagulant; however, glucose and viscosity determinations do not require

| **TABLE 57-2** -- Emergency Department Arthrocentesis Tray |
|---|
| Gloves |
| Surgical scrub or plain green soap |
| Povidone-iodine solution |
| Alcohol sponges |
| Sterile towel (with center perforation) |
| Vapor coolant (e.g., fluoromethane solution) |
| 1% or 2% lidocaine |

| |
|---|
| Sterile saline for injection |
| Sterile gauze dressings (2 in. × 2 in.) |
| Sterile syringes (2 mL, 10 mL, 20 mL) Luer-Lok |
| Needles (18, 20, 22, and 25 ga) or over-the-needle intravenous catheters |
| Hemostat |
| Three-way stopcock (optional) |
| Plastic adhesive bandages |
| Sterile basin |
| Plain test tubes |
| Test tubes with liquid anticoagulant |
| Microscope slides and coverslips |
| Clear nail polish (to seal coverslip over material) |

anticoagulants. One should immediately examine fresh synovial fluid in its unadulterated form for crystals. Calcium oxalate and lithium heparin anticoagulants have been

reported to introduce artifactual crystals into the fluid. Joint fluid to be analyzed for crystals should be collected in a green-topped tube containing sodium heparin. If one is culturing for *N. gonorrhoeae*, the fluid should be immediately placed on proper medium and stored in a low-oxygen environment in the emergency department.

## GENERAL ARTHROCENTESIS TECHNIQUE

Joint fluid may be obtained even when there is little clinical evidence of an effusion. Although one may successfully aspirate where the joint bulges maximally, certain landmarks are important. The most crucial part of arthrocentesis is spending adequate time in defining the joint anatomy by palpating the bony landmarks as a guide. These are described in detail later in this chapter. A puncture site and an approach to the joint should be selected; tendons, major vessels, and major nerve branches should be avoided. In most instances, the approach is via the extensor surfaces of joints, because most major vessels and nerves are found in flexor surfaces. Also, the synovial pouch is usually more superficial on the extensor side of a joint.

Aseptic technique is essential to avoid infection. Only sterile instruments should be used. *Arthrocentesis should not be attempted if the skin or subcutaneous tissue overlying the joint is infected.* Sterile gloves should be worn for the remainder of the preparation. The skin is thoroughly scrubbed with a surgical scrub, such as povidone-iodine scrub, and the skin is painted with an iodinated solution, such as povidone-iodine (Betadine). This antiseptic solution should be applied 3 times, allowing it to dry for several minutes, because the bactericidal effects of iodine are both concentration and time dependent. The iodine solution is then removed with an alcohol sponge to prevent transference of iodine into the joint space with a resultant inflammatory process. Gloves should be changed after preparing the skin. Generally a sterile perforated drape is placed over the joint; alternatively, sterile cloth drapes can be used.

With appropriate local anesthesia, arthrocentesis should be a relatively painless procedure; without anesthesia, it may be quite painful and distressing to the patient. The synovial membrane itself has pain fibers associated with blood vessels, and the articular capsule and bone periosteum are richly supplied with nerve fibers and are very sensitive. The articular cartilage has no intrinsic pain fibers. It is important to have the patient relax during the procedure. Tense muscles narrow the joint space and make the procedure more difficult, requiring repeated attempts at aspiration, or result in inadequate drainage. Distraction of the joint may enhance the target area, especially in areas such as the wrist and the finger joints. Traction not only increases the chance of entering the joint, it also lessens the chance of scoring the articular cartilage with the needle.

Using a vapor coolant topically and then rapidly inserting the needle through the skin minimizes patient discomfort. Alternatively, one can infiltrate the skin down to the area of the joint capsule using a local anesthetic agent such as 1% or 2% lidocaine (Xylocaine) with a 22- or 25-ga needle before performing arthrocentesis. For extremely painful

joints, a regional nerve block before the procedure (see Chapter 32) is often greatly appreciated by the patient.

The landmarks described under Specific Procedures should be used, and care should be taken not to bounce the needle off bony structures as a means of finding the joint space, because this may damage the cartilage. [26] An 18- to 22-ga needle or IV catheter and needle set of appropriate length attached to a syringe is inserted at the desired anatomic point through the skin and subcutaneous tissue into the joint space. The largest needle that is practical is used to avoid obstructing the lumen with debris or clot. In large joints such as the knee, which can accommodate large effusions, it is suggested that one use a 30- to 55-mL syringe, because it may be difficult to change a syringe when the needle is within the joint cavity. A three-way stopcock placed between the needle and syringe is an option for draining large effusions. If the syringe must be changed during the procedure, the hub of the needle should be grasped with a hemostat and held tightly while the syringe is removed. If an IV catheter and needle set is used, the needle is removed, leaving the outer atraumatic plastic catheter in the joint space. The syringe is then attached to the catheter for aspiration. Now manipulation of the joint or catheter can occur with little threat of tissue injury.

Aspiration of synovial fluid and the easy injection and return of fluid indicate intra-articular placement of the needle tip. As a general rule, *one should completely remove all fluid or blood.* If the fluid stops flowing, this is a sign that the joint has been drained completely, the needle tip has become dislodged, or debris or clot is obstructing the needle. One should slightly advance or retract the tip of the needle, rotate the bevel, or ease up on the force of aspiration. Occasionally, reinjecting a small amount of fluid back into the joint space confirms the needle placement and may clear the needle. If fluid flows freely back into the joint and is easily reaspirated, one has probably removed all the fluid. If resistance is met, the needle has probably been jarred from the joint space and is lodged in the soft tissue. In some instances, minor position changes produced by flexion or extension of the joint may allow the fluid to flow more freely. Scraping or shearing the articular cartilage with the needle should be avoided, since this may produce permanent cartilage damage. One should enter the joint in a straight line and avoid unnecessary side-to-side motion of the syringe. After aspiration is complete, the needle is removed, and a sterile dressing is applied over the puncture site.

Synovial fluid should be sent for studies as indicated by the clinical situation. Studies usually obtained include cell count with differential, crystal analysis, Gram staining, bacterial culture and sensitivity analysis, and synovial fluid glucose measurement. Less frequently obtained studies include synovial fluid protein measurement, rheumatoid factor analysis, lupus erythematosus (LE) cell preparation, viscosity analysis, mucin clot, fibrin clot, fungal and acid-fast stains, fungal and tuberculous culture, and synovial fluid complement analysis. If the arthrocentesis is performed for the relief of a hemarthrosis, the fluid need not be sent for analysis. One should be selective in ordering tests. There is no need to order a large battery of tests routinely on all fluids.

If the volume of fluid collected is low, culture and examination of the "wet prep" under

regular and polarizing microscopy have the highest priority.

To avoid misdiagnosing borderline inflammatory fluids, missing crystals that dissolve with time, or overinterpreting the findings because of new artifactual crystals that appear over a prolonged time, prompt examination of synovial fluid specimens should be performed.

## COMPLICATIONS

Significant complications are rare with arthrocentesis and include the following:

1. *Infection.* Skin bacteria may be introduced into the joint space during needle puncture. One can, of course, limit this complication by maintaining rigorous sterile technique and avoiding inserting the needle through obviously infected skin or subcutaneous tissue. The chance of introducing infection with arthrocentesis through a noninfected area is minimal if proper attention is paid to technique. Various studies report the incidence of infection following routine arthrocentesis to be in the range of 1 per 10,000 aspirations. [28] Joint aspiration in the presence of a bacteremia has been discussed previously.
2. *Bleeding.* Bleeding with subsequent hemarthrosis is rarely a complication, except in the patient with a bleeding diathesis. If a patient has a bleeding diathesis, such as hemophilia, arthrocentesis should be delayed until clotting competence has been enhanced by the infusion of specific clotting factors. Occasionally, a small quantity of blood may be aspirated along with the synovial fluid. This happens most often when the joint is nearly emptied. A small amount of blood-tinged fluid is generally the result of nicking a small synovial blood vessel; this is usually inconsequential. A grossly bloody effusion must be investigated. [4]
3. *Allergic reaction.* Hypersensitivity to the local anesthetic that is used can usually be prevented by thorough history taking. Fainting during the procedure is not uncommon and is the result of vasovagal influences.
4. *Corticosteroid-induced complications.* See Intra-articular Corticosteroid Injections.

## SPECIFIC ARTHROCENTESIS TECHNIQUES

### First Carpometacarpal Joint (Fig. 57-1) (Figure Not Available)

**Landmarks.**

The radial aspect of the proximal end of the first metacarpal is the arthrocentesis landmark for this joint. The abductor pollicis longus tendon is located by active extension of the tendon.

**Position.**

The thumb is opposed against the little finger so that the proximal end of the first metacarpal is palpable. Traction is applied to the thumb in order to widen the joint space

between the first metacarpal and the greater multangular bone.

**Needle insertion.**

A 22-ga needle is inserted at a point proximal to the prominence at the base of the first metacarpal, on the palmar side of the abductor pollicis longus tendon.

**Comments.**

Degenerative arthritis commonly affects this joint. Arthrocentesis is of moderate difficulty. The anatomic "snuff box" (located more proximally and on the dorsal side of the abductor pollicis longus tendon) should be avoided, because it contains the radial artery and superficial radial nerve. A more dorsal approach may also be used.

## Interphalangeal and Metacarpophalangeal Joints (Fig. 57-2) (Figure Not Available)

**Landmarks.**

The landmarks are on the dorsal surface--the prominence at the proximal end of the proximal phalanx for metacarpophalangeal joints and the prominence at the proximal end of the middle or distal phalanx for interphalangeal joints. The extensor tendon runs down the midline.

**Position.**

The fingers are flexed to approximately 15° to 20° and *traction is applied.*

**Needle insertion.**

A 22-ga needle is inserted into the joint space dorsally, just medial or lateral to the central slip of the extensor tendon.

**Comments.**

Synovitis causes these joints to bulge dorsally. Normally, it is unusual to obtain fluid in the absence of a significant pathologic condition.

## Radiocarpal Joint (Wrist) (Fig. 57-3) (Figure Not Available)

**Landmarks.**

The dorsal radial tubercle (Lister tubercle) is an elevation found in the center of the dorsal aspect of the distal end of the radius. The extensor pollicis longus tendon runs in a groove on the radial side of the tubercle. The tendon can be palpated by active

extension of the wrist and thumb.

**Position.**

The wrist should be positioned in approximately 20° to 30° of flexion and accompanying *ulnar* deviation. *Traction is applied to the hand*.

**Needle insertion.**

A 22-ga needle is inserted dorsally, just distal to the dorsal tubercle and on the ulnar side of the extensor pollicis longus tendon. The anatomic snuff box, located more radially, should be avoided.

## Radiohumeral Joint (Elbow) (Fig. 57-4) (Figure Not Available)

**Landmarks.**

The lateral epicondyle of the humerus and the head of the radius are the arthrocentesis landmarks for the radiohumeral joint. With the elbow extended, the depression between the radial head and the lateral epicondyle of the humerus is palpated.

**Position.**

With the palpating finger still touching the radial head, the elbow is flexed to 90°. The forearm is pronated, and the palm is placed down flat on a table.

**Needle insertion.**

A 22-ga needle is inserted from the lateral aspect just distal to the lateral epicondyle and is directed medially.

**Comments.**

Effusions in the elbow joint may bulge and be readily palpated. Often the effusion appears inferior to the lateral epicondyle. The bulge can then be aspirated from a posterior approach on the lateral side. A medial approach should not be used, because the ulnar nerve and the superior ulnar collateral artery may be damaged. This is a common joint for gout or septic arthritis. A small hemarthrosis need not be aspirated.

## Glenohumeral Joint (Shoulder), Anterior Approach (Fig. 57-5) (Figure Not Available)

**Landmarks.**

The coracoid process medially and the proximal humerus laterally are palpated

anteriorly.

**Position.**

The patient should sit upright with the arm at the side and his or her hand in the lap.

**Needle insertion.**

A 20-ga needle is inserted at a point inferior and lateral to the coracoid process and is directed posteriorly toward the glenoid rim.

**Comments.**

Arthrocentesis of this joint is of moderate difficulty. Other approaches have been suggested but are less well accepted.

## Knee Joint, Anteromedial Approach (Fig. 57-6 (Figure Not Available) *A*)

**Landmarks.**

The medial surface of the patella at the middle or superior portion of the patella is the landmark for the knee joint.

**Position.**

The knee is fully extended as far as possible. Relaxation of the quadriceps muscle greatly facilitates needle placement. The foot is kept perpendicular to the floor.

**Needle insertion.**

An 18-ga needle or catheter and needle set is inserted at the midpoint or superior portion of the patella approximately 1 cm medial to the anteromedial patellar edge. The needle is directed between the posterior surface of the patella and the intercondylar femoral notch. The patella may be grasped with the hand and elevated (see Fig. 57-6 (Figure Not Available) *B*).

**Comments.**

If the patient is tense, contraction of the quadriceps will greatly hinder entering the joint. However, the knee is probably the easiest joint to enter. Removal of a tense hemarthrosis will relieve pain and facilitate examination for ligamentous injury. If fluid stops flowing, one should *squeeze the soft tissue area of the suprapatellar region to "milk" the suprapatellar pouch of fluid*. The knee can easily accommodate 50 to 70 mL of fluid, and the clinician should therefore be prepared to change syringes during the procedure. The knee is a common site for septic arthritis (especially gonococcal) and

various inflammatory or degenerative diseases. An anterolateral approach can be accomplished in a similar manner if the patella is approached laterally.

## Tibiotalar Joint (Ankle) (Fig. 57-7) (Figure Not Available)

**Landmarks.**

The medial malleolar sulcus is bordered medially by the medial malleolus and laterally by the anterior tibial tendon. The tendon can be easily identified by active dorsiflexion of the foot.

**Position.**

With the patient lying supine on the table, the foot is plantar flexed.

**Needle insertion.**

A 20-ga needle is inserted at a point just medial to the anterior tibial tendon and directed into the hollow at the anterior edge of the medial malleolus. The needle has to be inserted 2 to 3 cm to penetrate the joint space.

**Comments.**

If the joint bulges medially, one may use an approach that is more medial than anterior, entering at a point just anterior to the medial malleolus. The needle may have to be advanced 2 to 4 cm with this approach.

## Metatarsophalangeal and Interphalangeal Joints (Fig. 57-8) (Figure Not Available)

**Landmarks.**

For the first digit, landmarks are the distal metatarsal head and the proximal base of the first phalanx. For the other toes, the landmarks are the prominences at the proximal interphalangeal and distal interphalangeal joints. The extensor tendon of the great toe can be located by active extension of the toe.

**Position.**

With the patient supine on the table, the toes should be flexed 15° to 20°. *Traction is then applied.*

**Needle insertion.**

A 22-ga needle is inserted on the dorsal surface at a point just medial or lateral to the

central slip of the extensor tendon.

## SYNOVIAL FLUID INTERPRETATION

Synovial fluid examination is essential for the diagnosis of septic arthritis, gout, and pseudogout. Inflammatory joint disease of previously unknown etiology can often be diagnosed precisely by synovial fluid studies. Joint fluid is a dialysate of plasma that contains protein and hyaluronic acid. Normal fluid is clear enough to allow newsprint to be read through it, and it will not clot. Normal fluid is straw colored and flows freely, with the consistency of motor oil. Normal fluid produces a good mucin clot and gives a positive "string sign" (see next section). The uric acid level of joint fluid approaches that of serum, and the glucose concentration is normally at least 80% that of serum. A normal joint contains only a few milliliters of fluid. Clarity of fluid reflects the leukocyte count. High leukocyte counts result in opacity, the degree of which generally correlates with the degree of elevated synovial fluid leukocytes.

### String Sign

Viscosity correlates with the concentration of hyaluronate in the synovial fluid. Any inflammation degrades hyaluronate, characteristically resulting in low-viscosity synovial fluids. The string sign is a simple test for assessing viscosity. The

practitioner measures the length of the "string" formed by a falling drop extruded from a syringe of synovial fluid. Normal joint fluid produces a string of 5 to 10 cm (Fig. 57-9) . If viscosity is reduced, as in inflammatory conditions, the synovial fluid forms a shorter string or falls in drops.

### Mucin Clot Test

The mucin clot test also corresponds to viscosity and inflammation. Therefore, the greater the inflammatory response, the poorer the mucin clot and the lower the viscosity. The mucin clot test is useful to define the degree of polymerization of hyaluronate. Mucin clots are produced by mixing 1 part joint fluid with 4 parts 2% acetic acid. A good clot indicates a high degree of polymerization and correlates with normal high viscosity. In inflammatory synovial fluid, such as that seen in osteoarthritis and rheumatoid arthritis-related effusions, the mucin clot is poor. [29]

### Cell Count and Glucose

A leukocytosis consisting predominantly of neutrophils is usually seen with inflammatory arthritides; a white blood cell count >50,000/mm3 (i.e., >50,000/muL) is highly suggestive of a septic joint. Joint fluid glucose usually decreases as inflammation increases, but a proper interpretation requires a simultaneous blood glucose evaluation. A joint fluid-to-serum glucose ratio of <50% suggests a septic joint. Shmerling and coworkers [30] have found a white blood cell count of >2000/mm3 to be 84% sensitive and 84% specific for *all* inflammatory arthritides. Of their septic arthritis patients, 37% had a total white blood cell count <50,000/ mm3 . However, 89% of their patients with a

total white blood cell count >50,000/mm3 had a septic joint.

## Serology

The detection of succinic acid is helpful in identifying patients with septic arthritis who have received antibiotic treatment before arthrocentesis. [31] Gas-liquid chromatography, a rapid and sensitive method for the detection of short-chain fatty acids, may complement the currently available methods used to diagnose septic arthritis of synovial fluid. [32] Counterimmunoelectrophoresis and latex agglutination also are useful and are available in some centers on an emergency basis. Other immunologic markers such as complement, rheumatoid factor, and antinuclear antibodies have little diagnostic value in the acute setting but may be useful when compared to serum levels.

## Fluid Processing

Proper collection of the joint fluid is essential for examination and testing. Tests for viscosity, serology, and chemistries are done on fluid collected in a red-topped (clot) tube, whereas cytology samples are collected in tubes with an anticoagulant (purple top). One should always transfer the fluid for crystal examination into a tube with liquid heparin (green top), because undissolved heparin crystals from powdered anticoagulant tubes can be seen on microscopy. Early transfer of synovial fluid to this green-topped tube is essential to prevent clotting. Culture requirements for transport and processing should be accessed before the procedure to ensure appropriate processing or plating of specimens. A useful data form and summary of specimens developed by Alexander Trott, MD, of the University of Cincinnati is shown in Figure 57-10 (Figure Not Available) .

## Polarizing Microscope

No synovial fluid analysis is complete until the fluid has been examined under a polarizing light microscope for crystals. Microscopic analysis requires a compensated polarized light microscope with 10×, and 100× (oil immersion) objectives; a phase condenser and an oil immersion phase objective are highly recommended (Fig. 57-11) . The polarizing microscope used for crystal identification differs from the ordinary light microscope because it contains two identical polarizing prisms or filters. [33] One filter, called the *polarizer,* is positioned below the condenser. The other filter is called the *analyzer* and is inserted at some point above the objective. In some instruments these filters are mounted to permit horizontal rotation of the polarizer and analyzer. The mechanical stage of the polarizing microscope is mounted on a circular stage that rotates on a vertical axis coinciding with the center of the field; this allows the objective lens to be centered, keeping the specimen in the field of view. A removable first-order red compensator is located between the objective and the analyzer. All lenses and objectives are of "strain-free" (nonpolarizing) glass. Although these microscopes can be expensive, relatively inexpensive ones can be used and are quite adequate.

One can also obtain polarizing filters for insertion in a regular light microscope. One filter is placed between the light source and condenser; another is placed above the objective or in the eyepiece. The filters are rotated until a black field is obtained. This produces

the white birefringence that shows crystals more easily than ordinary light but cannot separate positive and negative birefringence.

## Polarization Physics

The polarizer allows passage of light in only 1 specific orientation. The analyzer acts as a crossed filter, removing all light in the light path unless the material being examined rotates the beam from the polarizer into the plane of the analyzer. The compensator functions by imparting color of a certain wavelength (red at about 550 nm). Birefringent materials change the wavelength to blue or yellow, depending on the direction (negative or positive) of refringence.

## Preparation of the "Wet Prep"

To prepare the "wet prep" for polarized microscopy, a drop of fluid is put on a clean slide, and a small coverslip is placed over the fluid. Sedimented or centrifuged "button" material is best, although any part of the specimen that ensures the drop contains cells, cellular debris, or unidentified material likely to contain crystals may be used. Liquid heparin should be the anticoagulant used, because undissolved powdered (crystalline) anticoagulants may appear as crystals under the microscope. Clear nail polish can be used to seal the coverslip over a specimen used for crystal analysis. This procedure preserves the slide and arrests fluid motion. The specimen is examined as noted subsequently.

## Viewing Techniques

Long periods of scanning can cause fatigue, frustration, and inaccurate observations. This can be prevented by appropriate viewing techniques. The most effective initial approach to a slide is scanning under low power (10✕) with compensated polarized light. One should vary the light intensity and adjust the condenser iris for better vision. The field should not be too light, because this will cause the crystals to be "washed out." With the naked eye, the test material or a bubble is placed on the stage in the center of the light path. If a small amount of specimen is present, this may be difficult to do. One approach is to place an ink dot on the underside of the slide and focus on this first, and then focus on the test material. If focusing to the correct depth is still difficult, one can focus on the edge of the coverslip. Frequently, trapped air bubbles, streaming cells, areas of increased cell concentration, or precipitated nail polish that is refractile along this edge will be of assistance with focusing.

Once focused on the slide's upper surface, scanning is performed under low power, looking for a cluster of cells and fibrils. Areas of clumping are scrutinized for regularly shaped material in or about the cells by rotating the microscope stage 90° back and forth while fine-focusing slightly up and down. The crystal length may be up to one tenth the diameter of a white blood cell. Thinking small will help identify crystals promptly.

To use the polarizer for crystal identification, one must use the compensator and adjust the light source and mirror to maximum light intensity. Both the polarizer and analyzer

are then engaged by pulling to the far right and adjusting both to 90°. The slide to be examined is placed on the stage and focused as noted earlier. At this point the background should be dark and the crystals bright white. If the background is not dark, the polarizer and the analyzer are adjusted as before. Crystals (preferably ones within leukocytes) are centered on the crosshairs. The compensator is engaged with lettering up. At this point the background should be red. Note that the X and Z axis are marked on the compensator. The stage is rotated so that the long axis of the crystal is parallel to the Z axis (the axis of slow vibration of the compensator). The color of the crystal is noted; the stage is rotated 90°, and the change in color of the crystal is again noted.

Although high dry magnification (40×) may confirm crystal identification, a complete examination should include evaluation under oil immersion (100× to 12.5× eyepiece or a total magnification of 100× to 1250× will achieve an optimal two-point discrimination of 0.5 to 1.0 mm). Often a fluid that initially appears to have only a few crystals or none at all is found to have a large population of small crystals or a second, different crystal population.

Thorough searching of many cellular clumps with a variation of light and condenser settings may be needed to find the thin, flat crystals of intracellular calcium pyrophosphate. A phase oil immersion objective (100×) is helpful in this situation. Once one crystal is identified, others are sought to confirm the findings. One should estimate the number of crystals of each type that are present as "few," "moderate," or "many" and what percentage are intracellular and extracellular. A systematic scan is necessary for this until one is satisfied that a fair estimate is possible. These data are helpful and relate to the acuteness of the arthritic process.

| TABLE 57-3 -- Synovial Fluid Interpretation | | | | |
|---|---|---|---|---|
| Diagnosis | Appearance | WBCs/mm3 | Polymorphonuclear Leukocytes | Glucose: % Blood Level |
| Normal | Clear | <200 | <25 | 95-100 |
| Degenerative joint disease | Clear | <4000 | <25 | 95-100 |

| | | | | |
|---|---|---|---|---|
| Traumatic arthritis | Straw-colored, bloody,xanthochromic,occasionally with fat droplets | <4000 | <25 | 95-100 |
| Acute gout | Turbid | 2000-50,000 | >75 | 80-100 |
| Pseudogout | Turbid | 2000-50,000 | >75 | 80-100 |
| Septic arthritis | Purulent/turbid | 5000->50,000 | >75 | <50 |
| Rheumatoid arthritis/ seronegative arthritis (Reiter disease, psoriatic arthritis, ankylosing spondylitis, inflammatory bowel disease) | Turbid | 2000-50,000 | 50-75 | 75 |

W BC, White blood cell.

* Negative birefringence means that crystals appear yellow when lying parallel to the axis of the slow vibration of light of the first-order red compensator. With the same orientation to the compensator, positive birefringence crystals appear blue. When the crystals lie perpendicular to the axis, the opposite is true--that is, negative birefringence crystals are blue, and positive ones are yellow. A polarizing microscope is necessary for this distinction to be made.

May be coexisting infection.

Occasionally, a joint fluid specimen has so few cells and such sparse extracellular material that centrifugation of the fluid and microscopic examination of the button are necessary. When these are done, one must record that the results were obtained from a concentrated specimen to avoid confusion.

**Microscopic Analysis**

If the long axis of the crystals is blue when parallel to the Z axis and yellow when perpendicular to it, it is calcium pyrophosphate and is termed *positively birefringent.* If the long axis of the crystal is yellow when parallel to the Z axis and blue when perpendicular to it, it is monosodium urate and is termed *negatively birefringent.* Urate crystals are 2 to 10 mum and are usually needle shaped. Calcium pyrophosphate crystals range from 10 mum down to tiny crystals that have to be examined with the oil objective; they appear as rods, rhomboids, plates, or needle-like forms and are weakly birefringent. Cholesterol crystals are sometimes seen and are large, very bright, square, or rectangular plates with broken corners.

Items found in synovial fluid that can be confused with sodium urate (Fig. 57-12) (Figure Not Available) or calcium pyrophosphate crystals (Fig. 57-13) (Figure Not Available) include collagen fibrils, cartilage fragments (Fig. 57-14) (Figure Not Available) , cholesterol crystals (Fig. 57-15) (Figure Not Available) , metallic fragments from prosthetic arthroplasty, and corticosteroid esters. [32] One may also identify fat globules (Fig. 57-16 (Figure Not Available) *A* and *B*). Note that rare cases of uric acid spherulites in gouty synovia have been reported.  The spherulites are birefringent and do not take up fat stains.

Table 57-3 summarizes synovial fluid features for the joint diseases commonly encountered and studies commonly performed in the emergency department.

## CONCLUSION

When performed correctly, arthrocentesis is a relatively safe procedure that is used to obtain valuable diagnostic information as well as to provide therapy for acute joint disease. The key to success is strict adherence to sterile technique, observance of anatomic landmarks, and proper preparation of the synovial fluid for examination.

# Chapter 58 - Compartment Syndrome Evaluation

**Lawrence B. Stack**

Compartment syndrome is a condition of increased pressure within a limited space that results in compromised tissue perfusion and ultimate dysfunction of neural and muscular structures contained within that space. [1] This is manifest clinically by pain (usually out of proportion to the injury), worsening of the pain with passive stretch of the involved muscles, paresthesias in the distribution of the involved nerves, paresis or paralysis of the involved muscles, and palpable tenseness of the involved compartment. It should be stressed that *severe pain may be the only sign or symptom in patients with compartment syndrome.* [1] Compartment syndrome requires prompt recognition and treatment for optimal outcome. One theory that explains how increasing tissue pressure compromises local blood flow is the "arteriovenous gradient theory," [2] which proposes that increased tissue pressure decreases the arteriovenous gradient and, hence, blood flow. [1] When blood flow is reduced to a level at which metabolic demands of the tissues are not met, dysfunction of those tissues occurs and a compartment syndrome ensues.

Although compartment syndrome is relatively uncommon, recognition of this process has increased with greater physician awareness of its clinical features. The lower leg and forearm are the most frequent locations of compartment syndrome [1] ; however, gluteal, hand, foot, upper arm, thigh, and back compartment syndromes are being reported with increasing frequency. Causes of compartment syndrome have been categorized into those that decrease compartment volume, increase compartment content, or create externally applied pressure. [1] If left untreated, compartment syndrome may result in permanent neurologic-muscular dysfunction and extremity deformity or lead to shock or renal failure if myonecrosis is extensive. [3]

The differential diagnosis of compartment syndrome includes neuropraxia, arterial injury, cellulitis, osteomyelitis, tenosynovitis, synovitis, and thrombophlebitis. Nerve and arterial injury may coexist with compartment syndrome. Differentiating compartment syndrome from these disease processes may be difficult even for the experienced clinician. Although compartment syndrome is a clinical diagnosis, objective measurement of compartment tissue pressure may help confirm the diagnosis and determine if operative treatment is required. This chapter discusses the indications, complications, and interpretation of compartment pressure monitoring. The equipment and techniques required to perform compartment pressure monitoring are described.

## BACKGROUND

Post-ischemic myoneural dysfunction and contractures were first described in the 1870s by Von Volkmann. [4] In 1935, Henderson and associates developed an open-needle technique

for measuring muscle "tonus." [5] Their method consisted of the 3-way connection of a syringe, a manometer, and a needle placed into the muscle itself. In the 1960s, the technique was applied to muscle compartment pressure measurement. In 1975,

Whitesides and colleagues refined the technique and described its ability to accurately reflect muscle compartment pressures. [6] They also related elevated pressures to a need for fasciotomy to relieve a compartment syndrome.

Other investigators were less confident in the reproducibility of the intermittent readings. In 1976, Matsen and coworkers modified the technique to include a constant infusion pump that allowed for prolonged, continuous monitoring. [7] Mubarak and associates objected to the modification made by Matsen and coworkers, because the continuous infusion method injected more fluid into a compartment already compromised with increased pressure. [8] Modifying a technique developed by Scholander and colleagues [9] for fluid monitoring in plants, Mubarak and associates showed that a "wick" catheter accurately reflected compartment pressures in humans. [7] [10] This method proved to be as reproducible as the infusion technique. Objections subsequently arose to the degeneration of the biodegradable wick as a source of error and to the potential for retaining the wick on removal of the catheter. Rorabeck and colleagues developed a "slit" catheter to replace the wick. [11] Accuracy and reproducibility of the wick and the slit catheter techniques have been similar. In the mid-1980s, a solid-state transducer intracompartmental (S.T.I.C.) catheter was developed. This device, produced by Millar Instruments (Houston), is a catheter with a built-in pressure transducer that does not require saline-filled tubing to transmit the compartment pressure to an external transducer. [14] Arterial line transducer monitoring systems have been used for acute monitoring of compartment pressure, although no study has been conducted to describe the accuracy of this technique. The Stryker intracompartmental pressure monitoring system (Kalamazoo, Mich) is a solid-state handheld device that is currently available for temporary or continuous compartment pressure monitoring.

## PATHOPHYSIOLOGY OF COMPARTMENT SYNDROME

Pressure studies clearly show a linear relationship between increased tissue pressure and decreased blood flow. [1] These data argue against a critical "closure" pressure of compartment vessels or a microvascular occlusion mechanism. The most acceptable theory for the reduced perfusion relates local blood flow to the arteriovenous pressure gradient: the greater the gradient, the greater the blood flow. ] In this model, veins are easily collapsed, and therefore venous pressure can be no lower than tissue pressure. As tissue pressure increases, venous pressure increases. Without a concomitant increase in arterial pressure, the arteriovenous gradient, and hence local blood flow, decreases. When local blood flow fails to meet metabolic needs, ischemia causes tissue dysfunction, and a compartment syndrome follows. This theory accounts for observed exacerbations of compartment syndromes by decreased arterial pressure such as that occurring with systemic hypotension or elevation of a limb. These relationships have been explored and upheld in several tissue pressure studies.  In an elegant evaluation by Heppenstall and colleagues, nuclear magnetic resonance analysis of muscle cell phosphorus metabolism confirmed the relationship between arteriovenous gradient (perfusion pressure) and cellular ischemia. [19]

Early in the syndrome, the dysfunction is reversible if conditions are changed. Histologic studies have shown that as ischemia continues, degeneration and necrosis occur. [20] As cell death occurs, edema may further exacerbate the pressure problem, and the entire

process may become worse. If the situation has progressed to this point, some permanent dysfunction is inevitable. Early attention to ischemic symptoms, coupled with pressure measurements, helps identify this syndrome and leads to early therapy and potential avoidance of these sequelae.

## CLINICAL PRESENTATION

Even experienced personnel may find it difficult to evaluate a potential compartment syndrome, because the time of onset is extremely variable. Matsen and Clawson have found the onset of symptoms to range from 2 hours to 6 days after the insult. [21] The peak time seems to be 15 to 30 hours (Fig. 58-1) .

The limiting envelope required to produce a compartment syndrome may include fascia, skin, casts, external dressings, or even epimysium alone. [1] General categories for the many sources of increased pressure within these envelopes include decreased compartment volume, increased compartment contents, and externally applied pressure. Table 58-1 (Table Not Available) lists the reported causes in each category. Because of the nature of the limiting envelopes and the acknowledged causes, compartment syndromes are most commonly seen in the extremities. The lower leg is at high risk because of its propensity for injury and the existence of several low-volume compartments. It is interesting to note that lumbar paraspinal compartment syndrome may represent an unusual presentation of low back pain. [22]

The essential elements that constitute the diagnosis of compartment syndrome are revealed in its definition: a condition of increased pressure within a limited space that results in compromised tissue perfusion and ultimate dysfunction of neural and muscular structures contained within that space. Clinical history is the first step in the evaluation of an injury or condition that may produce a compartment syndrome, and it may reveal the etiology (see Table 58-1) (Table Not Available) . Clinical examination confirms the diagnosis when there is clear evidence of increased tissue pressure, inadequate tissue perfusion, and loss of tissue function. The diagnosis is less certain when one or more of these factors is absent. [1] Signs and symptoms resulting from locally decreased tissue perfusion are pain and neurologic dysfunction. Evidence of dysfunction forms the basis for the physical diagnosis.

Often the first symptom described by the patient is pain greater than expected for a given clinical situation. Pain often increases with the passive stretching of muscles in the involved compartment. The muscles also may be weak in comparison to normal. Hypesthesia may be present in the distribution of nerves and tenseness may be palpable in the involved compartment. Decreased vibratory sensation may be one of the earliest sensory findings. [23] These findings usually progress during a period of observation. As a rule, *the presence or absence of arterial pulsation is not an accurate indicator of increased tissue pressure*; pulses may be present in a severely compromised extremity compartment. [24] When pulses are obliterated distally, irreversible damage has often occurred. Table 58-2 lists symptoms and signs of the respective compartments when compartment syndrome is suspected.

Patients who have an altered mental status and younger, uncooperative patients may

make the interpretation of neuromuscular signs difficult. In addition, casts or bulky dressings may make careful examination impossible. Attributing the signs and symptoms to other pathologic entities is also a problem (Table 58-3) (Table Not Available) . Primary nerve and muscle injuries can produce similar findings, but the deficit should be maximal

| **TABLE 58-2** -- Compartment Syndromes and Associated Physical Signs | | | | |
|---|---|---|---|---|
| **Compartment** | **Sensory Loss** | **Muscles Weakened** | **Painful Passive Motion** | **Tenseness Location** |

| *Foot* | Digital nerves | Foot intrinsics | Toe flexion/extension | Dorsal/plantar foot |
| *Lumbar* | -- | Erector spinae | Lumbar flexion | Paraspinous |

initially and should not progress. Arterial injuries and subsequent ischemia may produce pain and dysfunction, although neurologic changes may be less pronounced unless secondary edema produces a compartment syndrome. Thrombophlebitis [25] and cellulitis [21] must also be considered in the differential diagnosis. Pain out of proportion to obvious injury may raise the issue of drug-seeking behavior, but a focused evaluation

for potential compartment syndrome should precede such a diagnosis.

## INDICATIONS FOR INVASIVE (COMPARTMENT PRESSURE) MONITORING

The earliest manifestation of acute compartment syndrome is an elevated tissue pressure. Signs and symptoms occur after tissue pressure has been elevated beyond a critical time period. Measurement of this pressure allows earlier diagnosis and treatment. In some patients, the diagnosis of compartment syndrome is clinically obvious, and one can proceed directly to fasciotomy. However, when clinical findings are equivocal or difficult to interpret, tissue pressure measurement may help guide treatment (Fig. 58-2) (Figure Not Available) . Three groups of patients for whom clinical findings are difficult to interpret, and who may benefit from compartment pressure measurement, are unresponsive patients, uncooperative patients (such as children or intoxicated patients), and patients with peripheral nerve deficits attributable to other causes (e.g., tibial fracture with peroneal nerve injury).

## PATIENT PREPARATION

Patient preparation includes obtaining informed consent when appropriate, positioning the patient and extremity for optimal results, performing skin preparation at the site of needle introduction, local anesthesia, and conscious sedation when necessary. Because compartment pressure monitoring is an invasive procedure with potential complications and may require conscious sedation and possibly an operative procedure, informed consent should be obtained from the patient or guardian, using standard hospital forms. The patient's clinical status and lack of availability of family may prohibit formal written consent in some circumstances.

Patient and extremity position for compartment pressure measurement depends on the extremity being studied, the compartment being studied, and presence of coexisting injury. Patients should be comfortable, usually in the supine or prone position, and the compartment to be measured should be at the same level as the heart. The patient and extremity should be positioned to allow the needle to be introduced perpendicular to the muscular compartment being measured. Any obstructions to the needle entry point into the skin and all structures that may put pressure on the compartment and falsely elevate the pressure should be removed. That is, the extremity of the compartment being measured should be positioned so that no external pressure is applied to that compartment. This may require that the extremity be held slightly above the stretcher by an assistant.

Once the location for needle placement has been identified, preparation of the skin should be conducted as for any sterile procedure. Care should be taken to avoid needle placement in areas in which the overlying skin is possibly infected, to avoid introduction of bacteria into deep tissues. If an overlying cast is present, it should be bivalved, and if necessary, a window overlying the desired area of needle penetration should be cut from the cast. The skin should be anesthetized with a small amount of local anesthetic, with care taken to avoid injection into muscle or fascia. Excessive, deep infiltration may

falsely elevate the compartment pressure reading.

Conscious sedation should be considered in any patient who may be uncooperative and unable to hold the extremity still during the procedure. Any struggling or movement that requires restraint of the extremity may falsely elevate the compartment pressure. Short-acting narcotics or benzodiazepines are ideal because of their brief duration of action and the availability of specific antagonists (see Chapter 35) . Caution should be taken because these agents may blunt the pain and paresthesias that are paramount in the diagnosis of compartment syndrome. The benefits of accurate pressure measurement must be weighed against obliterating these clinical findings for the duration of sedation.

## TISSUE PRESSURE MONITORING

The methods described in this chapter focus on the acute compartment pressure measurement with equipment commonly found in the emergency department (ED) or intensive care setting. These include the mercury manometer system, [18] arterial line system, and the Stryker 295 intracompartmental pressure monitor system (Fig. 58-3) (Figure Not Available) . All techniques are based on the premise that pressure is equal in an open system. The described methods provide rapid compartment pressure measurement with acceptable accuracy. Although the mercury manometer system is the least expensive and most readily available, it is also the least accurate and its results are the least reproducible. [1]

Devices commercially available for placement into the compartment for pressure measurement include the simple 18-ga needle, 18-ga spinal needle for deep compartments, the side-port needle (Stryker Instruments, Kalamazoo, Mich), wick catheter, slit catheter, and the solid-state transducer intracompartmental catheter (S.T.I.C.). The latter 3 devices are generally not available to most EDs and are discussed only briefly. All pressure measurement systems described above can be used with the simple 18-ga needle, 18-ga spinal needle, and the side-port needle. The side-port needle and slit catheter have comparable accuracy when used for compartment pressure measurement. [26]

### Mercury Manometer System

#### Equipment

> 2 18-ga needles (or spinal needles)
>
> 2 plastic extension tubes
>
> 1 20-mL syringe
>
> 1 3-way stopcock
>
> 1 vial of sterile normal saline

1 mercury manometer

1. The patient and extremity are prepared according to the guidelines above.
2. The syringe, tubing, extension tubing, and needle are assembled as shown in Fig. 58-4 (Figure Not Available) *A*.
3. The needle is inserted into a vented vial of sterile saline. A column of saline is aspirated into the tubing halfway to the stopcock; care should be taken to avoid bubble formation. The 3-way stopcock is turned to close off this tube to avoid losing saline during movement of the needle into the patient.
4. The needle is inserted into the muscle of the desired compartment (see Needle Placement for details).
5. The second extension tubing is attached to the monitor and to the third port of the 3-way stopcock. The stopcock is turned so that the syringe is open to both extension tubes (Fig. 58-4 (Figure Not Available) *B*). This closed system has equal pressure in both extension tubes.
6. The pressure in the system is increased gradually by *slowly* depressing the syringe plunger while simultaneously watching the column of saline. The mercury manometer will rise as the pressure in the system rises. When the pressure in the system exceeds the tissue pressure, saline is injected into the compartment, causing the saline column to move. The manometer is read at the time at which the saline moves. This reading corresponds to the tissue pressure in millimeters of mercury.
7. A second reading should be obtained by completely removing the needle and repeating steps 4 to 6. A third

   measurement may be necessary to get 2 readings in agreement. The needle should be checked between readings for tissue plugs and blood clots.

**Procedural Pearls**

The most common error with this system is depressing the syringe plunger too quickly. Only when the saline is slowly injected into the compartment will the mercury column (which has greater inertia) accurately reflect the compartment pressure. Another source of error with this system is obstruction of the needle with a plug of tissue if the syringe plunger is pulled back. Finally, aneroid manometers are not calibrated at lower pressure ranges and should not be substituted for the more accurate mercury manometers.

## Arterial Line System

**Equipment**

Intracompartment needle

High-pressure tubing

Pressure transducer with cable

Pressure monitor/module

Sterile saline

Transducer stand that allows variable height

2 3-way stopcocks

1 20-mL syringe

**Setup and Procedure**

1. The patient and extremity are prepared according to the guidelines above.
2. The transducer cable is connected to the pressure monitor/module.
3. The stopcocks, transducer, transducer cable, syringe, high-pressure tubing, and needle are assembled as in Figure 58-5 (Figure Not Available) .
4. The syringe is filled with 15 mL of sterile saline and placed on 1 stopcock. The stopcocks are turned to allow filling of the transducer, high-pressure tubing, and needle. The stopcock to the high-pressure tubing is then closed.
5. The top stopcock is opened to air and the transducer placed at the height of the compartment to be measured. The transducer is calibrated to zero and the top stopcock closed.
6. The lower stopcock to the high-pressure tubing is opened and the needle is inserted into the muscle of the desired compartment (see Needle Placement for details). Appropriate placement is determined by digitally compressing the compartment or passively moving the muscles within the compartment. The compartment is allowed to equilibrate for several seconds after this maneuver, and the *mean* pressure is measured.
7. A second reading should be obtained by completely removing the needle and repeating steps 4 through 6. A third measurement may be necessary to get 2 readings in agreement. The needle should be checked between readings for tissue plugs and blood clots.

## Stryker 295 Intracompartmental Pressure Monitor System

**Equipment**

Handheld pressure monitor

Stryker 295 quick-pressure monitor set (disposable pouch)

1 prefilled syringe with saline

1 side-port needle

1 diaphragm chamber

**Setup and Procedure**

1. The 295 quick-pressure monitor set (disposable) is opened, and contents are removed, maintaining appropriate system sterility.
2. The needle is placed firmly on the tapered chamber stem (Fig. 58-6 (Figure Not Available) *A*).
3. The blue cap on the prefilled syringe is removed and screwed onto the remaining chamber stem (Fig. 58-6 (Figure Not Available) *A*). Care must be maintained to not contaminate the fluid pathway.
4. The cover of the monitor is opened. The chamber is placed in the device well (black surface down) and pushed gently until it seats (Fig. 58-6 (Figure Not Available) *B*).
5. The cover is snapped closed-- *NOT FORCED*. The latch must have "snapped" in place.
6. The clear end cap is pulled off the syringe and the plunger rod is attached to the syringe.
7. The needle is held at approximately 45° up from horizontal while fluid is slowly forced through the disposable system to purge it of air. *Caution:* Saline *MUST NOT* roll down the needle into the transducer well.
8. The unit is turned on and should read between 0 and 9 mm Hg.
9. The intended angle of insertion of the needle into the skin is approximated while the "zero" button is pressed. The display should read "00" (Fig. 58-6 (Figure Not Available) *C*). *Note:* The display must read "00" before continuing. If it does not, troubleshooting using that section of the maintenance manual should be undertaken.
10. The needle is inserted into the compartment (see Needle Placement for details). Less than 0.3 mL of saline should be slowly injected into the compartment for equilibration with interstitial fluids.
11. The pressure is read after the display reaches equilibrium.
12. *For additional measurements:* The unit is turned off and steps 8 through 11 are repeated. The unit must be recalibrated to zero before each measurement.

## NEEDLE PLACEMENT TECHNIQUES

### General Principles

Once the decision to perform compartment pressure measurement has been made, the approach for needle placement and confirmation of correct placement must be considered. The requirements for a useful approach include: (1) reliable placement in the compartment to be measured; (2) avoidance of important neurovascular structures; (3) simplicity and reproducibility; and (4) minimal discomfort to the patient. [27] Most compartments are superficial and are easily accessible. Only the deep posterior compartment of the lower leg and the gluteal compartment may require deeper needle placement (spinal needle). Most approaches allow the needle to enter perpendicular to the skin. Figures 58-7 through 58-18, in conjunction with the text, provide landmarks for

proper needle placement and passage to ensure proper compartment placement and avoidance of neurovascular structures.

## Lower Leg

The lower leg traditionally has 4 compartments [1] : anterior, lateral, deep posterior, and superficial posterior (Fig. 58-7) . However, it has been theorized that the tibialis posterior muscle is contained within a separate osseofascial muscle compartment, [28] creating a fifth compartment of the lower leg. This chapter considers the tibialis posterior as part of the deep posterior compartment. The lower leg, especially the anterior compartment, is predisposed to compartment syndrome because of its high vulnerability to injury and the relatively limited compartment compliance. The anterior compartment was the most frequent site of compartment syndrome in one patient population. [28]

The easiest cross-sectional level for needle placement for all 4 compartments is approximately 3 cm on either side of a transverse line drawn at the junction of the proximal and middle thirds of the lower leg (Figs. 58-8 (Figure Not Available) to 58-11). When measuring the leg compartment pressures, the patient should be placed in the supine position with the leg at heart level (however, when measuring the superficial posterior compartment, the patient should be prone). Patient preparation should be performed as previously described.

### Anterior Compartment

With the patient supine, the anterior border of the tibia is palpated at the level of the junction of the proximal and middle thirds of the lower leg (see Fig. 58-8 (Figure Not Available) *A*). The needle entry point is 1 cm *lateral* to the anterior border of the tibia. The needle should be directed perpendicular to the skin to a depth of 1 to 3 cm (see Fig. 58-8 (Figure Not Available) *B*). Proper needle placement can be confirmed by seeing a rise in pressure during (1) digital compression of the anterior compartment just proximal or distal to the needle insertion site, (2) plantar flexion of the foot, and (3) dorsiflexion of the foot. These maneuvers should produce a several-fold rise in pressure on the monitor.

### Deep Posterior Compartment

With the patient supine, the leg should be slightly elevated off the stretcher if the clinical situation permits. The medial border of the tibia is palpated at the level of the junction of the proximal and middle thirds of the lower leg. The needle entry point is just posterior to the medial border of the tibia (see Fig. 58-9 (Figure Not Available) *A*). The posterior border of the fibula should be palpated on the lateral aspect of the leg at the same level. The needle path should be perpendicular to the skin and directed toward the palpated posterior border of the fibula to a depth of 2 to 4 cm, depending on the amount of subcutaneous fat (see Fig. 58-9 (Figure Not Available) *B*). Proper needle placement can be confirmed by seeing a rise in pressure during (1) toe extension and (2) ankle eversion.

**Lateral Compartment**

With the patient supine, the leg should be slightly elevated off the stretcher if the clinical situation permits. The posterior border of the fibula is palpated at the level of the junction of the proximal and middle thirds of the lower leg. The needle entry point is just anterior to the posterior border of the fibula (see Fig. 58-10 (Figure Not Available) *A*). The needle path should be perpendicular to the skin and directed toward the fibula to a depth of 1 to 1.5 cm (see Fig. 58-10 (Figure Not Available) *B*). If the needle contacts bone, the needle should be retracted 0.5 cm. Proper needle placement can be confirmed by seeing a rise in pressure during (1) digital compression of the lateral compartment just inferior or superior to the needle entrance site and (2) inversion of the foot and ankle.

**Superficial Posterior Compartment**

With the patient prone and the leg at heart level, a transverse line at the level of the junction of the proximal and middle thirds of the lower leg is identified. The needle entry point is at this level and 3 to 5 cm on either side of a vertical line drawn down the middle of the calf (see Fig. 58-11 (Figure Not Available) *A*). The needle path should be perpendicular to the skin and directed toward the center of the lower leg to a depth of 2 to 4 cm (see Fig. 58-11 (Figure Not Available) *B*). Proper needle placement can be confirmed by seeing a rise in pressure during (1) digital compression of the superficial posterior compartment just inferior or superior to the needle entrance site and (2) foot dorsiflexion.

## Forearm

The forearm traditionally has 2 compartments, [1] volar and dorsal, which are divided by the interosseus membrane. However, some authors place the extensor carpi radialis longus, extensor carpi radialis brevis, and brachioradialis muscles into their own compartment, called the "mobile wad." [29] The latter group of muscles is considered a separate compartment in this chapter. The forearm compartments are predisposed to compartment syndrome, especially the volar compartment, because of their use during vigorous exercise, accessibility for drug injection, and vulnerability to burns. [1]

The junction of the proximal and middle thirds of the forearm is the cross-sectional level for needle insertion (Fig. 58-12) (Figure Not Available) . [27] When measuring forearm compartment pressures, the patient should be placed in the supine position with the arm at heart level. Patient preparation should be performed as described previously.

**Volar Compartment**

The forearm should be held in supination. The palmaris longus tendon is identified and its course traced proximal to the level of the junction of the proximal and middle thirds of the forearm. The posterior border of the ulna is palpated. The needle entry point is just medial to the palmaris longus (Fig. 58-13 (Figure Not Available) *A*). The needle path

should be perpendicular to the skin and directed toward the palpated posterior border of the ulna to a depth of 1 to 2 cm (g. 58-13 *B*). Proper needle placement can be confirmed by seeing a rise in pressure during (1) digital compression of the volar compartment just proximal or distal to the needle entry point and (2) extension of the fingers or wrist.

**Dorsal Compartment**

The forearm should be held in supination with the elbow flexed, allowing the dorsum of the forearm to face downward. The posterior aspect of the ulna is palpated at the level of the junction of the proximal and middle thirds of the forearm. The needle entry point is 1 to 2 cm lateral to the posterior aspect of the ulna (Fig. 58-14 (Figure Not Available) *A*). The needle should be directed perpendicular to the skin to a depth of 1 to 2 cm (Fig. 58-14 (Figure Not Available) *B*). Proper needle placement can be confirmed by seeing a rise in pressure during (1) digital compression of the dorsal compartment just proximal or distal to the needle entry point and (2) flexion of the fingers or wrist.

**Mobile Wad**

The forearm should be held in supination. The most lateral portion of the forearm is identified at the level of the junction of the proximal and middle thirds. The needle entry point is the muscle tissue lateral to the radius. The needle should be directed perpendicular to the skin (Fig. 58-15 (Figure Not Available) *A*) and inserted to a depth of 1 to 1.5 cm (Fig. 58-15 (Figure Not Available) *B*). Proper needle placement can be confirmed by seeing a rise in pressure during (1) digital compression of the mobile wad just proximal and distal to the needle entry point and (2) ulnar deviation of the wrist.

## Gluteal Musculature

The gluteal musculature is enclosed by an enveloping fascia that splits into 2 layers and encases the muscle bellies of the tensor fascia lata anteriorly and gluteus maximus posteriorly. This fascia divides the musculature into 3 distinct compartments: maximus, tensor, and medius/minimus (Fig. 58-16) (Figure Not Available) . The sciatic nerve is deep to the fascia but lies between the pelvis-external rotator complex and the gluteus maximus, making it susceptible to injury in compartment syndrome of the gluteus maximus. Most reported cases of gluteal compartment syndrome result from prolonged immobilization and local compression in association with drug or alcohol intoxication. [30] Gluteal compartment syndrome is rare, making the diagnosis difficult, as local tenderness is often attributed to contusion or hematoma. Rhabdomyolysis should be considered in patients with gluteal compartment syndrome because of the large muscle mass that may be injured.

**Gluteal Compartments**

The patient should be placed in the prone position with the buttocks at heart level. Patient preparation should be performed as described previously. Cutaneous landmarks for the 3 compartments are not consistent from patient to patient. In all cases of suspected gluteal compartment syndrome, the needle insertion point can be at the point

of maximal tenderness. [30] An 18-ga spinal needle should be used. The needle should be directed perpendicularly to the skin toward the point of maximum tenderness to a depth of 4 to 8 cm. Proper needle placement is confirmed by seeing a rise in pressure during digital compression of the gluteal musculature.

## Foot

Compartment syndrome of the foot is rare, but it is being reported with increasing frequency as physicians become more aware of the disease process. The 4 compartments of the foot as seen from a coronal section at the base of the first metatarsal are the central, interosseous, medial, and lateral compartments (Fig. 58-17) (Figure Not Available) . The foot is vulnerable to isolated extremity injury by virtue of its location. Most compartment syndromes in the foot are the result of crushing forces.

When measuring compartment pressures in the foot, the patient should be placed in a supine position with the foot at the level of the heart. [31] Patient preparation should be performed as described previously.

### Medial Compartment

The medial compartment contains the abductor hallucis and flexor hallucis brevis muscles and is bounded medially and inferiorly by the extension of the plantar aponeurosis, laterally by an intermuscular septum, and dorsally by the first metatarsal (Fig. 58-18 (Figure Not Available) *A*). The medial aspect of the base of the first metatarsal is palpated. The needle entry point is the medial aspect of the foot just inferior to the base of the first metatarsal and into the abductor hallucis muscle. [32] The needle is advanced to a depth of 1 to 1.5 cm. Proper needle placement is confirmed by seeing a rise in pressure during digital compression of the medial compartment of the foot.

### Central Compartment

The central compartment contains the flexor digitorum brevis, the quadratus plantae, the lumbricals, and the abductor hallucis muscles. Its boundaries are the plantar aponeurosis inferiorly, the osseofascial tarsometatarsal structures dorsally, and the intermuscular septa medially and laterally. The medial aspect of the base of the first metatarsal is palpated. The needle entry point is the medial aspect of the foot just inferior to the base of the first metatarsal and through the abductor hallucis muscle. The needle is advanced to a depth of 3 cm. [32] Proper needle placement is confirmed by seeing a rise in pressure during digital compression of the central compartment of the foot.

### Lateral Compartment

The lateral compartment contains the abductor, flexor, and opponens muscles of the fifth toe. The boundaries are the fifth metatarsal dorsally, the plantar aponeurosis inferiorly and laterally, and an intermuscular septum medially. [33] The base of the fifth

metatarsal is palpated. The needle entry point is just inferior to the base of the fifth metatarsal (Fig. 58-18 (Figure Not Available) *B*). The needle should be directed parallel to the plantar aspect of the foot to a depth of 1 to 1.5 cm. Proper needle placement is confirmed by seeing a rise in pressure during digital compression of the lateral compartment of the foot.

**Interosseous Compartment**

The interosseous compartment contains the 7 interossei muscles and is bounded by the metatarsals and the interosseous fascia. The dorsum of the bases of the metatarsals are palpated and the second and fourth web spaces are identified. The first web space is avoided to prevent inadvertent puncture of the dorsalis pedis or deep peroneal nerve. [32] The needle entry point is the dorsum of the second and fourth web spaces at the metatarsal bases (Fig. 58-18 (Figure Not Available) *C*). The needle is directed perpendicularly to the skin to a depth of 1 cm. [32] Proper needle placement is confirmed by seeing a rise in pressure during digital compression of the interosseous compartment adjacent to the needle entry point.

## COMPLICATIONS

All of the procedures described have a similar risk of infection, both local and systemic; exact risk figures are unavailable. Strict adherence to aseptic technique, careful sterilization of catheters, and use of sterile, disposable components whenever possible help to minimize this risk.

All monitoring procedures cause some pain. The pain associated with the actual insertion of needles and catheters may be reduced by local anesthesia. Caution is advised to avoid injections into the compartment, which might result in inaccurate readings or further increases in tissue pressure. Once inserted and secured, the needle or catheter should produce only minimal discomfort. However, the injection of saline into an already tense compartment may produce further discomfort. Reassurance and systemic analgesia may be required to gain the cooperation necessary for accurate readings. Technically, the injection of fluid may actually exacerbate a compartment syndrome. Whitesides and colleagues found an increase in compartment pressure of 1 mm Hg for each milliliter of saline infused into human anterior leg compartments. [6] It is difficult to assess the relevance of this problem, but recognition of the potential for its occurrence is important.

## INTERPRETATION

When properly performed, each method has an acceptable accuracy in the clinical setting. Investigators report standard deviations from 2 to 6 mm Hg with any of the techniques.   It is generally agreed that the mercury manometer system is the least accurate. The arterial line system used with a simple or side-port needle provides a high degree of accuracy for simple, episodic readings. The Stryker intracompartmental pressure monitor system provides consistent, accurate readings for episodic and

extended monitoring situations.

Reports of normal human compartment pressures vary in the literature. In comparing several techniques, Shakespeare and associates found an average pressure of 8.5 mm Hg. [12] Other investigators have found similar pressures with a range from 0 to 16 mm Hg. Shakespeare and

associates found higher pressures in individuals who were physically fit.

Hargens and coworkers found dog muscle capillary pressures to be 20 to 30 mm Hg. [18] Whitesides and associates showed a significant decrease in tissue perfusion when compartment pressures rose to 10 to 30 mm Hg below diastolic blood pressure. [6] Mubarak and colleagues showed that tissue pressures of 30 mm Hg closely corresponded to the onset of pain and paresthesias. [10] Therefore, a tissue pressure of 25 to 30 mm Hg is abnormal but does not necessarily precipitate a compartment syndrome in the absence of other factors.

Some variability seems to exist among patients for tolerance of increased pressures. Matsen found that no patients with pressures of less than 45 mm Hg had symptoms of compartment syndrome, whereas all patients with pressures greater than 60 mm Hg had symptoms. [1] Heppenstall and colleagues used phosphorus metabolism to study perfusion pressures and anaerobic metabolism in skeletal muscle. Cellular injury was confirmed by electron microscopy. Their results confirm that cellular perfusion is dependent on the pressure differential (DeltaP). This value is obtained by subtracting the compartment tissue pressure from the mean arterial blood pressure. Anaerobic metabolism became significant in normal muscle when the DeltaP was 30 mm Hg or less. More important, in traumatized muscle (in which metabolic demands are greater), the critical DeltaP was 40 mm Hg. [19] Factors other than compartment pressure alone may become important. Situations in which the mean arterial pressure is lowered (e.g., hypovolemia) may compromise a patient's ability to tolerate even mildly elevated compartment pressures. Zweifach and associates showed that there is significant muscle damage with tissue pressure at 20 mm Hg in the presence of a systemic blood pressure at 65 mm Hg. [17] Duration of increased pressure is also important. Matsen found that 12 hours of increased pressure reliably produces deficits. [1] One series showed that none of the patients undergoing fasciotomy for compartment syndrome before the passage of 12 hours had residual deficits. In another series by Matsen, 3 of 18 patients who had compartment decompression *before* 12 hours vs 22 of 24 patients who had decompression *after* 12 hours had residual deficits.

Compartment pressures must be interpreted within the context of the clinical picture. Inaccurate measurements are far worse than no measurement at all. Falsely elevated pressures may be a result of needles placed into tendons or fascia, plugged catheters, or faulty electronic systems. Falsely low readings may result from bubbles in the lines or transducer, plugged catheters, or faulty electronic systems. One must carefully troubleshoot the system before making a decision to treat a presumed compartment syndrome.

Actual treatment consists of improving the perfusion pressure gradient. Support of

arterial pressures in hypotensive patients can prevent ischemia in marginal compartments. If external pressure is at fault, removal of pneumatic antishock garments, casts, or dressings may be therapeutic. Interstitial edema may be a factor in increased tissue pressure as well. Significant reduction of tissue pressure, resulting in an improved perfusion gradient, has been observed after the use of systemic diuretics [34] and intracompartment hyaluronidase. If noninvasive therapies fail, fasciotomy, which involves opening the skin and muscle fascia at key points overlying the involved compartments, should be performed. The escape of enclosed muscles causes a decrease in compartment pressure, thereby improving blood flow to the tissues. This procedure is left to personnel who are experienced in the problem and who will subsequently manage the patient. Details of fasciotomy technique may be found in surgical or orthopedic texts. Escharotomy for release of circumferential burn injury may be required on an emergent basis (see Chapter 41) .

## CONCLUSION

A compartment syndrome, with its myriad potential causes, is a challenging problem for all physicians. If untreated, the sequelae are devastating. Appropriate management requires rapid assessment and treatment. In the early stages of the syndrome, clinical examination findings may be equivocal. Pressure readings can be an objective aid to prompt recognition of this problem. All of the techniques outlined in this chapter are clinically acceptable. Whether using an arterial line system or a mercury manometer system, placement of a needle into the compartment for a pressure reading appears to be the technique best suited to episodic ED evaluation of acute compartment syndromes.

For more prolonged in-hospital monitoring or research, a technique with reliable serial measurement capability is needed. For these applications, the wick or slit catheter techniques (or the continuous-infusion technique, discussed elsewhere [1] ) may be preferable. The complications from all of these procedures are negligible in comparison to delayed recognition of a compartment syndrome.

# Chapter 59 - Urologic Procedures

**Robert E. Schneider**

This chapter addresses urologic conditions that either are initially or eventually associated with an emergency procedure or may need to be performed in the absence of a urologic surgeon.

Paraphimosis and priapism are both urologic emergencies. Treatment options must be instituted as soon as they are encountered. Phimosis by itself is not an emergency unless it results in complete obstruction of the preputial opening (rare) or is transposed into paraphimosis.

Testicular torsion is an emergency that can be difficult to diagnose under the best of clinical conditions. Surgical exploration, rather than radionuclide scanning or color Doppler ultrasonography, is the diagnostic and therapeutic procedure of choice. This chapter addresses bedside maneuvers including testicular detorsion for this entity in the setting of scrotal pain.

Access to and the subsequent evaluation of bladder urine is clinically important to every practicing physician. Various approaches to urine sampling, including the techniques and complications of male and female urethral catheterization in various clinical situations, are addressed.

Finally, a discussion of radiographic imaging of the genitourinary system is provided, with an emphasis on assessing lower urinary tract injury. Although the timing of genitourinary radiologic examinations within the workup of the critically ill multiple trauma patient must be individualized, general guidelines are provided.

## PHIMOSIS AND DORSAL SLIT

### Background

Phimosis has been recognized since ancient times. Models of phimotic foreskin have been found near the altars of Hygeia and Aesendopius in ancient Greece. Orikosius (A.D. 325-403) was the first to describe the dorsal slit as definitive treatment for phimosis.

Following any injury or inflammatory event, the foreskin (prepuce) reacts by forming scar tissue. The normally soft pliable foreskin can develop sufficient distal scarring to make routine retraction of the tissue over the glans penis difficult or impossible. This is especially true if the end of the foreskin is injured, such as in zipper injuries, toilet seat trauma, or other crush injuries (known as the Tristram Shandy syndrome, after the well-known literary character who had a window sash fall on his penis while he was urinating out the window). A chronically irritated and infected foreskin often occurs in diabetic patients. [1] Rarely, a tight phimosis and accompanying poor hygiene may lead

to abscesses of the foreskin, which can result in further contracture.

Asymptomatic phimosis does not ordinarily require any treatment. It may prevent or make easy urethral catheterization more difficult. In such situations, the phimotic opening may need to be dilated or crushed and formally incised (dorsal slit), using light sedation and local anesthesia to allow access to the urethral meatus. This minor operative procedure can be performed in the emergency department (ED) by any practicing physician.

## Indications and Contraindications

Dorsal slit of the foreskin is performed in any emergent situation either to gain access to the urethral meatus for urethral catheterization or as definitive treatment following simple foreskin reduction or phimotic ring incision and foreskin reduction in a patient with paraphimosis. Elective circumcision rather than dorsal slit of the foreskin is the definitive procedure of choice in nonemergent situations.

## Procedure

The equipment needed to perform dorsal slit of the foreskin is listed in Table 59-1 . After cleansing and draping the penis with sterile towels, one infiltrates 1% plain lidocaine *without* epinephrine into the dorsal midline of the foreskin just beneath the superficial fascia throughout the course of the proposed incision, starting proximally at the level of the coronal sulcus and proceeding distally to the tip of the foreskin (Fig. 59-1) . After 3 to 5 minutes, the foreskin is grasped with

| TABLE 59-1 -- Equipment Needed to Perform Dorsal Slit for the Emergency Treatment of Phimosis | |
| --- | --- |
| 1% lidocaine (Xylocaine) without epinephrine | 1 straight Crile clamp |
| | 1 straight scissors |
| 5-mL syringe | 1 needle holder |
| 27-ga needle | 4-0 absorbable suture |

toothed forceps to test for anesthesia. The operator must be certain that the inner surface of the foreskin is also anesthetized. If this area is not numb, a dorsal nerve block or "ring block" at the base of the penis should be used (Fig. 59-2) (Figure Not Available) . [2] [3]

After achieving both adequate local anesthesia and light sedation, the operator takes a straight hemostat and carefully advances both jaws of the hemostat proximally to the area of the coronal sulcus between the inner layer of the foreskin and the smooth glans penis, carefully separating any existing preputial adhesions. Care must be taken that the meatus and urethra are visualized at all times so they are not inadvertently injured during this maneuver. Once release of adhesions is complete, the hemostat is then opened, and one jaw of the hemostat is placed in the recently developed plane between the glans penis and the superior overlying inner layer of foreskin; the hemostat is advanced to the level of the coronal sulcus and then closed, effectively crushing the interposed anesthetized foreskin (Fig. 59-3) . The closed hemostat is left in place for 3 to 5 minutes, after which it is removed, and the resultant serrated, crushed foreskin is cut longitudinally with straight scissors throughout the extent

of the crushed tissue. Normally, the incised, anatomically approximated skin edges bleed and ooze. Not infrequently, these skin edges may separate (Fig. 59-4 A and B). Two absorbable chromic or Vicryl running hemostatic sutures may be placed, each beginning proximally at the apex of the dorsal slit and carried distally, reapproximating the 2 leaves of foreskin.

After successful dorsal slit of the foreskin, the prepuce is easily retracted for cleansing of the glans penis or exposure of the urethral meatus. Postprocedural conscientious foreskin reduction to its normal anatomic position must be assured after any distal penile procedure, to avoid iatrogenic paraphimosis.

Ideally, a definitive elective circumcision is recommended following a dorsal slit. Some patients complain about the appearance of their incised foreskin ("dog ears") and the relative inconvenience during urination, whereas others are pleased they no longer have their phimosis and refuse further treatment (Fig. 59-4 C and D).

### Complications

Injury to the urethral meatus and the glans penis may occur if the hemostat or straight scissors are blindly and unknowingly introduced into the urethra. Bleeding may occur if the hemostat has not adequately crushed the foreskin or the scissor incision is made lateral to the serrated crushed tissue. The latter 2 problems are easily resolved with the previously described running hemostatic suture.

## PARAPHIMOSIS AND FORESKIN REDUCTION

### Background

Paraphimosis is a urologic emergency. By definition, it is the inability to reduce the proximally positioned foreskin over the glans penis back to its normal anatomic position. Paraphimosis is most often associated with phimosis. In the obtunded or demented patient, subjective pain may not be perceived or communicated. Today, the most common cause of paraphimosis is iatrogenic: the catheterist or examining health care provider forgets to reduce the foreskin after penile examination or urethral instrumentation. Paraphimosis can be quite subtle and may either be unrecognized or misdiagnosed as an allergic reaction, penile trauma, or an infection, by those unfamiliar with the condition (Fig. 59-5 *A*).

The coexisting phimotic ring initially interferes with venous and lymphatic drainage, precipitating foreskin swelling. Over time, the degree of swelling prevents manual reduction of the retracted foreskin. When left untreated, eventual arterial embarrassment leads to tissue anoxia, skin ulceration, and, ultimately, to infection and/or penile gangrene. [4]

Emergent manual or surgical reduction of the edematous foreskin is mandatory to restore proper circulation, relieve discomfort, and permit resolution of potential serious sequelae: skin ulceration and gangrene. It must be done as soon as a paraphimosis is recognized. Once the foreskin is successfully reduced, dorsal slit as previously described is advised in those cases of potential patient noncompliance until definitive circumcision can be performed.

### Indications and Contraindications

Emergent reduction of a paraphimotic foreskin is indicated whenever the condition exists. There are no contraindications.

### Procedure

The equipment needed for reduction of paraphimosis is listed in Table 59-2 .

#### Manual Reduction

A nonirritating topical anesthetic lubricant is applied to the inner surface of the foreskin (not to the shaft of the penis)

| **TABLE 59-2** -- Equipment Needed for Reduction of Paraphimosis |
| --- |
| **For Nonoperative Emergency Reduction of Paraphimosis** |

| |
|---|
| 1% lidocaine (Xylocaine) jelly |
| Crushed ice |
| Size 8 latex surgical glove |
| Babcock clamps (6 to 8) |
| **For Operative Reduction of Paraphimosis** |
| Sterile preparation solution |
| 1% lidocaine (Xylocaine) without epinephrine |
| 5-mL syringe |
| 27-ga needle |
| No. 15 surgical knife with handle |
| Needle holder |
| 4-0 absorbable suture |

and the glans to reduce friction and decrease the discomfort of the procedure. A

previously described penile block may be performed if required. Light sedation is an excellent adjunct. The foreskin is then manually compressed for several minutes to reduce as much edema fluid as possible (Fig. 59-5 *B*). Snugly wrapping the distal penis in a 5-cm piece of Elastoplast (or elastic bandage) for 10 minutes has also been described. [6] Injection of hyaluronidase [7] has been reported to reduce edema, but seems unnecessary. If the patient is catheterized, *the catheter generally should be removed and replaced later*. If the swelling is minimal, reduction can at times be completed with the catheter in place.

The index and long fingers of both hands are placed in apposition proximal to the phimotic ring. Both thumbs are aligned on the urethral meatus. Constant force is applied as the thumbs try to invert the glans penis proximally while the index and long fingers attempt to reduce the phimotic ring distally over the glans penis into its normal anatomic position (Fig. 59-5 *C*). Successful reduction results in the appearance of an uncircumcised penis with a phimotic foreskin. Alternatively, the thumb may be used to push the glans through the foreskin that has been encircled by the entire palm--in a maneuver similar to taking off a rubber glove (Fig. 59-5 *D* and *E*). The key to success in both of these maneuvers is the application of slow, steady pressure.

### Assisted Manual Reduction ("Iced-Glove" Method or Babcock Clamp Method)

If the constricting phimotic ring cannot be brought down over the glans easily, additional measures may be used. In the "iced-glove" method, [8] cold compression is used to reduce foreskin swelling and to induce vasoconstriction in the glans penis. A large latex glove is half filled with crushed ice and water, and the cuff end is securely tied. The thumb of the glove is invaginated by the operator and then is drawn over the lubricated paraphimotic penis. The thumb of the glove is held securely in place over the penis for 5 to 10 minutes. The combination of cooling and compression usually decreases the edema sufficiently to permit manual reduction of the foreskin. If the constricting ring cannot be brought down over the glans after this maneuver, it may be necessary to use Babcock clamps. From 6 to 8 Babcock clamps ( *not* Allis clamps, which are serrated and intolerably painful for the patient) are used to grasp the phimotic ring circumferentially. [9] The clamps are then slowly pulled distally over the glans. With gentle, slow traction, the phimotic ring can hopefully be reduced over the glans penis (Fig. 59-6) (Figure Not Available) .

### Phimotic Ring Incision

This procedure is indicated when other methods fail or when skin ulceration, infection, or gangrene is present. [10] [11] [12] Although it is usually recommended that this procedure be performed in the operating room, it may be undertaken in the emergency department using local anesthesia and light sedation.

The penis is cleansed and draped with sterile towels. Using a 1% solution of lidocaine *without epinephrine*, one infiltrates the phimotic ring on the dorsum or 12 o'clock position (when facing the patient), making sure to infiltrate proximally and distally as well as into the constricting ring (Fig. 59-7 *A*).

The skin, the edematous subcutaneous tissue, and the constricting ring are then slowly incised perpendicular to the phimotic ring. You must incise directly on the ring so as not to injure the penile shaft. When the constricting ring is completely incised, it will spring open, and the foreskin edges will relax laterally and produce a diamond-shaped defect (Fig. 59-7 *B*). At this point, successful foreskin reduction can be accomplished quite easily and an immediate dorsal slit incision carried out by extension of the wound, if recurring paraphimosis or patient compliance is a concern. Definitive circumcision, as always, is elective, and should be delayed 7-10 days until edema, inflammation, and ulceration have resolved.

### Complications

Penile shaft laceration or simple tearing of compromised penile skin may occur during manual or surgical paraphimotic reduction. Simple suturing will resolve most injuries.

## PRIAPISM AND PENILE ASPIRATION

Priapism is manifested by a persistent, painful, penile erection, unrelated to sexual stimulation and not relieved by ejaculation. Priapism is a urologic emergency that is associated with a high incidence of impotence, regardless of treatment. It is characterized clinically by a soft glans penis and spongy urethra in the presence of 2 painfully erect penile bodies or corpora cavernosa. Although reported in most age groups, the condition is most common between the ages of 30 and 50 years. In the past, priapism was most often encountered as a complication of a number of medical (e.g., hematologic, neoplastic, and drug-related) conditions (Table 59-3) (Table Not Available) .

Today the majority of cases are idiopathic or iatrogenic, resulting from the current practice of using vasoactive substances (e.g., papaverine and phentolamine) to induce penile erections in impotent men. These vasoactive drugs promote engorgement of the corpora cavernosa, which may result in priapism. Prostaglandin $E_1$ (PGE$_1$ ) is currently the only FDA-approved drug for impotence. PGE$_1$ produces increased penile blood flow by enhancing smooth muscle relaxation, and the incidence of priapism with this medication is quite low. Penile rigidity due to a nondeflating penile prosthesis (pseudopriapism) or malignant replacement of the corpora in patients with bladder or prostate cancer should not be confused with true priapism.

Increased arterial inflow of blood into the corpora cavernosa secondary to dilation of the cavernosal arteries with relaxation of the cavernosal tissue and secondary compression of the emissary veins leads to engorgement of both corpora cavernosa during an erection. When the cavernosal pressure approaches the arterial pressure, blood flow is markedly reduced. Ischemia results after several hours of continuous erection, leading to intracavernosal acidosis and sludging of blood with subsequent thrombosis of the cavernosal arteries, fibrosis of the corporal tissue, and irreversible impotence.

Detumescence is mediated primarily by adrenergic nerves that produce

vasoconstriction, resulting in a decreased inflow of blood to the penis. Priapism may be due to either increased or unregulated inflow or failure of venous outflow. By far, the most common cause is failure of the blood to leave the corporal bodies, as is the case with drug-induced priapism and intracavernosal injections. Although an increased inflow of blood is an uncommon mechanism of priapism, the condition is most commonly associated with a trauma-induced fistula between the cavernosal artery and the corpus cavernosum.

**Indications and Contraindications for Priapism Procedures**

The emergency physician should attempt to identify reversible causes for the patient's priapism and, in conjunction with a urologist, initiate specific corrective therapy as soon as possible. Almost 66% of cases of priapism in children are due to sickle cell disease, and such cases may respond to noninvasive standard anti-sickling measures (including exchange transfusion).

Regardless of the etiology, empiric terbutaline, 0.25-0.5 mg given subcutaneously (SQ), is recommended for every patient presenting with priapism as soon as the diagnosis is made; this treatment may be repeated, when needed, in 15 to 20 minutes. If a patient with previous priapism calls from home and has the appropriate supplies, he should be instructed to inject himself with terbutaline (as above) or take a 5 mg terbutaline tablet by mouth, if available, before coming to the ED. [16] The pharmacotherapeutic action of terbutaline for priapism is not well elucidated. Oral pseudoephedrine (60 to 120 mg) also has been suggested as a noninvasive initial therapy for priapism secondary to intracavernosal agents, but its efficacy has not been well studied. [17] Table 59-4 lists the reversible causes of priapism with their respective therapies.

In the majority of patients, no reversible cause will be disclosed. In about 50% of patients, detumescence will not occur with SQ terbutaline, thus necessitating corporal aspiration alone or corporal aspiration and irrigation with an alpha-agonist (epinephrine or phenylephrine [Neo-Synephrine]) to promote detumescence. Conservative measures, such as sedation and analgesia, oral estrogens, ice-water enemas, transurethral diathermy, spinal/epidural/general anesthesia, and local anesthetic injections have not proven to be of value and should not be used in lieu of definitive intracavernosal therapy. [17]

Should initial medical and corporal aspiration and irrigation fail, Lue and associates recommend that further therapy be guided by cavernosal blood gas and pressure measurements. [18] If one elects to use blood gas analysis of aspirated corporal blood to help guide therapy, the initial results will reflect the degree of ischemia present in the priapismic penis. Sequential blood gas analyses that fail to show an improvement in the initial acidosis (pH remaining at 7.10) despite corporal aspiration and/or irrigation suggests that a more aggressive definitive corpus cavernosum-spongiosum shunt may be indicated, and urgent urologic intervention should be sought. In addition, the aspirating or irrigating corporal needle may also be used for measurement of intracorporal pressures similar to the approach outlined for muscular compartmental pressures (see Chapter 58) .

The mainstay of therapy for advanced priapism is aspiration of the corpora cavernosa combined with saline irrigation, often coupled with the intracavernosal injection of alpha-adrenergic agents. When urologic consultation is unavailable or delayed, the emergency physician must be familiar with diagnostic and therapeutic corporal aspiration. Because prolonged priapism increases the risk of subsequent erectile dysfunction, an aggressive management strategy is advised. Impotence rates of up to 35% to 60% have been reported when priapism persists for 5 to 10 days, respectively. [17] If present for >24 hours, priapism often does not respond to aspiration alone. In such cases, irrigation should always be performed.

## Equipment

The equipment needed for aspiration and irrigation of the corpus cavernosum is listed in Table 59-5 .

## Procedure

The patient is placed in the supine position (Fig. 59-8 *A- D*). Local anesthesia is recommended for this procedure. An injection of 1% plain lidocaine placed at the base of the penis for a dorsal penile nerve block or placement of a circumferential penile block can be done (see Fig. 59-2) (Figure Not Available) . The penis is sterilely prepared and draped. When standing to the right of the patient, the clinician grasps the shaft of the penis with the left hand using the thumb and index finger. An engorged corpus cavernosum is palpated laterally and a 21- to 19-ga butterfly needle is inserted into one of the corpora cavernosa (at 2 or 10 o'clock). [19] The site of needle placement is one of personal preference, and locations from the base to the distal shaft of the penis have been suggested. *The glans should not be used as a puncture site.* Deep penetration is to be avoided to minimize the risk of injury to the cavernosal artery during this procedure.

An initial 20 to 30 mL of corporal blood is aspirated while the operator milks the corpus with the left hand. This initial aspiration is continued until the original egress of dark blood ceases and bright red arterial blood is obtained. Because multiple anastomoses exist between the 2 corpora cavernosa, bilateral aspiration is not required.

If detumescence is achieved after initial aspiration, no further treatment is required. Simple aspiration is most likely to be successful if the priapism has been present for <24 hours. If retumescence occurs, then repeated aspiration, followed by an equal exchange of an alpha-agonist solution for aspirated corporal blood, should be carried out (i.e., 20 to 30 mL of a phenylephrine/normal saline solution [10 mg of phenylephrine in 500 mL of normal saline] in exchange for 20 to 30 mL of aspirated corporal blood). Some clinicians add 2500 to 5000 units of heparin to the solution, but the value of heparin is unproven. The use of beta-agonists for

**TABLE 59-4** -- Treatment of Priapism Based on Etiology

A. Terbutaline 0.25 to 0.5 mg SQ in the deltoid muscle area or thigh for all patients with priapism (may be repeated in 15-20 min); alternatively 5 mg terbutaline PO may be used (1 dose)

B. Reversible causes

  1. Sickle cell anemia

    a. Packed RBC transfusion

    b. Hyperbaric oxygenation (investigational)

  2. Iatrogenic injection of $PGE_1$ , papaverine or phentolamine for impotence

    a. Corporal aspiration of 30-60 mL of blood, followed by observation

     1) Detumescence: no further treatment

     2) Persistent erection: inject an equal volume of alpha-agonist (i.e., phenylephrine, 10 mg in 500 mL of normal saline)

  3. Leukemic infiltration

    a. Specific chemotherapy

corporal injection or irrigation also has been reported, and the advantage of pure alpha-agonists over beta-agonists is a subject of debate. O'Brien and associates recommend a 1:100,000 solution of epinephrine (1 mg/100 mL of saline), irrigating with 2 to 3 mL at a time to a maximum dose of 0.1 mg (10 mL). [19] Alternatively, 1 mg of epinephrine can be added to 1 L of saline, with irrigation performed using 20 to 30 mL aliquots. A norepinephrine solution also may be used (Table 59-5) . Some clinicians wrap the penis snugly in an elastic wrap with the needle securely in place following aspiration to discourage retumescence and to decrease hematoma formation of the penile shaft.

**Complications**

Although hematoma and infection can occur with properly performed aspiration, these complications are infrequent. Both phenylephrine and epinephrine can be absorbed systemically, with the potential for toxic effects. [18] Therefore, the intracavernosal use of vasoactive agents is contraindicated in patients with conditions sensitive to these agents (e.g., severe hypertension, dysrhythmias, monoamine oxidase inhibitor use). Blood

pressure and cardiac rhythm should be closely monitored throughout the procedure. Supplemental O$_2$ should be considered in any patient with underlying respiratory or cardiac disease. Because impotence is a well-recognized complication following priapism, regardless of the cause or the promptness of therapeutic intervention, the patient must be advised both verbally and in writing of this potential complication.

# ADJUNCTIVE TESTING IN

ACUTE SCROTAL PAIN

Establishing a diagnosis in the patient with acute scrotal pain creates significant physician anxiety. The condition most

* Systemic absorption of vasoactive agents may occur with adverse cardiovascular effects.

easily confused with torsion of the testicle is acute epididymitis. The prompt diagnosis of testicular torsion and differentiation of this condition from epididymitis can be quite difficult, but it is obviously crucial to the patient's care. The treatment of acute epididymitis requires appropriate antimicrobial and supportive therapy. The treatment of testicular torsion requires emergent operative intervention, not adjunctive testing! [20]

Torsion of the testicle is the most frequent cause of acute testicular pain in celibate men younger than 20 years. One pediatric series of patients presenting with a painful scrotum reported a 6% incidence of epididymitis vs a 42% incidence of testicular torsion and a 32% incidence of torsion of the appendix testis and epididymis. [21] It is interesting to note that pyuria was seen in 10% of the patients with testicular torsion and in 80% of the children with epididymitis. In men 20 years or older, testicular torsion is less common, but it must always be considered in the differential diagnosis as it may occur well into the seventh decade of life. [22]

In contrast, epididymitis is an *uncommon* condition in young celibate boys unless a congenital lower urinary tract abnormality is present that promotes urinary tract infection

with subsequent epididymitis.

As with all difficult diagnostic dilemmas, the patient's history is of paramount importance in establishing the correct diagnosis. The evaluation of acute scrotal pain is no different. In considering epididymitis, detailed and often probing questions must be asked regarding the patient's work habits and his sexual experiences. The pathophysiology of epididymitis emanates from the generation of increased pressure in the prostatic urethra as a result of either heavy lifting (e.g., in roofers or construction workers), detrusor external sphincter dyssynergia (e.g., in patients with neurogenic bladder dysfunction), or iatrogenic promotion of a Valsalva maneuver for whatever reason. These mechanisms force sterile or infected urine out through the ejaculatory ducts into the vas deferens (urethrovasal reflux) then retrograde down the vas into the tail of the epididymis (globus minor). This may initially cause nonspecific lower quadrant abdominal pain or inguinal canal pain (vasitis) before it causes scrotal or testicular pain, and vasitis should be included in the initial differential diagnosis in any male presenting with lower abdominal pain.

Sexually transmitted diseases with subsequent epididymitis are quite common in sexually active men younger than 40 years, usually associated with chlamydial or gonococcal urethritis. Signs and symptoms of infection may be minimal when the patient is first examined. [23] The presence of genitourinary infection, a history of previous sexually transmitted diseases, or a history of multiple sexual partners and the absence of penile protection during intercourse may all be important clues to the diagnosis of epididymitis. In older men, epididymitis is usually due to urinary tract infection secondary to outlet obstruction or urethral stricture disease. In such cases, enteric gram-negative bacilli and *Pseudomonas* species are the predominant organisms. If one cannot be certain after taking a careful history and examining the patient that epididymitis or torsion of the appendix testis or epididymis is the correct diagnosis, then urologic consultation to exclude testicular torsion is required. A clinical diagnosis of epididymitis should be based on the focal finding of epididymal induration and tenderness (the vas deferens also may be involved) in the proper patient population. The site of tenderness is best discerned when examining the patient in the relaxed supine position. Although testicular tenderness can develop with advanced epididymo-orchitis, the time course is generally gradual and on an order of days. However, marked testicular tenderness in a patient with advanced epididymo-orchitis may reflect secondary testicular ischemia and also warrants urologic consultation. [24]

The "gold standard" for the diagnosis of testicular torsion is scrotal exploration. [25] However, some clinicians incorporate radionuclide testicular scanning or color Doppler ultrasound examination in their diagnostic workup. [26] Unfortunately, these studies are time-, technician-, and reader-dependent examinations in a clinical situation in which *TIME IS TESTICLE*. The quintessential point in testicular torsion is that there are no markers, signs, or symptoms that will distinguish incomplete from complete testicular ischemia. One minute there may be total absence of blood flow to the involved testis, the next minute sufficient spontaneous detorsion may have occurred to provide temporary testicular perfusion. This is the dilemma. Scrotal exploration, detorsion, and orchiopexy or orchiectomy of the involved testis and orchiopexy of the contralateral

testis, is a relatively benign, straightforward operative procedure.

Remember that intravaginal testicular torsion is a congenital bilateral abnormality. The ischemic testis must be detorsed and pexed with nonabsorbable (e.g., nylon, polypropylene), rather than absorbable (e.g., chromic, Vicryl), suture. The torsed testis that is pexed with absorbable suture remains at risk for subsequent postoperative torsion. And last, orchiopexy of the nonischemic contralateral testis is mandatory to ensure prevention of future torsion.

Once the diagnosis of testicular torsion is suspected, a call should be placed immediately to notify a urologist of the suspected diagnosis, the perceived need for surgical exploration, and the fact that you will be attempting testicular detorsion while awaiting patient transport to the operating room. At some point before the patient leaves the ED, meticulous charting to document time, suspected diagnosis, notification of the urologist, and any manipulation of the affected

testis must be done. All efforts are then focused on attempting testicular detorsion.

## Doppler Assessment of Testicular Perfusion

### Indications and Contraindications

The most important nonoperative adjunctive procedure in suspected testicular torsion is testicular *detorsion*. This can be carried out with or without the aid of a Doppler stethoscope. Using the Doppler stethoscope alone to make a diagnosis of testicular torsion or successful detorsion is *not* recommended. Nonetheless, the Doppler device may be used to support one's clinical assessment in cases strongly suggestive of epididymitis or to monitor the response to detorsion efforts.

### Equipment

In circumstances in which one wishes to use the Doppler, the directional Doppler operating on a 10-MHz transducer is recommended. See Chapter 70 for further discussion of Doppler ultrasound physics. A pencil transducer is the most appropriate (e.g., the Model 806 directional 10-MHz Doppler, Park Electronics Laboratory, Beaverton, Ore). The Doppler response may be transmitted over a loudspeaker, copied on a measuring device, or transmitted through a stethoscope to the physician. The higher the frequency of the transducer, the narrower the beam and the less the distance of transmission through the tissues. In this respect, a 10-MHz transducer is preferred over a lower-frequency transducer for examination of the testicle.

### Technique

Because scrotal tenderness often precludes adequate examination, anesthesia may be needed. A cord block using 1% lidocaine may be applied at the external ring (see discussion of this block under Testicular Detorsion below). The area of maximum testicular swelling is determined. An aqueous transmission gel is then placed over the

scrotum. Holding the testicle in one hand and the Doppler probe in the other, one displaces as much of the scrotal wall as possible between the skin and the underlying testicle. The Doppler probe should be placed in the center of the testicle, pointing slightly caudally so that pulsations in the cord are not detected (Fig. 59-9) . (Firm probe pressure "focuses" the ultrasound waves deep to the scrotum into the testis.) The pulsation in the tender, ipsilateral testicle is then compared with that in the contralateral testicle. Decreased or absent flow to the ipsilateral testicle is most surely a result of torsion. Increased flow to the ipsilateral testicle may be a result of epididymitis, inflamed scrotal tissue, a false signal from either the cord or the examiner's fingers, or a false comparison with a contralateral partial torsion of the testis. [27]

The *funicular compression test* should be performed to confirm that flow signals are related to perfusion to the testicle. If the increased signal lessens on compression of the patient's spermatic cord, then the signal is most probably coming from the patient's testicle and not from inflamed scrotal tissues. If there is no change in the signal on adequate cord compression, the increased flow may be originating in inflamed scrotal tissue, and torsion should still be suspected.

### Complications

Absolute proficiency with the Doppler stethoscope is difficult to achieve, and examination findings are subject to misinter pretation. The greatest risk comes in those cases that represent a later stage of testicular torsion. Although the testes may not be necrotic, a secondary inflammatory response may develop as a result of the underlying ischemia. Any perceived Doppler signal in the hyperemic surrounding scrotum may be misinterpreted by an inexperienced examiner as epididymitis rather than late torsion with an associated inflammatory response, the result of which may be inappropriate treatment. Obviously, the affected testis would remain ischemic, but more important, the contralateral testis would remain at risk for later torsion.

Failure to perform the funicular compression test may lead to the mistaking of scrotal blood flow for testicular blood flow. The Doppler signal should fade and then promptly return as the spermatic cord is first compressed and then released. With an incomplete torsion, one may also hear an attenuated arterial pulse in the testicle. For these reasons, it should be evident that one cannot rely entirely on the Doppler ultrasound examination. [28]

## Manual Detorsion and Spermatic Cord Anesthesia

Manual detorsion is performed in the following manner. Advise the patient that the procedure will be uncomfortable and painful and offer light sedation if it seems appropriate. The rationale for not using spermatic cord anesthesia with attempted detorsion is that the anesthesia takes away an important subjective end point (i.e., relief of the patient's pain after manipulation of the testis). However, many authors do advocate spermatic cord anesthesia prior to detorsion, and if anesthesia of the spermatic cord is elected, it can be done in the following manner.

**Spermatic Cord Anesthesia**

Local anesthesia of the spermatic cord using 1% plain lidocaine is usually done at the external inguinal ring. [29] The skin is first prepared with an iodophor solution. The cord can usually be grasped between the thumb and index finger, and 10 mL of 1% plain lidocaine can be directly injected into the cord. If the cord is swollen, as it often is in testicular torsion, or if the testicle is lying very high in the hemiscrotum as a result of spermatic cord torsion (so as to preclude

grasping), the cord may be palpated at the pubic tubercle as it passes over the pubis and the lidocaine injected at this landmark. Lee and colleagues [30] were able to perform manual detorsion with local spermatic cord anesthesia in 70% of their adult cases of torsion. Kresling and associates [31] had success in 15 of 16 patients and noted a fair amount of associated cremasteric muscle spasm, which must also be relieved. In their experience, torsion usually resulted from an initial lateral-to-medial rotation (Fig. 59-10) , with an occasional caudal-to-cranial component.

**Manual Detorsion**

The goal of manual detorsion is to reestablish or increase blood flow to a previously ischemic testis. This should be done in conjunction with preparation of the operating suite. *It should never delay operative intervention*.

Before initiating detorsion, one must ensure that the patient is as comfortable as possible in a reclining or supine position. Lithotomy position gives the examiner the most access to the patient's genitalia and prevents the patient from retreating during the procedure. If light analgesia/sedation are selected they should be implemented at this time.

Manual detorsion begins with the physician standing comfortably at the side of the bed or stretcher, preferably on the patient's right side if the physician is right handed, or vice versa. Detorsion is begun just as one would open a book (i.e., an initial 180° detorsion of the patient's right testis is done in a counterclockwise fashion. The patient's left testis is detorsed 180° in a clockwise fashion (see Fig. 59-10) . Pain relief and an increase in the Doppler signal are the objective end points. If one rotation relieves some but not all of the pain, continue with another rotation. If the initial detorsion is mechanically difficult (which it will be if you are detorsing in the wrong direction) or makes the pain worse, detorse the testis in the opposite direction and observe your result. The objective success or failure of any testicular manipulation can be substantiated by an increase in Doppler signal and the patient's relief of pain.

With successful detorsion, the testicle returns to its normal anatomic position. Resolution of induration and swelling of the spermatic cord, testis, and epididymis will depend on the degree and duration of ischemia. Thus, the more severe the torsion and the longer it has been present, the longer it will take for the edema and induration to resolve. With significant ischemia, the entire epididymis often becomes enlarged like a

link sausage (uncommon in epididymitis except in severe cases or those that are initially misdiagnosed or seen late in their clinical course), and the testis becomes quite firm, simulating a testicular tumor. In the author's experience, both of these reversible changes usually resolve over 3 to 4 hours. Occasionally the testis will torse in the opposite direction (medial to lateral) or have multiple twists. This may become apparent as the clinician assesses the results of the detorsion procedure by palpation, relief of edema, and return or increase of the Doppler signal. Even though manual detorsion will save an ischemic testicle, *it should not be substituted for definitive scrotal exploration.*

# URETHRAL CATHETERIZATION

## Alternatives to Catheterization

The merits of alternative approaches to urine specimen collection over patient catheterization are dependent on the patient's age and clinical setting.  In children, the collection technique reported by Amir and coworkers consists of placing the young child on his or her back. [32] In very young children, collection and analysis of spontaneously voided urine specimens following penile cleansing or suprapubic "finger tap" showed identical urine

culture results to those specimens obtained by suprapubic aspiration. [32] The applicability of this to a busy ED is questionable. Often, it is possible to collect a spontaneously voided midstream specimen in a child if ED personnel are prepared in advance. The problem is that the voiding events tend to occur as the child is undergoing venipuncture, spinal tap, or attempted urethral catheterization. And more important, if the first specimen is missed or inadequate, how long are we willing to wait for another chance? Urethral catheterization is quick, definitive, and routinely used.

In adult men without anatomic lesions, first-voided specimens can define the presence or absence of culture-proven bacteriuria. [33] This certainly represents a user-friendly approach to urine collection in a busy ED and needs to be carefully considered.

In adult women, collection of clean-catch midstream specimens has been found to be as reliable bacteriologically as catheterized specimens. [34] A few caveats are worth mentioning: patients must sit backward on the toilet when collecting the specimen (i.e., facing the wall, which theoretically promotes labial spreading). Of more concern is the fact that these studies excluded patients with vaginitis, urologic abnormalities, pregnancy, and vaginal bleeding. These are the clinical circumstances for which urine is commonly examined in young women visiting the ED. In this "at risk" population, catheterized urine specimens are preferred.

Urethral catheterization seems a simple task--insertion of one tube into a larger tube. Nonetheless, many difficulties may arise. Patients often remember catheterization as either painful or uneventful and reflective of the operator's expertise, confidence, and gentleness.

Patients are often apprehensive about catheterization. If the physician shows concern

regarding position and exposure, the patient will be reassured. A moment should be spent in making sure a patient is positioned comfortably and appropriately for the procedure. Although adequate exposure may be obtained from a frog-legged position, the use of a table with stirrups (lithotomy position) is ideal, especially for female catheterization.

Anticipation and preparation of all materials necessary for urethral catheterization beforehand is reassuring to the patient. It is frustrating for the health care provider and upsetting to the patient when he or she is told "not to move or touch anything" while a search is made for additional equipment. Most catheterizations are performed using a standard catheterization tray. Often, these trays contain more equipment than is truly needed. This necessitates opening the tray and establishing a sterile field at the bedside, selecting those items that will be needed, and discarding the rest of the equipment. Once the penis or labia has been touched in preparation for the procedure, the touching hand is contaminated and ideally should not be handling any of the sterile equipment. When a standard catheterization tray is not used or is not available, catheterists should go through the anticipated procedure mentally to secure all of the appropriate equipment before actually starting the procedure.

## Indications and Contraindications

Urinary catheterization and instrumentation are rarely a primary cause of urinary infection in otherwise healthy patients who urinate normally and carry small amounts of post-void residual urine. As with any procedure, catheterization needs to be limited to those clinical situations in which the benefits outweigh the risks. The following are considered to be indications for urethral catheterization:

1. Acute urinary retention.
2. Urethral or prostatic obstruction leading to compromised renal function.
3. Urine output monitoring in any critically ill or injured patient.
4. Collection of a sterile urine specimen for diagnostic purposes.
5. Intermittent bladder catheterization in patients with neurogenic bladder dysfunction.

Urologic study of the lower urinary tract.Urethral catheterization should be avoided when other less invasive procedures will be as informative. The only absolute contraindication to urethral catheterization is the trauma patient with suspected urethral injury as evidenced by blood at the urethral meatus, an abnormal-feeling or high-riding prostate on rectal examination, or penile, scrotal,

---

**TABLE 59-6** -- Sterile Equipment Required for Urethral and Suprapubic Catheterization

| Urethral Catheterization |
|---|
| Foley catheter of appropriate size |
| Water-soluble lubricant for catheter |
| 10-mL syringe of sterile water for Foley balloon |
| Sterile drainage bag with tubing |
| Sterile drapes |
| Sterile gloves |
| Povidone-iodine |
| Sterile gauze pads or cotton balls |
| Sterile specimen cup with lid |
| Cloth, paper, or plastic tape (to secure catheter to trunk or leg) |
| Benzoin (for increasing tape adherence) |

| |
|---|
| Forceps |
| **Suprapubic Catheterization** |
| Foley catheter of appropriate size * |
| Sterile gloves |
| Sterile drapes |
| Sterile drainage bag with tubing |
| Sterile specimen cup with lid |
| Cloth, paper, or plastic tape (to secure catheter to trunk or leg) |
| Benzoin (for increasing tape adherence) |
| **Materials in Cook "Peel-Away" Catheter Set** |
| 10-mL syringe |
| 25-ga needle |

| |
|---|
| 22-ga needle |
| 1% plain lidocaine |
| Povidone-iodine swab-sticks |
| Fenestrated drape |
| Gauze sponges |
| Disposable scalpel |
| Suture with needle |
| Introducer needle |
| Curved J-tipped wire guide |
| Peel-away sheath |
| Introducer |

* Select the sheath size (in catheter set) based on the Foley catheter size. Generally, the sheath is 1 to 2 Fr sizes larger than the catheter (e.g., use an 18 Fr peel-away sheath with a 16 Fr Foley).

| TABLE 59-7 -- Pediatric Urethral Catheter Size | |
| --- | --- |
| **Age Group** | **Pediatric Catheter Size** * |
| Infants | 5-8 Fr feeding tube |
| 1-3 yr | 8 Fr feeding tube |
| 4-6 yr | 10 Fr feeding tube |
| 7-12 yr | 10-12 Fr red rubber catheter (Robinson) |
| >12 yr | 14 Fr red rubber catheter (Robinson) |

* 6 Fr is the smallest balloon catheter and is quite flimsy; would recommend 8 Fr in most cases; 12 Fr is the smallest coude catheter.

or perineal hematoma. These findings dictate the need for retrograde urethrography to define the integrity of the urethra prior to any attempted urethral catheterization.

## Equipment

The equipment listed in Table 59-6 is included in most standard catheterization trays and must be at hand before attempting urethral catheterization. The catheterist should check the list of contents *before* opening the tray, as some trays do not include certain items. For most routine adult in-and-out catheterizations, a 14 Fr red rubber catheter or Foley balloon catheter is adequate. In infants or neonates, a 2 or 5 Fr feeding tube taped in place produces the least amount of urethral trauma. In older boys, a 5 to 12 Fr red rubber catheter or Foley balloon catheter may be used. Table 59-7 lists appropriate-sized catheters and feeding tubes for all ages. A 14-18 Fr coude catheter should be considered after unsuccessful passage of a straight Foley balloon catheter or in any male patient with known enlargement of the prostatic median lobe. If a coude catheter is not available, a larger 18 to 22 Fr Foley balloon catheter can be tried. In a male patient with a urethral stricture in whom attempts at catheterization with a straight Foley or coude catheter have failed, passage of filiforms and followers is the next logical

step. This requires special expertise, but it can be learned quickly. If immediate bladder access is required in this circumstance or in any emergency, suprapubic placement of a peel-away sheath and Foley balloon catheter using the Seldinger technique will be needed. [36]

## Anatomic Considerations

### Female Catheterization

The female urethra is a short (approximately 4 cm), straight tube, usually of wide caliber, lying on top of the vagina. It must be approached between double labia, and the urethral meatus is occasionally hidden and not obvious (in contradistinction to that of most males, except those with hypospadias). If the female patient nervously adducts her legs, successful catheterization is most uncertain.

The female urethral meatus is an anteroposterior slit with rather prominent margins that is situated directly superior to the opening of the vagina and approximately 2.5 cm inferior to the glans clitoris (Fig. 59-11) (Figure Not Available) . [37] It is the first of 3 orifices encountered when examining any female genitalia cephalad to caudad in the lithotomy position. The urethral meatus may be especially difficult to find in the very young infant and the older postmenopausal woman. Anticipation of this and knowledge of the anatomic variances will help to modify any patient discomfort associated with needless catheter tip probing, which is an unsettling experience for both the patient and the catheterist.

Occasionally, the urethral meatus recedes superiorly into the vagina and is not immediately visible, because of either prior surgical procedures or atrophic postmenopausal changes. Anticipation of such cases will allow the examiner to gently advance an index finger into the vagina in the superior midline. The urethral meatus can usually be palpated and often visualized as a soft mound surrounded by a firmer ring of supporting periurethral tissue. Rarely, the meatus will have receded so far superiorly that it cannot be visualized at all, and catheterization must be carried out by palpation alone. From the meatus (if the patient assumes a supine position), the urethra proceeds straight back to slightly downward as it advances into the bladder just behind the symphysis pubis (Fig. 59-12 *A*).

In women with a *urethrocele or cystourethrocele,* in whom the urethra or the bladder falls into the vagina, the "normal" urethral course may be more significantly posterior (Fig. 59-12 *B* and *C*). The normal anatomic relationships in these situations may be recreated by spreading the index and long fingers and placing them along the superior vaginal wall and gently applying upward support (Fig. 59-12 *D* and *E*). This reconstitutes the normal anatomic relationships and permits straight, rapid urethral catheterization.

Because the female urethra is so short, only half the total length of the catheter has to be inserted before it is safe to inflate the Foley balloon.

**Male Catheterization**

Because the urethral meatus is usually evident in most males, it may seem a simple matter to insert a urethral catheter. [38] Yet catheterization can be quite difficult. The normal male urethra is approximately 20 cm long from the external urethral meatus to the bladder neck (Fig. 59-13) (Figure Not Available) . The posterior prostatic urethra is approximately 3.5 cm long, and the contiguous external sphincter or urogenital diaphragm that encompasses the membranous urethra is 4 cm from the bladder neck. In males, any catheter must be fully inserted to the balloon-inflating side-arm channel before it is safe to inflate the balloon (Fig. 59-14) . At the first egress of urine from the catheter, the balloon is just passing through the membranous urethra. The catheter still has 3 cm to go before clearing the bladder neck. Inflation of the Foley balloon at any point other than full insertion of the catheter may result in iatrogenic urethral injury.

The male urethra is relatively fixed at the level of the urogenital diaphragm and symphysis pubis; traction downward on the penis kinks and promotes urethral folding at the level of the penile suspensory ligament (Fig. 59-15 (Figure Not Available) *A*). This creates a level of spurious obstruction. For this reason, the penis should always be held taut and upright during any urethral instrumentation including catheterization (see Fig. 59-15 (Figure Not Available) *B*). The catheter then needs to make only a single curve rather than a complex S curve as it traverses into the bladder.

## General Procedure

As stated previously, urethral catheterization must be done using sterile technique. Both male and female patients have special urethral meatal considerations. In the male, absolute total control of the penile foreskin is paramount to ensuring success. This is true for any male patient, but it is especially important in uncircumcised patients. Prior to establishing a sterile field, the foreskin should be retracted to its fullest extent proximal to the glans penis (Fig. 59-16 *A*). A standard 4 × 4 gauze pad is unfolded, then refolded in its longest dimension, and carefully wrapped around the retracted foreskin at the level of the coronal sulcus (Fig. 59-16 *B*). This will prevent the tendency for normal anatomic foreskin reduction during catheterization and provide a continuously dry and sterile field. The folded 4 × 4 gauze surrounding the foreskin is secured between the nondominant long and ring fingers when beginning the procedure and is not released until the procedure is completed (Fig. 59-17) . This position leaves the nondominant index finger and thumb available for manipulating the catheter. Following catheterization, removal of the 4 × 4 pad and reduction of the penile foreskin to its normal anatomic position will prevent the development of iatrogenic paraphimosis.

In the female patient, the catheterist's nondominant thumb and index finger are used to separate the labia and create exposure of the urethral meatus. Once meatal visualization is achieved, the nondominant hand should not be removed (see Fig. 59-11 (Figure Not Available) *B*). This underscores the importance of proper equipment preparation. Access to antiseptic solution, viscous lubricating jelly, the appropriate catheter, and the urinary collection device should be prepared in advance to permit

single-handed sterile use.

Following exposure of the urethral meatus in the female and the glans penis and urethral meatus in the male, an antiseptic solution (e.g., povidone-iodine) soaked into cotton balls or oversized cotton-tipped applicators is used to cleanse the exposed meatus and surrounding tissues. This is best done by hand but can also be done using the plastic forceps in the catheterization tray. The cleansing circular motion should begin on the urethral meatus and proceed outward, intentionally moving any debris toward the periphery and thus creating a sterile field.

An appropriately sized catheter (10 Fr is adequate for small children, whereas 14 to 16 Fr is commonly used in adults) that has been lubricated with viscous rather than inspissated lubricating jelly is gently passed by hand, or with the aid of a hemostat or plastic forceps, into the urethra and upward into the bladder. Injection of the male urethra with 5 mL of 2% viscous lidocaine (Anestacon) or a similar anesthetic lubricant administered through a syringe can be helpful for urethral distention and topical anesthesia. Regardless, the patient should be advised of mild urethral discomfort and the potential urge to void. During slow, gentle passage of the catheter, one should be aware of the anatomic considerations discussed previously. A catheter that inadvertently enters the vagina should be discarded.

After passing the catheter "to the hilt" in all male patients, the balloon should be slowly inflated with 10 mL of air or tap water. Sterile water or saline is not required. Most 5 mL balloons will easily accommodate up to 30 to 50 mL of air or water without bursting. Obvious resistance or patient discomfort on balloon inflation should signal potential erroneous urethral positioning and mandates reevaluation. If this occurs, the Foley balloon should be immediately deflated and the catheter repositioned or withdrawn slightly, then passed "to the hilt" again prior to balloon reinflation. If this is unsuccessful a second time, catheter removal and urethral evaluation for a potential obstructive problem or false passage using retrograde urethrography is recommended (see Retrograde Urethrogram below).

Following successful catheter passage and Foley balloon inflation, the catheter should be slowly withdrawn until the approximation of the balloon with the bladder neck precludes further withdrawal. The catheter is then connected to either a sterile leg bag or closed-system bedside drainage bag. If the patient will be released with an indwelling Foley catheter, it can be initially connected to a leg bag, which is then comfortably fastened to the lower thigh and upper calf. The patient and family must be instructed regarding proper care of the catheter and drainage device. In most other cases, the catheter may be secured either to the thigh or the lower abdomen (preferred with males) with adhesive tape or simply placed under the knee and left to drain dependently into the bedside drainage bag.

The use of antibiotics before simple catheterization is not warranted. However, patients with known valvular heart disease, suspected urinary tract bacteremia, chronic urinary tract infection, urethral stricture disease, or outlet obstruction associated with infection are considered to be at risk for procedure-induced bacteremia. In these patients, any urinary instrumentation, especially urethral dilation, requires early prophylactic

parenteral gram-negative antibiotic coverage before any instrumentation is begun. These patients must also be released with appropriate antibiotic coverage and be scheduled for early urologic follow-up within 1 to 2 days. [39]

## Difficulties in Male Catheterization

### Phimosis

Physiologic adhesions between the foreskin (prepuce) and glans penis with associated inability to retract the foreskin are normal in children. This condition must be distinguished from phimosis, which is the inability to retract the foreskin proximally over the glans penis due to recurrent inflammation or trauma, which results in gradual scarring of the preputial opening. [40] It is not essential to retract the foreskin in uncircumcised boys at the time of catheterization if the urethral meatus can be visualized. At birth, the foreskin is fully retractable in only 4% of boys. Sufficient foreskin retraction to visualize the urethral meatus is possible in only half of newborn boys. Although the foreskin can be retracted completely in only 20% of 6-month-old boys, 90% of 3-year-old boys have a fully retractable prepuce. By 17 years of age, the foreskin should be physiologically separated and fully retractable in all males unless they have experienced secondary infections or repeated preputial trauma. [41]

The foreskin, especially in diabetics, is susceptible to recurrent infections and inflammation. A scarred, contracted, difficult-to-retract preputial opening may result, leading to phimosis. Phimosis precludes optimal hygiene of the glans penis and coronal sulcus, resulting in an increased risk of bacterial infection, transmission of sexually transmitted diseases (especially human immunodeficiency virus), and the development of penile malignancies. Occasionally the phimotic opening becomes so tight that the meatus cannot be visualized or palpated, even for nonsterile catheterization. If the patient requires catheterization, it will be necessary either to perform a dorsal slit of the foreskin to expose

the glans and urethral meatus sufficiently for cleansing and catheterization or to dilate the phimotic opening sufficiently to identify the urethral meatus and blindly pass the catheter. These procedures are discussed at the beginning of the chapter.

### Edema of the Foreskin

Patients with penile trauma, paraphimosis, anasarca, or significant lymphatic obstruction from irradiation or cancer may have marked edema of the foreskin, subsequently burying the urethral meatus and glans penis in several centimeters of boggy foreskin (Fig. 59-18) . Because the latter group of patients often require careful fluid monitoring, they may need an indwelling catheter. The physician's first responsibility is to disclose the proper etiology for the foreskin edema. This will require enough foreskin manipulation to identify the glans penis, coronal sulcus, and urethral meatus, as well as the relationship of the prepuce and preputial opening to these structures, to ensure the absence of foreign body strangulation or paraphimosis (Fig. 59-19) .

Two separate methods of visualizing the glans penis and urethral meatus are available to the physician. [42] The simplest method is to manually compress the swollen foreskin by hand or between opposing cold packs in an attempt to reduce the edema fluid (see Fig. 59-5 *C* and *D*). Snugly wrapping the distal penis with Elastoplast for 10 minutes may also be helpful. In most mild cases, manual compression is often successful, and no further maneuvers are required. In more severe cases, the foreskin may be 6 cm thick in diameter. In such cases, the least traumatic but unfortunately most cumbersome way to visualize the glans penis and urethral meatus is to use a pediatric-sized vaginal speculum. The outer surfaces of the speculum are lightly lubricated, and the speculum is inserted into the opening of the edematous foreskin. The operator then opens the speculum gently and visualizes the glans penis, similar to viewing the cervix. Commonly, the 2 leaves of the speculum will slip out of the foreskin, making adequate visualization quite difficult. Subsequent meatal cleansing and catheterization performed with plastic instruments is cumbersome and is not recommended. It is much easier to palpate the urethral meatus with the index finger of the nondominant hand, then use the same index finger as a guide to blindly insert the Foley or coude catheter into the urethra and upward into the bladder.

**Meatal Stenosis**

The urethral meatus may be either congenitally or secondarily narrowed by scarring, resulting in meatal stenosis. The stenosis may prevent admission of a normal-sized catheter. If the meatus admits a small-caliber tube (i.e., 5 Fr pediatric feeding tube or larger), this may be all that is required for the short term. It should be remembered that the inner diameter of the feeding tube or catheter is the important diameter for urinary drainage. A smaller, single-lumen tube may provide better drainage than a larger, double-lumen Foley balloon catheter.

If a larger-caliber catheter or a Foley balloon catheter is required, meatal dilation or meatotomy may be necessary. Meatal dilation is accomplished by repeatedly inserting larger meatal dilators to a certain end point. This procedure is painful and should be performed with topical meatal anesthesia in conjunction with light IV sedation.

On occasion, a ventral meatotomy may be required in men in whom repeated instrumentation or long-term catheterization has resulted in severe meatal stenosis. Using a 25- or 27-ga needle, infiltration of the ventral midline of the glans from the coronal sulcus to the distal tip of the meatus is performed with 1% plain lidocaine. A straight hemostatic clamp is then gently applied to the anesthetized area, with one jaw inside the meatus and the other on the anesthetized ventral midline of the glans. After the hemostat has been closed and left in place for 3 to 5 minutes, it is opened and removed. The crushed tissue is then cut with straight scissors. Some physicians place a running hemostatic 4-0 chromic suture through the apex of the meatal incision and carry it out distally on both sides of the incision to prevent restenosis of the meatus. A 16 or 18 Fr Foley catheter left indwelling for 3 to 4 days may serve the same purpose.

**Urethral Stricture**

Urethral obstruction encountered in the anterior or bulbous urethra during catheterization is usually the result of urethral stricture disease. [43] Urethral strictures develop as a result of trauma, infection (especially sexually transmitted diseases), lower urinary tract instrumentation, or long-term indwelling catheter drainage. Strictures may remain asymptomatic for a period of time, but eventually most become symptomatic and cause urethral voiding symptoms, hematuria, or bloody urethral discharge that may or may not be associated with infection. *Manual force should not be used to negotiate or to dilate urethral strictures*. Force merely promotes a vicious cycle of false passages, bleeding, and eventual increased scarring, which makes catheterization more difficult. Inability to negotiate a urethral stricture with a simple straight Foley catheter or coude catheter leads to consideration of urethral dilation using filiforms and followers.

*Filiforms* are very narrow, flexible, solid catheters, usually not exceeding 4 Fr in caliber. They are not dilators. Their sole function is to locate and successfully negotiate a strictured urethral segment. Each filiform has a straight or pigtailed (curved) distal end and a proximal female-threaded coupling into which the distal male end of a follower may be threaded. Following generous topical anesthesia with 2% lidocaine (Anestacon), the previously prepared penis is grasped between the nondominant long and ring fingers and stretched upward. The filiform is slowly passed down the urethra in an attempt to negotiate the strictured iris or narrowed segment of involved urethra (Fig. 59-20 *A*). This is all done by "feel" and experience and may require several attempts. It is always best to advance the filiform with the gentlest of pressure.

Filiforms should never be forced through the urethra. Any encountered resistance represents the potential edge of the strictured urethra or fold of urethral mucosa. Undue force applied to the filiform at this point may result in perforation of the urethral mucosa and creation of a false passage along the urethral body or inferiorly into the perineum. If the filiform meets resistance, it should be partially withdrawn, rotated 90° to 180°, then gently reinserted. If resistance is met again at the same location, the first filiform may be left in place (to fill up that particular obstructing site) and a second filiform advanced alongside it. A third and a fourth filiform may be necessary before one of them successfully navigates the narrowed aperture of the stricture and advances upward through the normal proximal urethra and into the bladder (Fig. 59-20 *B-D*). The sine qua non of success is the effortless passage of the filiform through the strictured area without spontaneous discharge of the filiform when it is released. Any amount of filiform return should alert the catheterist that the filiform has not negotiated the stricture and requires replacement. Pigtail filiforms (with a corkscrew-shaped tip) (Fig. 59-20 *E*), rather than straight-tipped filiforms, are often easier to advance over an abrupt urethral edge and through the smallest of strictured openings. Once through the stricture, the filiform is advanced until the threaded coupling is near the urethral meatus (Fig. 59-20 *F*).

Because filiforms are very pliable, they must be grasped securely. This is ensured by stabilizing the retracted foreskin and penis just proximal to the glans between the long and ring fingers of the nondominant hand as described previously (see Fig. 59-17) and holding the filiform between the nondominant index finger and thumb. This allows controlled attachment and subsequent detachment of graduated followers as serial

dilation is performed *G*).

A follower of the smallest caliber (usually 8 Fr) should always be selected first; it should be copiously lubricated and threaded onto the filiform. When it has been threaded completely (no threads showing), it is gently advanced without pressure through the upwardly stretched penis and urethra into the bladder (see *G*). Stretching the penis upward discourages telescoping of the urethra and subsequent kinking of the filiform and follower (see Fig. 59-15 (Figure Not Available) *A* and *B*). The follower is advanced into the bladder until there is spontaneous egress of urine from the follower, guaranteeing successful passage. Note that the side drainage holes of the 8 and 10 Fr follower are quite small and frequently become occluded with lubricating jelly. This may prevent spontaneous urinary drainage from the follower even though it has successfully negotiated the stricture and passed into the bladder. In this circumstance, easy passage of the 8 Fr follower into the bladder and the lack of gross blood or bloody drainage at the filiform-follower coupling when changing follower sizes are indicative of successful passage and dilation rather than of the creation of a false passage.

Absolute certainty of location of the 8 or 10 Fr follower can be established at any time by irrigating the follower with sterile saline, much like irrigating a Foley catheter. The irrigating fluid will dislodge any obstructing lubricating jelly from the side holes of the follower and will allow egress of urine from the follower. The entire dilating procedure is repeated with sequentially larger followers until one size larger than the proposed retention catheter is successfully introduced. Following completed dilation, the coupled filiform and follower are removed intact, the urethra is relubricated with topical lidocaine (Anestacon) anesthesia, and the previously selected 14 to 16 Fr balloon Foley or coude catheter is passed to its fullest extent into the bladder. After return of urine from the Foley ensures proper placement, the Foley balloon is inflated and the catheter is withdrawn and left to drain as described previously.

Occasionally, a urethral stricture is so dense and irregular that a filiform and 8 Fr follower may pass successfully, but the density and length of the stricture prevent further dilation. In this circumstance, the indwelling filiform and follower may be taped to the penile shaft for 1 to 2 days to provide adequate bladder drainage and probable softening of the stricture.

The following procedure is used to *tape the follower to the penis*. After wiping excess lubricant from the follower and from the penile glans and shaft, a small amount of tincture of benzoin is applied to the follower and to the unbroken skin of the penile shaft ( *not to the glans*). After the benzoin has dried, strips of paper tape 1.25 cm in width are placed longitudinally down the penile shaft without overlapping. The distal ends of each strip of tape are wrapped around the follower much like taping a nasogastric tube to the nose. These longitudinal strips will keep the follower in place. *It is important not to circumferentially wrap these strips around the penis*. If the tape were applied circumferentially, the tape might constrict venous and lymphatic return sufficiently to produce a relative paraphimosis.

Urethral dilation with filiforms and followers should be neither bloody nor excessively uncomfortable for the patient. If the procedure is bloody or uncomfortable or if no urine

is returned despite advancement of the follower for at least 24 cm, the physician should consider that the filiform may not be in the urethra, but instead has created a false passage. In such a situation, retrograde urethrography will define the urethral anatomy. In cases in which urethral instrumentation is unsuccessful for whatever reason, it may be necessary to place a suprapubic peel-away sheath cystostomy tube rather than persist with unsuccessful urethral dilation.

**Spasm of the External Urethral Sphincter**

The male patient may voluntarily or involuntarily contract the urogenital diaphragm (external sphincter), the striated urethral sphincter at the apex of the prostate. (This is especially true of trauma patients and men with neurogenic bladder dysfunction and pelvic floor spasms.) This produces spurious urethral resistance at approximately 16 cm from the meatus. Because increased abdominal pressure or voluntary perineal contraction causes reflex contraction of the external sphincter, the patient in these situations should be encouraged to lie supine and take slow, deep breaths, consciously trying to relax the perineum and rectum. Plantar flexion of the toes and ankles also aids in relaxation of the pelvic floor. Because the external sphincter is composed of striated muscle and fatigues within a few minutes, gentle but steady pressure exerted on the syringe or the catheter while the above maneuvers are undertaken usually results in successful catheterization. If these maneuvers do not result in successful passage of the catheter, the catheterist may be encountering an anatomic abnormality that will require definitive retrograde urethrography before instrumentation.

**High Bladder Neck**

Occasionally, a patient may have an enlarged intravesical portion of the prostate with a secondary high-riding bladder neck. The tip of the standard Foley catheter may encounter this intravesical portion of the prostate and may not readily pass above it into the bladder. Resistance is usually encountered after the catheter has been passed 16 to 20 cm into the urethra. Slow instillation or injection of 20 to 30 mL of sterile lubricating jelly into the urethra may allow the catheter to slip over the prostate and into the bladder. If this fails, a coude catheter may be inserted. This catheter has a bend in the tip, and one will almost always be able to maneuver it gently into the bladder (Fig. 59-21 *A* and *B*). Passage of the coude catheter often may be enhanced by having an assistant exert digital compression and flattening of the elongated prostate using a gloved finger in the patient's rectum (Fig. 59-21 *C*).

Use of a catheter guide or stylet is *best reserved for the urologist,* as such techniques encourage creation of a urethral false passage (Fig. 59-21 *D*). If the coude catheter cannot be advanced on its own or with the added help of an assistant, a scarred, fixed bladder neck contracture, usually the result of transurethral surgery, may be present. Such a contracture is often very difficult to blindly negotiate. An attempt with filiforms and followers may be warranted. Direct cystoscopic visualization and incision of the bladder neck obstruction by a urologist is usually required.

**Catheterization in the Patient with Pelvic Trauma**

The patient with pelvic trauma or a straddle injury presents special problems in urinary management. The patient may be in shock from associated injuries. Accurate minute-to-minute monitoring of urinary output requiring bladder catheterization may be required in the initial resuscitation. Furthermore, radiographic evaluation to define the extent of lower urinary tract injury may require a retrograde cystogram, which necessitates urethral catheterization. Prior to urethral catheterization in all trauma patients, the penis should be examined for evidence of blood at the urethral meatus, the absolute marker of urethral injury. [35] Blood at the urethral meatus, a "high-riding" or abnormal feeling prostate on rectal examination, and penile, scrotal, or perineal ecchymoses are all hallmarks of potential urethral injury and represent contraindications to empiric urethral catheterization without an antecedent normal retrograde urethrogram. [35]

The hazard of injudicious urethral catheterization in the pelvic trauma patient is the potential worsening of an already existing, less serious urethral injury that is often associated with such trauma. Pelvic fractures most often impart injury to the prostatomembranous urethra just above the urogenital diaphragm. The shearing pelvic fracture fragments transect the urethra and puboprostatic ligaments, thereby displacing the prostate superiorly from its normal anatomic attachment to the posterior surface of the pubic bone. A partial or complete urethral injury may occur. An appropriately recognized and treated partial urethral disruption may heal with little or no scarring. However, a complete urethral disruption requires surgical repair and usually results in some degree of postoperative urethral stricture and, occasionally, urinary incontinence and impotence, all of which portend significant morbidity. The danger of injudicious urethral catheterization in this situation is the potential conversion of a partial injury into a complete urethral injury, with its associated complications. Retrograde urethrography is the diagnostic procedure of choice in any suspected urethral injury (see Retrograde Urethrography).

In the event that contrast material flows easily from the urethra into the bladder without extravasation, complete urethral integrity is ensured, and an attempt to pass a 14 or 16 Fr Foley catheter should be made. If *any* urethral resistance is encountered other than that normally expected at the voluntary external sphincter (urogenital diaphragm) in a conscious, anxious patient, the catheterization should be immediately aborted and a urologist consulted. If passage is successful, the catheter balloon should be inflated and the catheter withdrawn until it approximates the bladder neck. At this point, it is left to dependent drainage, and very careful attention is paid to the initial bladder effluent. Any colored urine other than clear or yellow is considered gross hematuria and mandates evaluation of the bladder and upper urinary tract to disclose the source. If the retrograde urethrogram shows urethral extravasation *AND* passage of contrast into the bladder, a partial urethral injury has been identified. One gentle attempt at passage of a 12 to 14 Fr Foley or coude catheter may be attempted, depending on the experience and confidence of the catheterist. Once again, any degree of resistance dictates termination of the procedure and urologic consultation.

In the patient without external sphincter spasm in whom the retrograde urethrogram shows evidence of urethral extravasation without any contrast filling the bladder, a

complete urethral injury has been identified, and immediate urologic consultation is indicated for placement of a suprapubic catheter and subsequent surgical repair of the complete urethral injury. One caveat: if >50 to 60 mL of contrast is used at any time for urethrography and more than gentle pressure is exerted during urethral contrast instillation, it is possible to create objective penile venous intravasation of contrast, which is benign but may simulate urethral extravasation and produce a spurious examination result similar to urethral injury. The distinguishing feature with intravasation is that any subsequent film (i.e., post-void film) will disclose immediate clearing of the iatrogenic penile venogram, whereas urethral extravasation will persist indefinitely.

Suprapubic placement of a peel-away sheath and Foley catheter as an alternative to urethral catheterization for the trauma patient is covered elsewhere in this chapter.

**Complications of Urethral Catheterization**

Although urethral catheterization performed by skilled personnel in appropriate circumstances has an acceptable complication rate, untoward sequelae of catheterization are not unusual.

The frequency of bacteriuria after a single catheterization in a healthy outpatient population is probably <1%. [39] However, in hospitalized, elderly, debilitated, or postpartum patients, the rate may be considerably higher. Urinary catheterization is the leading cause of nosocomial urinary tract infections. The mortality in patients with nosocomial urinary tract infection is approximately 3 times that in patients not acquiring infection. [44] Of patients catheterized with a closed system for 2 to 7 days, 8% to 10% will have significant bacteriuria once the catheter is removed. [45] Patients with catheters indwelling >10 days almost always acquire an infection. Infection from the urethra and the bladder may disseminate to cause epididymitis, pyelonephritis, and bacteremia. Although the use of a povidone-iodine lubricating gel has been shown to reduce the inoculation of bacteria into the bladder at the time of catheterization, [46] further study will be needed to determine if this antiseptic lubricant actually reduces infectious sequelae.

With long-term catheterization, bacteriuria is inevitable. Although episodes of high temperature (38.8 °C) due to urinary tract infection in patients with long-term catheterizations are rare (2 per 1000 patient-days), these episodes can be associated with bacteremia and death. [47] Use of a condom catheter, adult diapers, and intermittent self-catheterization [48] represent noninvasive alternatives to long-term Foley catheterization in nonambulatory incontinent men and women. Other rare complications of long-term indwelling urethral catheterization include bladder stones, recurring bladder spasm, periurethral abscesses, bladder perforation, [49] and urethral erosion. [50]

In addition, complications may occur during the act of catheterization. False passages may be established in any area of the urethra when force is exerted on the catheter. In an uncircumcised patient, negligence in reducing the retracted foreskin to its normal anatomic position after urethral catheterization or instrumentation may lead to painful paraphimosis and associated complications.

Leaving a catheter indwelling too long or using a larger catheter than is needed

promotes poor drainage of the periurethral glands, urethritis, and periurethral abscesses, all of which may lead to urethral stricture disease. Likewise, concretions may form around the catheter balloon and lead to the formation of bladder stones, many of which require operative removal.

The use of silicone rather than latex catheters for postoperative urinary drainage in adult males undergoing cardiac surgery has been shown to reduce the incidence of subsequent urethral stricture formation. [51] Although patients with indwelling latex catheters were catheterized <48 hours, a 2% incidence of urethral stricture was still noted at 1 year and a 5% incidence at 2 years. None of the patients with indwelling silicone catheters developed a stricture.

Hematuria has long been considered to be common immediately following even atraumatic catheterization. Although

Sklar and colleagues found a small increase in urinary red blood cell (RBC) count with catheterization, only 1 in 47 patients had an increase of >4 RBCs per high-power field (HPF) attributable to the procedure. [52] They suggest that >4 RBCs per HPF following catheterization is unlikely to be due to the procedure and is, in fact, evidence of preexisting hematuria, which must be explained.

Undesirably retained urethral catheters are an uncommon but frustrating problem. Catheters may be retained because of balloons that do not deflate (see following section) or very rarely because of a knot that has spontaneously developed in the catheter (very rare). Catheter knotting has been associated with the insertion of a highly flexible catheter far into the bladder. [53] A guide wire passed up the catheter may be successful to manipulate some knots free, but urethral dilation with progressively larger catheters adjacent to the retained catheter may be needed to permit urethral passage of the knot.

## REMOVING THE NON-DEFLATING CATHETER

The self-retaining Foley balloon-type catheter obviates the need for cumbersome taping or suturing of the catheter to keep it in place. Occasionally, however, an indwelling catheter balloon does not deflate. Needless to say, this problem has challenged and frustrated many physicians and has produced a number of solutions. The usual cause of the nondeflating catheter balloon is the malfunction of the flap-type valve in the balloon lumen of the catheter, which normally allows fluid to enter the balloon of the catheter but prevents passive egress (Fig. 59-22) (Figure Not Available) . [54] The ideal solution is one that resolves the problem--deflating the balloon--without creating another problem (i.e., unnecessary bladder irritation or balloon fragmentation). Of the methods recommended to decompress non-deflating catheter balloons, the only technique that approaches the ideal directly attacks this flap valve deformity. Other methods of deflation are effective but require more creativity and dexterity on the part of the catheterist.

**Techniques**

One method of balloon deflation consists of simply overstretching the balloon with air or water to the point of rupture. Up to 200 mL of fluid can be injected before a 5-mL balloon will rupture. [54] [55] Adding volume to the empty bladder may not be a problem. Unfortunately, this technique may produce unacceptably painful bladder distention for the patient whose catheter is blocked and whose bladder is either secondarily contracted due to chronic infection or neurogenic bladder dysfunction or distended to the point of maximum filling. An even more compelling reason not to use this technique is the disconcerting frequency of balloon fragmentation and subsequent foreign-body bladder stone formation. In an experimental study of 100 catheters (50 of which were overdistended with water and 50 of which were overdistended with air), all 100 catheter balloons ruptured into fragments. [54] Cystoscopic inspection of the bladder and removal of any fragments will be required to prevent bladder stone formation if this method of balloon deflation is selected.

A second method of balloon deflation involves injecting an erosive substance into the balloon port. This causes the balloon to deflate after part of the balloon wall has been eroded. Organic compounds that attack the latex polymers are often used. Ether, acetone, mineral oil, and even petrolatum ointment have been used. In general, the more volatile the substance, the more rapidly it ruptures the balloon. Rupture of the balloon may be partly a result of the rapid expansion that some of these volatile substances--especially ether--undergo at body temperature. Ether was reported to rupture 58 of 60 catheter balloons within 2 minutes of injection into the balloon port. Unfortunately, in 56 of the catheters, a free fragment of the balloon was created. Mineral oil, which works more slowly, was associated with fragment production in 95 of 100 catheters tested. [54] When released into the bladder, organic substances often produce a symptomatic chemical cystitis. Use of these substances is discouraged.

A third method of deflating the balloon is to puncture it with a needle. With gentle traction, the balloon is located in the urethra or drawn against the bladder neck and is punctured with a thin 25- or 27-ga spinal needle. This needle may be directed suprapubically (transvesically), transvaginally, transperineally, or transrectally. The procedure may be done either blindly [57] or with the aid of ultrasound. In women, a spinal needle may be gently introduced transurethrally alongside the catheter. Fragmentation during puncture can occur, but it is much rarer than in the 2 techniques described previously.

The easiest way to deflate a non-deflating balloon is to attack the inflate-deflate channel that normally prevents the passive egress of inflating fluid. Patients may be sent to the ED in the late evening or early morning hours after their catheters have been progressively shortened by ingenious health care providers during the day. Cutting the catheter may result in rapid deflation if the valve-flap defect happens to be present in the part of the catheter that is cut off, an uncommon occurrence. A shorter catheter with a more proximal valve-flap defect can often be left for 24 hours with ongoing slow balloon deflation, but this maneuver leaves the problem of managing an unconnected catheter and an incontinent patient. Devising a waterproof and aseptic method of

collecting urine from the shortened Foley catheter may require use of a ureteral catheter drainage bag or other ingenious approaches.

When presented with this situation, it is often best to insert a thin, rigid wire into the balloon-port lumen in an effort to deflate the valve-flap defect sufficiently and promote the escape of fluid from the balloon. A stainless steel wire

suture of 3-0 or 4-0 gauge is the thinnest suitable material. The wire stylet from an angiographic catheter, guide wires from ureteral catheters, and very small, well-lubricated ureteral catheters themselves have all been reported to be successful. When a ureteral catheter guide wire was used in one series, 34 of 39 balloons were deflated without fragmentation. In the 5 unsuccessful cases, needle puncture of the balloon was required and was successful. [57]

One approach is to use a stepwise series of maneuvers. If the balloon does not deflate, remove the syringe adapter plug from the balloon-inflating channel. This rules out a malfunction of the adapter. If the balloon water does not escape, next insert an angiographic catheter stylet into the balloon-inflating channel and rotate it. Usually, the water from the balloon flows out along the wire. If it does not, place the catheter on traction and attempt to locate the balloon by palpation either perineally, transvaginally, or transrectally. If this is successful, a 25- to 27-ga spinal needle under local anesthesia is used to blindly puncture the balloon and then remove the catheter. If localization is unsuccessful, multiple blind passes with the 27-ga needle can be attempted; this is usually successful in decompressing the balloon and removing the catheter. [58] If the patient requires a permanent indwelling catheter one may be replaced immediately. Concomitant inadvertent needle punctures of the rectum are usually of no clinical significance.

Once a malfunctioning balloon has been deflated, it is mandatory to carefully inspect the balloon itself for missing fragments. If a piece of the balloon is missing, it is necessary to arrange for subsequent cystoscopy to look for and remove the fragment. Unfortunately, pretesting Foley catheter balloons by trial inflation and deflation before insertion does not eliminate the potential for a non-deflating Foley catheter balloon.

## SUPRAPUBIC ASPIRATION OF THE BLADDER

One of the problems of interpreting voided urine samples is that the urine from the bladder passes through a progressively more contaminated urethral conduit. In the female, the perineum is a culture medium where bacteria are seemingly eager to be swept along into the sterile collection cup and onto the agar plate. To avoid the dilemma of interpretation, physicians have devised maneuvers to minimize the presence of contaminating organisms. Male patients are instructed to retract the foreskin, cleanse the meatus, discard the first portion of urine, and catch the midstream part of the voided specimen. Female patients are asked to perform even more difficult maneuvers to avoid bacterial contamination: sit backward on the commode facing the wall, hold the labia apart with one hand, cleanse the periurethral skin blindly with the other, then reach for the cup, initiate voiding, and catch the midstream urine--all while holding the labia apart and maintaining the precarious position on the commode. Some experts [59] have

women void in the lithotomy position after an assistant retracts the labia, cleanses the perineum, and then catches the midstream urine.

In standard transurethral bladder catheterization, even under ideal circumstances, the procedure is often uncomfortable. The catheter must traverse the distal contaminated urethra and may infrequently introduce contaminating bacteria into the specimen and into the bladder of the patient, resulting in infection, primarily in patients who don't empty their bladder with normal voiding.

Suprapubic aspiration of the bladder, first reported as a method of collecting urine for bacteriologic study in 1956, [60] offers the physician a relatively simple means of obtaining uncontaminated bladder urine. Urethral contamination is successfully avoided, and positive results always represent true bacteriuria. The one caveat is that the bladder must be full to avoid multiple painful needle sticks, a clinical situation that may be difficult to discern in a sick child.

**Indications**

In the neonate or the young child, suprapubic aspiration or urethral catheterization can provide the physician with a sample that is reliable for bacteriologic interpretation. Although disconcerting to some parents (they may wish to leave the room or look away during the procedure), suprapubic aspiration is not a dangerous procedure, and the sensitivity of urinalysis of this urine for bacteriuria approaches 100%. However, for children 2 years or older, urine can generally be more easily collected by urethral catheterization.

For adult patients, the indications for suprapubic aspiration are more limited, because these patients usually can cooperate with the physician. Men with condom catheters or phimosis, however, may require suprapubic aspiration to minimize urethral contamination. Aspirated cultures, rather than catheterized specimens, may help rule out contamination in patients with asymptomatic bacteriuria on routine urine collection. In infections caused by organisms that in other circumstances are often discounted as contaminants (e.g., *Staphylococcus epidermidis* or *Candida albicans*), suprapubic aspiration or a catheterized specimen is required to confirm the presence of such pathogens.

In patients in whom the possibility of infravesical infection is a concern (e.g., patients with chronic infections of the urethra or the periurethral glands), suprapubic aspiration may help localize a bladder from a urethral source.

**Procedure**

The physician must first locate the bladder. A full, palpable, or percussible bladder should be readily apparent, but this can be difficult to discern in all but the thinnest patients. If there is any question about the location or the amount of bladder urine, a quick ultrasound examination is informative. The point of entry in the skin should be 1 to 2 cm above the superior edge of the symphysis pubis. The syringe and needle are

passed perpendicular to the abdominal wall toward the bladder, usually a 10° to 20° angle from the true vertical, somewhat *cephalad* in *children* (Fig. 59-23) and somewhat *caudad* in *adults* (Fig. 59-24) . Note that the bladder of a newborn is an abdominal organ and that it will be missed if the needle is inserted too close to the pubis or is angled toward the feet.

The child is placed supine and is restrained with the legs in a frog-legged position. Once the prepared skin has been draped and the point of entry has been chosen, a skin wheal of local anesthesia is raised to reduce discomfort. When the skin has been anesthetized, a longer, larger-caliber needle (usually 22 ga, 3.75 to 8.75 cm in length) is advanced in the midline through the skin and quickly into the bladder.

This author prefers to advance the needle attached to a syringe, with active aspiration during advancement. As soon as the bladder is entered, urine appears in the syringe. A short needle is adequate for virtually all pediatric patients. After the urine is collected, the syringe and needle are withdrawn. Microscopic hematuria always follows the procedure but gross hematuria is uncommon. A bandage may be placed over the puncture site. If urine is not obtained, the needle is not removed but withdrawn to a subcutaneous position and redirected at a different angle. Often a child may spontaneously start to void following any type of invasive stimulus (e.g., bladder irritation by a probing needle, venipuncture, or lumbar puncture). Hence, preparation to collect a spontaneously voided specimen is recommended, should that option arise. This should be anticipated before beginning blood or spinal fluid collection during the bacteremic workup of the febrile neonate.

In most patients, an acceptable urine sample can be obtained with the first needle pass. If the needle points too caudad in an effort to avoid entering the peritoneum, it is possible to enter the retropubic space, skimming the bladder muscle and never penetrating the bladder mucosa.

### Complications

Stamey has performed several thousand aspirations without complications. [59] Bacteremia does not result from this procedure. [63] Bowel penetration has occurred in children who had distended abdomens from gastrointestinal disturbances. [64] The combination of gaseous bowel distention and relative hypovolemia may displace and flatten the relatively empty bladder against the pelvic floor. Even when the large bowel has been penetrated, patients recover uneventfully. Simple penetration of the bowel with a needle is considered an innocuous event and requires no specific treatment.

## PERCUTANEOUS SUPRAPUBIC CYSTOSTOMY

### Background

Although suprapubic cystostomy was described as early as 4 centuries ago, the safety of the procedure was first demonstrated by Garson and Peterson in 1888. The first modern method was the Campbell trocar set, described in 1951. [65] [66] Campbell used a

sharp trocar passing through a sheath. The sheath had one longitudinal portion of its wall missing to permit a balloon-type Foley catheter to be passed into the bladder. The Campbell trocar is a large-diameter instrument, accepting up to a 20 Fr catheter. Newer technologies have made its use obsolete in the ED.

The development of punch thoracostomy tube sets suggested their use as modified cystostomy tubes. This led to the invention of medium-caliber cystostomy tubes, which were easier to insert than the Campbell trocar but provided more satisfactory drainage than adaptations of IV infusion sets. Ingram's trocar catheter is perhaps the best known of these tubes. It has 3 lumina: 1 for inflating the retention balloon and the other 2 for drainage or irrigation. The Ingram catheter is available in a 12 or 16 Fr size. The Stamey suprapubic catheter is another variation of this type, but it uses a 4-wing Malecot-type retention device rather than a preferred user-friendly inflatable balloon.

Perhaps the most widely known and frequently used trocar-type cystostomy tube is the Cystocath. [70] It is available in 8 and 12 Fr sizes. The latter is more commonly used for adult patients. The Cystocath is packaged as a self-contained set supplying virtually everything needed for insertion. The device is easy to insert and may be satisfactory for relatively long periods of trouble-free use if the patient is given conscientious nursing care.

The major difficulty with cystostomy tubes of all designs has been securing them to the patient's skin. Those with retention balloons, such as the regular Foley urethral catheter or the Ingram catheter, are most secure and only need tape to secure them to the anterior abdominal wall. Virtually all other systems depend on tape or skin adhesive to hold either the tube or the appliance in place. They become an annoyance to both the patient and the care provider.

The latest and most user-friendly device for suprapubic bladder access is the Cook peel-away sheath unit. [36] It uses the Seldinger (guide wire) technique to gain bladder access and allows suprapubic placement of a Foley balloon catheter for definitive bladder drainage. This device is recommended for ED use over other suprapubic bladder access approaches and is discussed in this section.

### Indications

In general, any patient who would require a urethral catheter but in whom a catheter cannot be passed is a candidate for a suprapubic cystostomy tube. In emergency situations, the majority of these patients are men with urethral stricture or complex prostatic disease and trauma patients with urethral disruption. Depending on the experience of the catheterist, dilation can usually be performed in patients with urethral strictures using filiforms and followers. If there is any difficulty with urethral instrumentation, a suprapubic cystostomy tube is prudent and prevents further urethral injury. Complete urethral transection associated with a pelvic fracture is an absolute indication for emergent suprapubic cystostomy. Many affected patients need laparotomy because of associated injuries, and a large suprapubic catheter can be placed intraoperatively. However, if the patient does not require laparotomy, a percutaneously placed Foley catheter allows urologic surgery to be done electively after the patient's

condition has stabilized clinically.

Patients with lower genitourinary infection deserve special care before instituting any type of urethral instrumentation. The risk of inciting an episode of gram-negative bacteremia with urethral dilation must be considered, and appropriate IV gram-negative antibiotic coverage started before the patient is instrumented. Foley catheter drainage is the first choice and suprapubic drainage is an option in patients with acute prostatitis or epididymitis who require bladder drainage. Ideally, a suprapubic catheter allows both bladder drainage and unobstructed drainage of prostatic, seminal vesicle, and urethral secretions but requires an invasive procedure with its associated risks.

Neurologically disabled patients (e.g., quadriplegics or paraplegics) or patients with any type of neurogenic bladder dysfunction who have been successfully maintained on a program of intermittent self-catheterization occasionally have difficulty with urethral catheterization. In these patients,

especially those with high spinal cord lesions, suprapubic needle aspiration or suprapubic cystostomy can be a rapidly effective method of relieving autonomic hyperreflexia associated with acute bladder distention. [71] Bladder decompression in the dysreflexic, profusely perspiring, hypertensive quadriplegic in sympathetic crisis provides dramatic symptom resolution, whether by suprapubic bladder decompression or Foley catheter placement.

Suprapubic catheterization is *not* recommended as first-line treatment for the patient who is voiding poorly from lower urinary tract prostatic obstruction. Such patients, although symptomatic, are better off with intermittent self-catheterization or an indwelling Foley catheter if they are in retention or have chronically infected urine. Young women with psychosocial or emotional neurogenic bladder dysfunction are best managed by intermittent self-catheterization. In all such cases, clinical judgment will dictate the most appropriate form of treatment and whether concomitant antibiotic therapy is required.

**Contraindications**

Because placement of a suprapubic tube involves some risk, patient selection is important. The procedure should not be performed in a patient whose bladder is not definable. Although no absolute reported minimum bladder volume has ever been established, there must be enough urine in the bladder to allow the needle to fully penetrate the bladder dome without immediately exiting through the base. There must also be enough urine in the bladder to displace the bowel away from the anterosuperior surface of the bladder and the entrance of the needle. Ultrasound may be helpful in defining bladder anatomy.

Individuals who have a history of previous lower abdominal surgery, intraperitoneal surgery, or irradiation may have developed adhesions or adherence of the bowel to the anterior bladder wall. They are potentially at greater risk for bowel injury during percutaneous suprapubic cystostomy tube placement than those without previous abdominal surgery. Blind suprapubic cystostomy tube placement in these patients

should be avoided. The absence of any of these risk factors does not totally exclude the risks of bowel or intraperitoneal injury, but it reduces them significantly.

Patients with bleeding diatheses are at greater risk for postinsertion bleeding, either into the bladder or into the retropubic space, than their normal counterparts.

## Equipment

The items of equipment needed for Cook's peel-away sheath placement are listed in Table 59-6 .

## Procedure

The following comments describe the placement of the Cook peel-away sheath. With modifications, these guidelines are adaptable for any type of suprapubic catheter placement.

### Preparing the Patient

If necessary, the lower abdomen is shaved. Povidone-iodine skin preparation or another suitable bactericide is used to cleanse the area. The extra liquid is removed, and the skin is allowed to dry. A 6-mL syringe is filled with 1% lidocaine, and a 22-ga, 7.75 cm spinal needle is attached. A skin wheal is raised in the proposed site (approximately 2 to 3 cm above the pubic symphysis), and the subcutaneous tissue and rectus abdominis muscle fascia is infiltrated at a 10° to 20° angle toward the pelvis.

The bladder is located by advancing the needle in the prescribed direction while aspirating the syringe. Urine is easily aspirated when the bladder is entered (Fig. 59-25 A).

### Placing the Tube

Once the bladder has been located, the syringe is removed from the needle and a guide wire is advanced through the needle into the bladder (Fig. 59-25 B). The needle is withdrawn, leaving only the guide wire traversing the anterior abdominal wall and positioned inside the bladder. A No. 15 scalpel blade is used to make a stab incision directly posterior to the wire through the skin, subcutaneous tissue, and superficial anterior abdominal wall fascia. The peel-away sheath and indwelling fascial dilator are then passed together over the wire into the bladder (Fig. 59-25 C). The guide wire and fascial dilator are removed, leaving only the peel-away sheath inside the bladder (Fig. 59-25 D). A preselected Foley balloon catheter is then passed through the indwelling intravesical sheath into the bladder (Fig. 59-25 E). Urine is aspirated to confirm proper placement. The Foley balloon is inflated with a minimum of 10 mL of air, water, or saline (Fig. 59-25 F). The peel-away sheath is withdrawn from the bladder and anterior abdominal wall and is literally peeled away from the catheter, leaving only the indwelling suprapubic Foley catheter (Fig. 59-25 G). The catheter is withdrawn slowly until the inflated balloon approximates the cystostomy site (Fig. 59-25 H). The catheter is

connected to a drainage bag, and the wound is dressed with 4 × 4 gauze pads to complete the procedure.

## Complications

A wide variety of complications specific to each procedure have been reported, which serve as reminders that suprapubic cystostomy is not innocuous. Occasionally, despite the best intentions, the suprapubic tube or catheter cannot be positioned or maintained successfully without untoward sequelae (Table 59-8) .

The most serious complications involve perforation of the peritoneum or the intraperitoneal contents. Any condition that might fix the anterior peritoneum so that the filled bladder cannot lift the peritoneum cephalad may result in either transperitoneal bladder puncture or possible perforation of small or large bowel. Although finding the bladder

| **TABLE 59-8** -- Reported Complications of Suprapubic Cystostomy |
|---|
| Bowel perforation |
| Intraperitoneal extravasation (without a prior history of surgery) |
| Extraperitoneal extravasation |
| Infection of space of Retzius |
| Ureteral catheterization |
| Obstruction of tubing by blood, mucus, or kinking |
| Tubing comes out |

using a small-gauge scout needle may help reduce bowel injury, even in the most apparently successful of bladder punctures, a complication may result.

The cystostomy tube or catheter that merely traverses the peritoneum may produce a mild ileus, serve as a route for peritoneal infection, or drain the bladder contents into the peritoneal cavity. The last situation would be expected if a Cystocath, rather than a peel-away sheath, were used, and one of the extra holes of the Cystocath tubing opened into the peritoneal cavity. Through-and-through bladder penetration with associated rectal, vaginal, or uterine injury has been reported, although the consistent use of small-gauge bladder locator needles and the judicious advancement of fascial dilators should reduce the incidence.

Occasionally the physician is tempted to proceed with suprapubic cystostomy when the bladder is not palpable and has not been located with a syringe and needle. Injury of adjacent organs is much more frequent in these circumstances. If physicians remind themselves that the bladder eventually refills, they will find waiting much more tolerable. If faced with an emergency, ultrasound guidance may be helpful for determining bladder size and location.

Infection may occur at the suprapubic cystostomy skin site or anywhere along the course of the catheter. [75] Use of antimicrobial ointment daily after cleaning the catheter entry site may reduce purulence around the tube. However, topical care does not prevent eventual deep space or bladder infection from the presence of a foreign body. Deeper tissue infections may result from extravasated infected urine or from a superficial infection spreading along the tube to a hematoma at the bladder or fascial level. Parenteral antibiotics may be required. Open drainage is rarely needed unless a loculated abscess has formed.

Hematuria is rarely more than a transient problem. [76] After suprapubic Foley catheter insertion, bladder irrigation may occasionally be required to clear the hematuria. Transient Toomey syringe aspiration may be needed to evacuate clots.

## EMERGENCY LOWER GENITOURINARY RADIOLOGIC PROCEDURES

Trauma to the urinary tract accounts for about 10% of all injuries seen in EDs. Although the signs of genitourinary trauma in general can be quite subtle, lower urinary tract injury can often be quickly identified and thoroughly evaluated radiographically in the ED. Radiologic imaging of the upper urinary tract is generally a less urgent matter and can usually be done in the radiology suite or, when important for emergency operative decision-making, as a single shot intravenous pyelogram (IVP) in the operating room. Hence, this section does not discuss the role or technique of IVP in detail. Note that the timing of any radiologic evaluation can be challenging to the emergency physician, especially when faced with a critically ill multiple trauma patient. The priority and extent

of such an evaluation, of course, must be determined by the trauma team of physicians involved in each resuscitation.

**Indications for Evaluation**

The urinary tract includes the kidneys, ureters, bladder, urethra, and external genitalia. Approximately 8% to 10% of *blunt* abdominal trauma is associated with injuries to the urinary tract. [77] In one large series, [78] 7% of gunshot wounds and 6% of stab wounds to the abdomen resulted in *penetrating* wounds to the kidney. For injury identification purposes, the genitourinary system is best divided into lower urinary tract (i.e., urethra and bladder), upper urinary tract (i.e., kidneys and ureter), and external genitalia (i.e., penis, scrotum, and testes or vagina, labia majora, and labia minora). Each of these subdivisions has its own markers for potential injury. These markers are addressed during the resuscitation phase of trauma care and during secondary injury survey when the abdomen, pelvis, external genitalia, vaginal vault, and rectum are systematically examined.

The markers for lower urinary tract injury are blood at the urethral meatus, abnormal position of the prostate on rectal examination (in men), and gross hematuria. [79] Perineal ecchymosis and scrotal hematoma also represent potential lower urinary tract injury, but these findings are usually seen later in the patient's course rather than acutely in the ED. Gross hematuria or microscopic hematuria (3 to 5 RBCs per HPF--spun specimen) *in conjunction with any history of shock* (systolic blood pressure 90 mm Hg) *in the field or in the ED following blunt trauma* are markers of potential upper urinary tract injury in any adult. [80] In children, there are no markers for upper tract injury; consequently, any degree of microscopic or gross hematuria indicates potential genitourinary injury and requires radiographic diagnostic evaluation. [81]

In genitourinary trauma, the lower urinary tract is always evaluated before the upper urinary tract. Retrograde urethrography and retrograde cystography are the diagnostic procedures of choice to evaluate potential injury to the lower urinary tract. These studies must be carried out in the proper sequence and in a retrograde fashion to avoid missing potential injuries. *Retrograde* refers to the technique of instilling contrast retrograde through the urethra or by gravity filling of the bladder. It must be distinguished from antegrade filling, in which IV contrast for IVP or abdominal computed tomography (CT) is excreted from the kidneys and allowed to fill the bladder passively over time.

Contrast-enhanced CT is the diagnostic examination of choice for suspected renal trauma. It provides greater resolution and sensitivity than bolus infusion IVP with nephrotomography and has the advantage of evaluating other intra-abdominal structures as well. [82] However, it is expensive, and in some hospitals it is not readily available on a 24-hour basis. A reasonable course of action under these circumstances would be to initiate the upper urinary tract investigation with bolus-infusion IVP with nephrotomography and to investigate further with contrast-enhanced CT if an ill-defined or poorly visualizing kidney is the result of the initial study. Contrast-enhanced CT should be performed initially if thoracic or intra-abdominal injuries are present or suspected, or if there is concern about renal pedicle injury.

**Gross Hematuria**

Gross hematuria is indicated by any color of urine other than clear or yellow. It is an *absolute* marker for urinary tract injury and an indication for diagnostic evaluation. The resuscitating physician must be responsible for observing the initial bladder effluent following Foley catheter insertion. Vigorous fluid resuscitation may quickly clear initial gross hematuria and eliminate the only marker for potential injury. When gross hematuria is encountered as an injury marker, the bladder and kidneys are thought of as potential sources for the hematuria. In most cases, gross hematuria in association with a pelvic fracture will implicate the bladder as the most likely source of injury. In the absence of a pelvic fracture and with a history of upper abdominal or chest trauma, the kidneys are the most likely source of the hematuria. In urologic trauma, the lower urinary tract must always be studied before the upper urinary tract (i.e., study the urethra before the bladder, study the bladder before the kidneys). The specific diagnostic studies must always be done in a retrograde fashion. This allows the responsible physician to directly control the amount of contrast used to investigate potential urethral or bladder injuries. Whenever any doubt exists about the mechanism of injury, the patient's physical examination, or the source of gross hematuria, the resuscitating physician is always advised to begin with an evaluation of the lower urinary tract before evaluating the upper urinary tract.

**Evidence of Lower Urinary Tract Injury**

In the resuscitation of any trauma patient, placement of a Foley catheter has become the standard method of monitoring urinary output. Blood at the urethral meatus, however, indicates a potential partial or complete urethral disruption and dictates the need for a retrograde urethrogram to delineate urethral integrity. This study can be done by the resuscitating physician in the ED or on the operating room table by the trauma surgeon or urologist if the patient requires immediate surgical intervention for life-threatening injuries.

The male posterior urethra, which includes the membranous and prostatic urethra, is injured more frequently than the anterior urethra. The urogenital diaphragm encloses and fixes the membranous urethra; the prostate and prostatic urethra are firmly attached to the posterior surface of the symphysis pubis by the puboprostatic ligaments. Blunt trauma and pelvic fractures, especially in the presence of a full bladder, may result in shearing forces that partially or completely avulse portions of the firmly attached posterior urethra. Usually the bladder and prostate gland are sheared from the membranous urethra, resulting in a complete urethral disruption (Fig. 59-26) . The female urethra, in contrast, is short and relatively mobile and generally escapes injury in blunt trauma. Occasionally, a significant pelvic fracture will result in a laceration or avulsion of the female urethra at the bladder neck. Direct injuries to the female urethra may also occur secondary to penetrating trauma to the vagina or perineum. These injuries often are disclosed by blood at the introitus or an abnormal vaginal examination in the female pelvic fracture patient. [83]

Contusions or lacerations of the male anterior urethra occur when the bulbous urethra is

compressed against the inferior surface of the symphysis pubis. This happens most commonly as a result of straddle injuries in males but may result from any blunt perineal trauma. Significant trauma to the penile urethra is rare without penetrating injuries or urethral instrumentation. *Anterior urethral injuries* may result in extravasation of blood or urine into the penis, scrotum, or perineum, or along the anterior abdominal wall, depending on whether or not Buck's fascia has been violated (Fig. 59-27) . [35] This is in contrast to *posterior urethral injuries*, in which blood and urine extravasate into the pelvis.

The rectal examination is highly specific in the evaluation of a posterior urethral disruption. If the prostate is not clearly defined (it should have the consistency of the examiner's thenar eminence), is high-riding rather than in its normal anatomic location, or if a pelvic hematoma can be palpated (see Fig. 59-26) , one should be suspicious of a posterior urethral injury, and a retrograde urethrogram should be performed before attempting urethral catheterization. However, a normal rectal examination, by itself, *should not be considered definitive evidence of an intact urethra* if other clinical signs raise suspicion for urethral injury. Retrograde urethrography is a quick, technically easy study to perform and should be part of every emergency physician's armamentarium.

**Pelvic Fracture**

Pelvic fractures occur commonly in patients with urethral or bladder injury. The incidence of lower tract injuries in males with pelvic fractures ranges from 7% to 25%. Conversely, approximately 80% of all posterior urethral and bladder injuries are associated with pelvic fractures. [79] Because of the severity of late complications, especially urethral strictures, which most often require difficult surgical repair, it is paramount that these injuries not be missed. Again, in any female patient with a pelvic fracture, it is most important to examine the introitus and vaginal vault for blood, which may be indicative of urethral, bladder neck, or vaginal wall lacerations. In male patients, rectal examination of the prostate to assess its position will be most helpful in assessing the posterior urethra. A pelvic fracture in association with gross hematuria is an absolute indication for retrograde cystography. In a review of 234 patients with traumatic pelvic fractures, no major lower urinary tract injuries were found in the absence of gross hematuria. [79]

## Radiographic Contrast Material

Radiographic contrast material is used to fill vessels and other structures to render them diagnostically radiopaque. To evaluate the urethra and bladder, contrast is injected or instilled into these structures in a retrograde manner. To evaluate the kidneys and ureters, a bolus of contrast material is injected into the venous system, opacifying the renal parenchyma and collecting system as it is excreted unchanged in the urine. Three types of contrast material are currently available (Table 59-9) . All contain iodine, and all are hyperosmolar with respect to blood. Conventional agents, such as Hypaque and Renografin (diatrizoate), are triiodinated water-soluble agents (ionic monoacetic monomers) that completely dissociate into anion and cation moieties on intravascular injection. Osmolality is quite high, ranging from 1200 to 2000 mOsm/kg. Many of the side effects of contrast agents have been attributed to their osmolarity. Although iodine

concentrations do determine the quality of the radiographic image, iodine itself is not thought to play a major role in the typical anaphylactoid side effects. [84]

Two new classes of contrast agents are ioxaglate (Hexabrix), an ionic monoacetic dimer, and nonionic (non-dissociating) agents, such as iopamidol (Isovue) and iohexol (Omnipaque). The newer agents have twice as many iodine atoms per particle in solution as conventional agents and therefore provide significantly higher urinary iodine concentration, offering better diagnostic imaging. The osmolality of the newer agents is markedly lower, ranging from 600 to 700 mOsm/kg. The lower osmolality and improved chemical structure may be associated with fewer adverse side effects. [85] [86] Although these new agents are promising for intravascular use, there is still some skepticism that they will truly limit major or clinically significant contrast reactions. [87] The lower-osmolarity nonionic agents have not been associated with a lower incidence of contrast-induced nephropathy. Furthermore, there is no indication for using these more expensive products in the retrograde evaluation of the injured lower urinary tract.

## Radiographic Techniques

### Kidneys, Ureters, and Bladder

The plain film, scout film, or KUB (for kidneys, ureters, and bladder) film of the abdomen, as this view is variously referenced, includes the kidneys, ureters, bladder, and full pelvis. It is essential as the initial diagnostic film because it serves as the film of reference for all subsequent films after injection or instillation of contrast material. Incidental nondiagnostic findings on initial KUB that may alert the physician to the possibility of urinary tract injury include the following:

1. Loss of one or both psoas shadows secondary to blood in the retroperitoneum.
2. Spinal curvature secondary to splinting--usually concave to the side of the injury.
3. Lower rib or transverse process fractures, both of which may be associated with upper urinary tract injury.
4. Pelvic fracture.

---

**TABLE 59-9** -- Clinical Use of Radiographic Contrast Material (RCM) for Intravenous Pyelogram (IVP) and Retrograde Studies

**Use of RCM for IVP**

| | Iodine Content (mg/mL of Solution) | Osmolality (mOsm/kg) ($H_2O$) | Average Volume for IVP |
|---|---|---|---|
| **Conventional ionic RMC** | | | |
| Renografin-60 (diatrizoate sodium) | 288 | 1511 | Adult: 100 mL over 30-60 sec * <br> Child: 1.5 mL/kg |
| Hypaque (50%) (diatrizoate sodium) | 300 | 1500 | Adult: 100 mL over 30-60 sec * <br> Child: 1.5 mL/kg |
| Conray (methyl glucamine iothalamate) | 282 | 1217 | Adult: 100 mL over 30-60 sec * <br> Child: 1.5 mL/kg |
| **New nonionic RMC** | | | |
| Isovue (iopamidol) | 300 | 616 | Adult: 50 mL over 30-60 sec <br> Child: 1-1.5 mL/kg |
| Omnipaque 300 (iohexol) | 300 | 672 | Adult: 50 mL over 30-60 sec <br> Child: 1-1.5 mL/kg |
| **Use of RCM for Retrograde Studies** | | | |

| RCM | Use | Procedure |
|---|---|---|
| Renografin-60 or Hypaque (50%) | Dilute stock solutions with saline 1:10 (10% solution) | Urethrogram: 10-15 mL of dilute solution injected slowly through urethral meatus. Children: 0.2 mL/kg<br>Cystogram: after plain film and with Foley catheter in place, fill bladder of adult with 400 mL of dilute contrast material, introduced under gravity. Children: 5 mL/kg |

* Average dose of iodine for IVP with ionic RCM: 350-400 mg/kg or 1.5 mL/kg
A dult: Low dose:
10 g
Intermediate dose:
30 g
High dose:
60 g
Do not exceed 3 mL/kg total dose.
Because the ratio of iodine atoms to dissolved particles is 1.5 with conventional ionic agents and 3.0 with the nonionic agents, less volume is required with the new agents. Average dose is 200-350 mg/kg.

The KUB must always precede the injection or instillation of contrast material, because radiopaque shadows seen on the plain film must be differentiated from extravasation on the postevacuation film.

**Retrograde Urethrogram**

Retrograde urethrography is indicated whenever there is uncertainty about the integrity of the urethra. In cases associated with pelvic fracture, the patient should remain supine throughout the entire radiographic examination. This is important to ensure stability of any possible retropubic hematoma that may result from extensive venous bleeding associated with the initial pelvic fracture. In cases of suspected urethral injury not associated with pelvic fracture, it is acceptable to obtain oblique films during the study that may complement the examination findings. Perpendicular stretching of the penis across the thigh or oblique films may be needed to ensure urethral unfolding and a high-quality urethrogram.

Although several techniques have been promoted for retrograde urethrography, one is emphasized in this section. The choice of technique is not as important as attention to detail. Solutions of either full-strength Hypaque (50%), Cystografin or Renografin-60, or the same agents diluted to a <10% solution using sterile saline as the diluent, are frequently used (see Table 59-9) . First, a plain film (KUB) of reference must be taken before injection of any contrast material. [80] The penile foreskin must be retracted and secured with a folded 4 × 4 gauze sponge. Second, the penis should be held between

the long and ring fingers of the nondominant hand to allow the thumb and index finger of the nondominant hand (see Fig. 59-17) to ensure a snug fit of the contrast-filled syringe inside the urethra (Fig. 59-28 *A*).

After sterile penile preparation, a catheter-tipped Toomey irrigating syringe or a regular 60 mL syringe with an attached Christmas-tree adapter (Fig. 59-28 *B*) is gently advanced inside the urethral meatus until a snug fit is ensured (Fig. 59-28 *C*). Third, approximately 50 to 60 mL of full- or half-strength contrast material is then injected *slowly* under constant pressure into the urethra. Prior to the injection of contrast, the penis should be stretched perpendicularly across the patient's thigh to prevent urethral folding (i.e., the double image of the proximal penile and bulbous urethra superimposed on one another) (Fig. 59-29) . Overly forceful injection of contrast material may cause intravasation of contrast material into the venous plexus of the urethra (Fig. 59-30) (Figure Not Available) . Finally, during the injection of the last 10 mL of contrast, a film (the urethrogram) is taken.  The alternative to this technique, which is discussed in most standard textbooks, is to insert a Foley catheter just inside the urethral meatus, inflate the balloon to ensure a snug fit in the fossa navicularis, and then inject contrast through the catheter (Fig. 59-31) . If not done carefully, this technique often results in the spillage and deposition of contrast outside the urethra and onto the patient and the examination table, thus yielding a spurious result.

The extravasation of contrast material from a urethral disruption usually appears as a flame-like density outside the urethral contour (Fig. 59-32 *A-C*). If any contrast material is seen within the bladder in conjunction with urethral extravasation, a partial rather than complete urethral disruption is more likely. In a complete urethral disruption, urethral extravasation will be present without evidence of contrast within the bladder. The examiner needs to be certain that the lack of bladder contrast is not secondary to voluntary contraction of the external sphincter. Occasionally, as mentioned previously, intravasated contrast material is seen in the periurethral penile venous plexus (see Fig. 59-30) (Figure Not Available) . It is of no clinical significance and should not be mistaken for urethral extravasation. As expected, penile venous intravasation (venous plexus opacification) is seen to clear spontaneously on any post-void films, as compared with urethral extravasation, which remains indefinitely.

If a Foley catheter has been successfully placed into the bladder and a partial urethral injury is suspected later, such an injury can be easily demonstrated without removing the catheter. The lubricated end of a pediatric feeding tube is placed into the penile urethra alongside the existing Foley catheter (Fig. 59-33) . A seal can be obtained by compressing the glans penis with the nondominant thumb and index finger and gently injecting contrast material via a Luer-Lock syringe with the dominant hand. In this way, extravasation can be demonstrated. It should be noted, however, that successful placement of the Foley catheter obviates the need for further treatment of a partial urethral tear in the emergency setting, because an indwelling catheter alone is appropriate initial management for this type of injury. The finding of an associated urethral injury must be conveyed to a urologist, as it will dictate the duration of definitive Foley catheter drainage.

**Retrograde Cystogram**

A retrograde cystogram is performed any time a bladder injury is suspected. It assumes the urethra is normal prior to passing the Foley catheter. A preliminary KUB is obtained that will serve as the reference film for the entire examination. Next, the bladder is filled under direct operator supervision by *gravity instillation of contrast material*. After the central piston is removed from a 60-mL catheter-tip syringe, the catheter-tipped end of the syringe is attached to the Foley catheter and held above the level of the patient's bladder. The contrast material is poured into the syringe and allowed to fill the bladder by gravity instillation to 1 of 3 end points: (1) 100 mL with evidence of gross extravasation on fluoroscopy or on plain film, (if the examiner elects to check at this point); (2) 400 mL in an adult or any child 11 years or older. In children younger than 11 years, bladder capacity, and therefore appropriate contrast volumes, are estimated based on the formula "(age in years + 2) × 30"; or (3) to the point of initiating a bladder contraction (see below), then adding an additional 50 mL by hand injection under pressure.

Anteroposterior (AP) and complementary oblique projections are obtained so long as there is no evidence of a pelvic fracture. In the presence of a pelvic fracture, all films are obtained with the patient in the supine position for the same reasons that were elucidated for retrograde urethrography. A lateral film may be informative when oblique films are not possible (Fig. 59-34) . An AP postevacuation film must be obtained in all cases following bladder drainage. This will disclose posterior perforation in selected cases, especially those associated with penetrating trauma (Fig. 59-35 *A-E*). Again, a *dilute solution of contrast material* (see Table 59-9) may be used, rather than full-strength contrast. Some authors recommend a dilute solution of contrast material (10%) because extravasation into periurethral or perivesical tissues may cause considerable inflammatory reaction at higher concentrations. The dilute solutions do not appear to compromise the quality of the study, but this must be a consideration. *Retrograde cystography done by any technique other than hand-poured gravity instillation is subject to inadequate bladder filling or connector tubing-catheter disconnection.* Both conditions will result in spurious examination results, which may adversely impact important patient management decisions.

It must be stressed that in the absence of initial gross extravasation, the bladder must be filled to 400 mL in an adult, and to an appropriate capacity in a child, and the catheter clamped with a Kelly clamp. Volumes <400 mL have been associated with false-negative findings, especially in penetrating bladder injuries. [88] At times, the patient may have difficulty cooperating with bladder filling because of a head injury or associated pain; and in the case of severe injury, the patient may have involuntary bladder contractions, causing contrast material to back up into the Toomey syringe. If this occurs, refill the bladder to the point of initiating a bladder contraction, clamp the Foley, remove the initial syringe, and replace it with a 60-mL contrast-filled syringe, unclamp the catheter, hand-inject the additional 50 mL under pressure, and reclamp the catheter. The goal is to overdistend the bladder. Once the filled-bladder films have been obtained and reviewed, the Foley catheter is unclamped and the contrast material is allowed to drain into a bedside drainage bag. The AP postevacuation film is then

obtained to visualize any posterior extravasation that may have been hidden by the distended bladder during the AP filled-bladder film. Once again, care must be taken to ensure that contrast material is not spilled onto the patient or the examination table during the procedure. Spilled contrast can lead to spurious examination results.

Extravasation from an injured bladder may be intraperitoneal, extraperitoneal, or both. Extraperitoneal extravasation is usually seen as flame-like areas of contrast material confined to the pelvis and projecting lateral to the bladder (Fig. 59-36) (Figure Not Available) . If the contrast material extravasates intraperitoneally, it tends to fill the paracolic gutters and outline intraperitoneal structures, particularly the bowel, spleen, or liver (Fig. 59-37) (Figure Not Available) . It is important to distinguish extraperitoneal from intraperitoneal injury, as the treatment options are totally different (i.e., surgical repair for all intraperitoneal injuries and for extraperitoneal injuries that extend into or primarily involve the bladder neck, especially in women). Most other extraperitoneal injuries can be managed confidently by Foley catheter drainage alone.

Retrograde cystography may be done in conjunction with contrast-enhanced abdominal CT scanning. The bladder must be filled just as if a conventional retrograde cystogram were being obtained. The catheter is clamped, and evidence for contrast ascites is sought on the CT scan (Fig. 59-38) . When this is encountered, bladder injury with extravasation must be looked for with selective images of the pelvis.

**Contrast Medium Reactions and Toxic Effects**

In the lower genitourinary tract radiologic procedures that are described in this section, the contrast material is administered within the urinary collecting and drainage system. Hence, the patient is at low risk for systemic absorption and allergic reaction. Even with IV infusion, contrast medium reactions are rare; the incidence of significant reactions (i.e., of sufficient severity to require medical intervention) with IV administration is between 1 in 1000 and 1 in 10,000 uses.

Although IV use of contrast medium is outside the scope of this text, volumes and administration information are outlined in Table 59-9 . The ED use of contrast agents is often necessary and justified despite the small possibility of untoward reactions. At times, the patient's past history may not be known, underlying renal function cannot be rapidly assessed, or alternative imaging techniques (e.g., ultrasonography) are unavailable. In such circumstances, the risks vs the benefits of emergent imaging using IV contrast must be carefully weighed. Often the potential information gain of contrast-enhanced imaging in the unstable patient far outweighs the small associated additional risk.

# Chapter 60 - Emergency Childbirth

**Lynnette Doan-Wiggins**

Since ancient times, midwives, specialists of the obstetric art, have supervised the labor of women and the delivery of babies. Physicians did not become involved in this practice until the end of the 18th century.

With improved prenatal and obstetric care, the perinatal death rate has fallen by nearly 50% in the past 25 years. [1] Similarly, the maternal death rate has decreased from 364 per 100,000 live births in 1940 to 8.0 per 100,000 live births in 1990. [1] [2] There are about 180 perinatal deaths for every maternal death. [1]

From the viewpoint of safer care during labor, the outstanding advance of the past 40 years has been the great increase in the proportion of in-hospital deliveries. As recently as 1940, only 60% of white births took place in hospitals; this figure now exceeds 99%. [1] In-hospital births have not only the advantage of better facilities but also care by individuals who are specially trained in obstetrics and perinatology.

The degree to which the emergency physician interacts in the process of labor and delivery varies among institutions, depending on the availability and readiness of inpatient obstetric services. The role of the emergency physician may be only to determine that the patient is indeed in active labor and to order transport directly to the labor and delivery area. In a hospital with little or no obstetric services, the emergency physician may alternatively be called on to manage a complicated delivery and neonatal resuscitation until transfer to another hospital is possible.

To this end the emergency physician must be able to assess the stage and timing of labor, aid the mother in delivery of the infant, and provide initial stabilization of the neonate.

## LABOR

*Labor* is defined as the coordinated effective sequence of involuntary uterine contractions that result in progressive effacement and dilation of the cervix. This, coupled with the voluntary bearing-down efforts of the mother, terminates in delivery, the actual expulsion of the products of conception.

Labor is normally divided into 3 stages. The first stage begins when uterine contractions reach sufficient force to cause cervical effacement and dilation and ends when the cervix is completely dilated. The average duration of the first stage of labor is 6 to 8 hours in multiparous patients and is 8 to 12 hours in primiparous patients. [3] The second stage of labor begins when dilation of the cervix is complete and ends with delivery of the infant. The duration of this stage is highly variable, with a median of 50 minutes in nulliparas and 20 minutes in multiparas. [1] [4] In general, if the second stage lasts >2 hours, abnormal labor has developed. [1] The third stage of labor begins after delivery of

the infant and ends after delivery of the placenta. Infrequently, a fourth stage of labor is described as that period during which myometrial contractions and vessel thrombosis occur (usually lasting approximately 1 hour), effectively controlling bleeding from the former placental implantation site. [1]

## Identification of Labor

### True vs False Labor

Before the establishment of true or effective labor, women may experience so-called false labor. Quite common in late pregnancy, false labor is characterized by irregular, brief contractions of the uterus, usually with discomfort confined to the lower abdomen and groin. The contractions, commonly referred to as *Braxton Hicks contractions*, are typically irregular in timing and strength; there is no change in the cervix and no descent of the fetus.

True labor, on the other hand, is characterized by a regular sequence of uterine contractions, with progressively increasing intensity and decreasing intervals between contractions. The discomfort produced by the uterine contractions of true labor begins in the fundal region and radiates over the uterus into the lower back. The uterine contractions of true labor are accompanied by effacement and dilation of the cervix, with descent of the presenting part of the fetus.

False labor is most common in late pregnancy and in parous women. Although false labor usually stops spontaneously, it may convert rapidly to the effective contractions of true labor (Table 60-1) (Table Not Available) . The interval between true labor contractions gradually diminishes from 10 minutes at the onset of the first stage of labor to as short as 1 minute or less in the second stage. [4]

### Show

A rather dependable sign of the approach of labor is the "show" or "bloody show." Occasionally preceding the onset of labor by as much as 72 hours, show consists of a small amount of blood-tinged mucus discharged from the vagina. Show represents extrusion of the mucus plug that filled the cervical canal during pregnancy and is evidence of cervical dilation and effacement. [1] [4] *Bloody show must be distinguished from more active third-trimester bleeding*, which is classified as a true emergency and in which vaginal examination is *contraindicated*.

### Rupture of the Membranes

Spontaneous rupture of the membranes usually occurs during the course of active labor, although it may occur before the onset of labor in approximately 10% of cases. [3] Rupture of the membranes is typically manifested by a sudden gush of a variable amount of clear or slightly turbid fluid. Rupture of the membranes can be verified if amniotic fluid is extruding from the cervical os or is found in the vaginal fornix on sterile

speculum examination.

Differentiation of amniotic fluid from vaginal fluid may be made by testing a drop of the fluid with *Nitrazine paper.* Amniotic fluid has a pH of 7.0 to 7.5 and turns the paper blue-green to deep blue. In the presence of vaginal secretions only, with a pH of 4.5 to 5.5, Nitrazine paper remains yellow. [1] [5] [6]

Because of its neutral pH, blood may cause a false-positive Nitrazine reading in women who have intact membranes and an unusually large amount of bloody show. [1] [4] [6] Abe found the Nitrazine test to be positive in 98.9% of women with known rupture of the membranes and negative in 96.2% of women with intact membranes. [5] In clinical practice, however, the test is less reliable, because it is frequently used in cases of questionable rupture in which the amount of amniotic fluid is small and therefore more subject to pH changes from admixed blood and vaginal secretions. [1]

A less frequently used method to test for amniotic fluid is *ferning.* A drop of fluid from the cervical os or vaginal fornix is placed on a clean glass slide. Owing to the high sodium chloride content of amniotic fluid, a fern pattern is seen through the microscope as amniotic fluid dries. [7]

Documentation of rupture of the membranes is important for 3 reasons. First, if the presenting part is not already fixed in the pelvis, the possibility of prolapse of the cord with cord compression and subsequent fetal distress is increased. Second, labor may be imminent. Finally, if labor does not begin within 24 hours after rupture of the membranes, the pregnancy must be considered to be complicated by prolonged premature rupture of the membranes with an increased chance of intrauterine infection. [1] [4] If rupture of the membranes is documented in the emergency department (ED), the patient's obstetrician should be notified and hospital admission of the patient should be considered.

## Evaluation of Labor

When a woman presents in labor, the general condition of the fetus and mother must be quickly ascertained by means of the patient history and physical examination. Inquiry is made as to the onset and frequency of contractions, the presence or absence of bleeding, the possible loss of amniotic fluid, and the prenatal care and condition of the mother and fetus. In the absence of active vaginal bleeding, the position, presentation, and lie of the fetus are determined by abdominal palpation and sterile vaginal examination. Staging of labor is assessed by vaginal examination. Fetal well-being is monitored by auscultation of fetal heart tones, particularly immediately after a uterine contraction.

### Lie, Presentation, and Position

In the latter months of pregnancy, the fetus assumes a characteristic posture within the uterus, usually forming an ovoid mass that corresponds roughly to the shape of the uterine cavity. Typically, the fetus becomes folded or bent on itself in such a way that

the back becomes markedly convex, with the head, thighs, and knees being sharply flexed. Usually the arms are crossed over the thorax and are parallel to the sides of the body. The umbilical cord lies in the space between the arms and the lower extremities. This characteristic posture is due in part to the mode of growth of the fetus and is also a result of accommodation to the uterine cavity.

*Lie* refers to the relation of the long axis of the fetus to that of the mother. Lie is either longitudinal or transverse (Fig. 60-1) (Figure Not Available) . Longitudinal lies occur in >99% of pregnancies at term. [1]

The *presentation*, or presenting part, refers to that portion of the body of the fetus that is nearest to or foremost in the birth canal. The presenting part is felt through the cervix on sterile vaginal examination. In longitudinal lies, the presenting part is either the fetal head or the buttocks or the feet. In *transverse lie*, the shoulder is the presenting part.

Cephalic presentations are classified by the relation of the fetal head to the body of the fetus (Fig. 60-2) (Figure Not Available) . Ordinarily, the head is sharply flexed so that the occipital fontanel is the presenting part. This is referred to as the *vertex* or *occiput presentation*. Less commonly, the neck is fully extended and the face is foremost in the birth canal; this is termed *face presentation*. Occasionally, the fetal head assumes a partially flexed or partially extended position, resulting in *sinciput* and *brow presentations*, respectively. Sinciput and brow presentations, associated with preterm infants, are almost always unstable and convert to either the occiput or face presentation as labor progresses.

Breech presentations are classified as frank, complete, and footling or incomplete (Fig. 60-3) (Figure Not Available) . When the fetus presents with the hips flexed and the legs extended over the anterior surfaces of the body, this is termed *frank breech.* Flexion of the fetal hips and knees results in *complete breech* presentation. When one or both of the feet or knees are lowermost in the canal, an *incomplete* or *footling breech* results.

At or near term, the incidence of the various presentations is approximately 96&2percnt; for vertex, 3.5% for breech, 0.3% for face, and 0.4% for shoulder. [1] [4]

*Position* refers to the relation of the presenting part to the birth canal and may be either left or right. The occiput, chin, and sacrum are the determining parts in vertex, face, and breech presentations, respectively. The presentation and position of the fetus are initially determined by abdominal palpation using Leopold maneuvers.

**Abdominal palpation (Leopold maneuvers).**

Although abdominal ultrasonography has largely replaced abdominal palpation for determination of fetal lie, these maneuvers may be helpful when ultrasound evaluation is unavailable. They can be performed throughout the latter months of pregnancy and during labor in the intervals between contractions. The findings from abdominal palpation provide information about the presentation and position of the fetus and the extent to which the presenting part has descended into the pelvis (Fig. 60-4) (Figure Not

Available) . The mother should be placed on a firm bed or examining table with her abdomen bared. For the first 3 of the 4 maneuvers, the examiner stands at the side of the bed facing the patient. During the first maneuver (see Fig. 60-4 (Figure Not Available) *A*), the upper abdomen is gently palpated with the fingertips of both hands to determine which fetal pole is present in the uterine fundus. The fetal breech gives the sensation of a large, nodular body, whereas the fetal head is hard, round, and freely movable.

During the second maneuver, the examiner places his or her hands on either side of the abdomen, exerting deep, gentle pressure (see Fig. 60-4 (Figure Not Available) *B*). On one side, the hard, resistant back is felt; on the other side, the fetal extremities or small parts are felt. By noting whether the back is directed anteriorly, posteriorly, or transversely, fetal orientation or lie is determined.

The third maneuver is performed by grasping the lower portion of the maternal abdomen just above the symphysis pubis with the thumb and forefinger of one hand (see Fig. 60-4 (Figure Not Available) *C*). If the presenting part is not engaged, the position of the head in relation to the back and extremities is ascertained. If the cephalic prominence is palpated on the same side as the small parts, the head must be flexed and therefore a vertex or occiput presentation exists. If the cephalic prominence is on the same side as the back, the head must be extended. If the presenting part is deeply engaged in the pelvis, the findings from this maneuver indicate that the lower pole of the fetus is fixed in the pelvis. The details of presentation and position are then defined by the fourth maneuver.

To perform the fourth maneuver, the examiner changes position and faces the mother's feet. With the tips of the first 3 fingers of each hand, the examiner exerts deep, gentle pressure in the direction of the axis of the pelvic inlet (see Fig. 60-4 (Figure Not Available) *D*). When the head is the presenting part, one examining hand will be stopped sooner than the other by a rounded body, the cephalic prominence, while the other hand continues more deeply into the pelvis. The cephalic prominence is felt on the same side as the small parts in vertex presentations and on the same side as the back in face presentations. In breech presentations, the information obtained from this maneuver is less precise. [1]

**Vaginal examination.**

Unless there has been bleeding in excess of a bloody show, a manual (not speculum) vaginal examination should be performed to identify fetal presentation and position and to assess the progress of labor.

First, the vulva and perineal area are prepared with an antiseptic solution such as povidone-iodine. The woman is placed on a bedpan with her legs widely separated. Scrubbing is directed from anterior to posterior and away from the vaginal introitus; each sponge should be discarded after it passes over the anal region. A dry sponge placed on the introitus prevents contaminated solution from running into the vagina.

After preparation of the vulvar and perineal regions, the examiner uses the thumb and

forefinger of a sterile-gloved hand to widely separate the labia to expose the vaginal opening; this prevents the examining fingers from coming into contact with the inner surfaces of the labia. The index and second fingers of the other hand are then introduced into the vagina to perform the examination. Cervical effacement, dilation, and fetal station are assessed. Fetal presentation and position are confirmed. [1]

*Effacement* of the cervix is the process of cervical thinning that occurs before and during the first stage of labor (Fig. 60-5) (Figure Not Available) . The degree of cervical effacement is assessed by palpation and is determined by the palpated length of the cervical canal compared with that of the uneffaced, or normal, cervical canal. Effacement is expressed as a percentage from 0%, or totally uneffaced, to 100%, or completely effaced. The completely effaced cervix is usually <0.25 cm thick. [3]

*Cervical dilation* is determined by estimating the average diameter of the cervical os. The examining finger is swept from the cervical margin on one side across the cervical os to the opposite margin. The transverse diameter is expressed in centimeters. Ten centimeters constitutes full cervical dilation. A diameter of <6 cm can be measured directly. For a diameter >6 cm, it is frequently easier to determine the width of the remaining cervical rim and subtract twice that measurement from 10 cm. For example, if a 1-cm rim is felt, dilation is 8 cm.

*Station* refers to the level of the presenting fetal part in the birth canal (Fig. 60-6) (Figure Not Available) . The ischial spines are used as the reference point. Zero station is used to denote that the presenting part is at the level of the ischial spines. When the presenting part lies above the spines, the distances are stated in negative figures (-1 cm, -2 cm, -3 cm, and floating). If the presenting part is below the spines, the distances are stated in positive figures (+1 cm, +2 cm, +3 cm).3 Determination is made by simple palpation. Progressive cervical dilation with no change in fetal station suggests fetopelvic disproportion.

*Position and presentation* of the fetus may be inconclusive before labor, because the presenting parts must be palpated through the lower uterine segment. After dilation and effacement of the cervix, however, further delineation of presentation and position of the fetus may be made by vaginal examination.

After the perineal area has been appropriately prepared, as described previously, 3 maneuvers are used to determine fetal presentation and position. In the first maneuver, 2 fingers of the examiner's gloved hand are introduced into the vagina and advanced to the presenting part, differentiating face, vertex, and breech presentations. In vertex presentations, the examiner's fingers are carried up behind the symphysis pubis and then swept posteriorly over the fetal head toward the maternal sacrum, identifying the course of the sagittal suture. The positions of the 2 fontanels, located at opposite ends of the sagittal sutures, are then defined by palpation. The anterior fontanel is diamond shaped; the posterior fontanel is triangular (Fig. 60-7) (Figure Not Available) .

In face and breech presentations, the various parts are more readily distinguished. In breech presentations, the fetal sacrum is the point of reference; in face presentations,

the easily identifiable fetal chin is used.

**Fetal Well-Being**

**Auscultation.**

Auscultation of fetal heart tones is necessary to determine fetal well-being. The heart rate of the fetus can be identified with a stethoscope, a fetoscope, or preferably a Doppler flow detector placed firmly on the maternal abdominal wall overlying the fetal thorax and repositioned until fetal heart tones are heard. When a Doppler flow detector is used, a conducting gel should be applied to the abdominal wall, interfacing with the Doppler receiver. The region of the abdomen in which fetal heart sounds are heard most clearly varies with fetal presentation and the degree to which the presenting part has descended. In cephalic presentations, fetal heart sounds are heard best midway between the maternal umbilicus and the anterosuperior spine of the maternal ilium. [1] To avoid confusion of maternal and fetal heart sounds, the maternal pulse should be palpated as the fetal heart rate is auscultated.

Normal baseline fetal heart rate is 120 to 160 beats/min. Changes in the fetal heart rate that are indicative of fetal distress are usually evident immediately after a uterine contraction. During labor, fetal distress is suspected if the fetal heart rate repeatedly drops below 120 beats/min immediately after a contraction. If prolonged monitoring of labor is necessary in the ED, fetal heart sounds should be assessed during and for 30 seconds after a contraction at 15-minute intervals during the first stage of labor and at 5-minute intervals during the second stage of labor. [1] [9] Additional information on the use of a Doppler monitor to measure fetal heart rate is provided in Chapter 70 . If trained personnel and equipment are available, external tocography provides a noninvasive method for continuous assessment of fetal heart rate and maternal uterine contractions.

**Management of fetal distress.**

If fetal distress is suspected on the basis of resting fetal heart rate or changes after contractions, changing of maternal position, typically into the left lateral recumbent position, may be beneficial. Maternal O2 should be administered to improve fetal oxygenation.

In the absence of bleeding, a vaginal examination should be performed to rule out the possibility of prolapse of the umbilical cord. [7] If immediate obstetric services are not available, consideration should be given to tocolytic therapy to improve fetoplacental blood flow until delivery can be accomplished. By stopping uterine contractions a more sustained placental blood flow is maintained and, in the case of cord prolapse, intermittent pressure on a compromised umbilical cord may be averted. [10] The definitive therapy for fetal distress is delivery of the infant, either vaginally or by cesarean section. [3]

*Cord prolapse* usually occurs at the same time as rupture of the membranes and is

diagnosed by palpation of the umbilical cord on vaginal examination or by visualization of the cord protruding through the introitus. The incidence of cord prolapse in labor is approximately 0.5% and most often occurs when the fetal presenting part does not completely fill the lower uterine segment during labor or when there is unusual mobility of the cord. [11] [12] Cord prolapse is frequently encountered with breech presentation, multiple pregnancies, prematurity, and premature rupture of the membranes. [12] [13]

The management of cord prolapse is directed at sustaining fetal life until delivery is accomplished. Unless immediate delivery is feasible or the fetus is known to be dead, preparations should be made for an emergency cesarean section. If immediate obstetric services are not available, tocolytic therapy may be instituted to decrease uterine contractions and improve fetoplacental perfusion. [11] [12] Compression of the umbilical cord should be minimized by exerting manual pressure through the vagina to lift and maintain the presenting part away from the prolapsed cord. The patient should be placed in the knee-chest or deep Trendelenburg position, and this position should be maintained until delivery is accomplished. Some physicians recommend that after manual elevation of the presenting part, 500 to 700 mL of saline be instilled into the bladder to maintain cord decompression. Once the bladder is filled, the vaginal hand may be removed. [11] [12]

With cord prolapse, the fetal prognosis is dependent on presentation, gestation, and the timing of diagnosis and management. Partial cord compression for <5 minutes may not be harmful. Complete occlusion for the same period or partial occlusion for a longer time is likely to cause death or severe central nervous system damage to the fetus. Perinatal mortality rate ranges from 5.4 to 49.0%. [11] [12]

## Inhibition of Labor

Tocolytic therapy may be indicated in the ED to prevent the progression of labor when fetal distress is noted, particularly that due to cord compression, and to treat preterm labor.

### Preterm Labor

Premature delivery complicates 8 to 10% of all births in the United States, and prematurity continues to be the single greatest cause of neonatal morbidity and mortality. [7] A wide variety of treatments for the inhibition of labor have been advocated, including bedrest, beta-agonist agents such as terbutaline and ritodrine, magnesium sulfate ($MgSO_4$ ), prostaglandin inhibitors, and calcium-channel blockers. Efficacy of each of these regimens is difficult to establish, because of a paucity of well-controlled clinical studies and inconsistently defined indications for the use of tocolytic therapy. [14] [15] Currently, the cornerstones of pharmacologic management of preterm labor are the use of beta-adrenergic receptor agonists and $MgSO_4$ . [7] [15]

The criteria for defining preterm labor vary among investigators. A presumptive diagnosis of premature labor may be made in the woman who is between 20 and 37 weeks' gestation in the presence of regular uterine contractions occurring at intervals of 5 to 8 minutes or less that are accompanied by one or more of the following: (1)

progressive cervical effacement and dilation, (2) cervical dilation of 2 cm, or (3) cervical effacement of 75 to 80% or more. [1] [15] Because rupture of the membranes frequently means that delivery is imminent, uterine contractions accompanied by membrane rupture may also be used to establish the diagnosis. [1] [15] External monitoring devices, when available, are helpful by providing objective evidence of the character of uterine contractions as well as the condition of the fetus. Extended

| TABLE 60-2 -- Agents Used for the Emergency Management of Preterm Labor | |
|---|---|
| **Ritodrine** | |
| Dose | 50 to 100 mug/min IV infusion |
| | 50 mug/min q 10 to 20 min |
| Endpoint | Cessation of uterine contrations |
| | Intolerable maternal side effects |
| | Maximum dose 350 mug/min |

| | or |
| | 2.5 to 5 mug/min IV infusion, |
| | 2.5 to 5 mug/min q 20 min |
| Endpoint | Cessation of uterine contractions |
| | Intolerable maternal side effects |
| | Maximum dose 25 mug/min |

**Magnesium sulfate**

| Dose | 4 to 6 g IV over 20 min 2 to 4 g/hr IV infusion |
|---|---|
| Endpoint | Cessation of uterine contractions |
| | Signs of magnesium toxicity (e.g., depressed respirations, hypotension, somnolence) |

observation is undesirable because the effectiveness of tocolytic therapy diminishes as labor advances.

Ideally, when preterm labor is suspected, obstetric consultation should be obtained and the patient transferred immediately to the labor and delivery area for monitoring and

determination of fetal maturity. When appropriate obstetric facilities are not available, attempts to arrest labor should be initiated in the ED.

**Tocolytic Therapy**

Basic maneuvers to improve uterine and fetal status should be initiated before instituting pharmacologic tocolytic therapy when either preterm labor or fetal distress is suspected (Tables 60-2 and 60-3) . Because uterine hypoxia may induce uterine contractions, supplemental $O_2$ , IV infusion of 500 mL of crystalloid, and assumption of the left lateral decubitus position should be attempted to improve uterine perfusion.  Because uterine, cervical, or urinary tract infections account for 30 to 40% of cases of preterm labor, a specific cause should be sought and treated as appropriate. [7]

| TABLE 60-3 -- Procedure for Instituting a Ritodrine Infusion | |
|---|---|
| **Dose**\* **(mug/min)** | **Infusion Rate (mL/hr)** |
| 50  } Initial dose | 10 |
| 100 | 20 |
| 150 | 30 |
| 200 | 40 |
| 250 | 50 |
| 300 | 60 |
| 350 | 70 |

*Note:* This is *not* a dose/weight calculation.
If fluid restriction is necessary, the concentration can be increased.

 If contractions persist and cervical changes are documented despite these basic interventions, pharmacologic tocolytic therapy with either the selective beta2 -adrenergic agents or MgSO4 may be indicated. [7] Relative contraindications to tocolytic therapy include uncorrected fetal distress or fetal death, chorioamnionitis, ruptured or bulging membranes, or obstetric complications requiring early delivery, such as severe pregnancy-induced hypertension, maternal hemorrhage, or polyhydramnios. [3]

**beta $_2$ -Receptor agonists.**

The mainstays of pharmacologic tocolytic agents are the selective beta2 -adrenergic agents ritodrine (Yutopar) and terbutaline (Brethine, Bricanyl).  Ritodrine was approved by the U.S. Food and Drug Administration (FDA) for the inhibition of preterm labor in 1980 and is the only agent approved for tocolysis in the United States. Terbutaline has also been used extensively as a tocolytic agent, has documented efficacy in inhibiting labor, is less expensive than ritodrine, and is frequently more readily available to the emergency physician.

The beta-adrenergic agents prevent contraction of the myometrium through activation of the enzyme adenyl cyclase, which causes an increase in the intracellular concentration of cyclic adenosine monophosphate. This increased level of cyclic adenosine monophosphate initiates a series of cellular reactions that leads to the phosphorylation of cell membrane proteins and the sequestration of intracellular calcium. The reduced intracellular calcium concentration prevents activation of myosin light-chain kinase, which prevents the interaction of the smooth muscle filaments actin and myosin, which normally results in uterine smooth muscle contraction. [16] [18] Although both ritodrine and terbutaline stimulate beta2 -receptors primarily, both have some beta1 -activity, which is responsible for their cardiovascular side effects. Both drugs should therefore be used cautiously in patients with cardiovascular disease, hypertension, hyperthyroidism, or diabetes and in patients with bronchospastic disease concurrently on sympathomimetic bronchodilator agents.

Intravenous administration of ritodrine is used to stop contractions; therapy may be repeated if further episodes of preterm labor occur. [17] When given as an IV infusion, 150 mg ritodrine is mixed in 500 mL diluent, yielding a final concentration of 0.3 mg/mL (i.e., 300 mug/mL). Because of the risk of pulmonary edema, saline diluents should not be used unless use of dextrose-containing solutions is undesirable. [17] The initial infusion rate of ritodrine is 50 to 100 mug/min (i.e., 10 to 20 mL/hr), which is increased by 50 mug/min (i.e., by 10 mL/hr) every 10 to 20 minutes until uterine contractions cease, intolerable maternal side effects develop, or a maximum dose of 350 mug/min (i.e., 70 mL/hr) is reached. If unacceptable side effects develop, the infusion is reduced to a tolerable level. If labor is successfully arrested, IV therapy is continued for at least 12 hours after contractions cease. A controlled infusion device is required.

The usual clinical side effects of ritodrine are related to its inherent activity as a

beta-mimetic drug. Maternal cardiovascular effects include a dose-related increase in heart rate, an increase in systolic pressure, and a decrease in diastolic blood pressure. Fetal heart rate also increases slightly. About one third of patients experience palpitations, and up to 15% have chest pain, shortness of breath, tremor, nausea and vomiting, headache, or erythema. Pulmonary edema has also been reported with beta-mimetic tocolytic therapy both with and without concurrent glucocorticoid therapy for fetal lung maturation. Maternal metabolic effects during IV therapy include transient increases in glucose, free fatty acids, lactic acid, and insulin with a moderate decrease in potassium and calcium. Side effects are usually self-limited and resolve with dosage reduction or discontinuation of the drug. Treatment of the majority of side effects is supportive; severe cardiovascular effects may be treated with beta-blocking agents. [16]

Although not approved by the U.S. FDA for use as a tocolytic, terbutaline has gained widespread popularity for the treatment of preterm labor in the United States. Available in both a parenteral and an oral form, terbutaline may be given subcutaneously or by IV infusion for the emergency treatment of preterm labor. Subcutaneously administered terbutaline is rapidly absorbed with an absorption half-life of only 7 minutes. [20] Subcutaneous terbutaline is administered as a 0.25-mg dose, which may be repeated every 20 to 60 minutes until contractions cease or intolerable maternal side effects occur. Alternatively, terbutaline may be administered as an IV infusion. Although recommended dosage regimens vary, a conservative approach is to begin the infusion at a rate of 2.5 to 5 mug/min, increasing the rate by 2.5 to 5 mug/min every 20 minutes until a maximum dose of 25 mug/min is reached, uterine contractions cease, or adverse maternal side effects develop. Oral maintenance therapy should be individualized and typically ranges from 2.5 to 5 mg every 4 hours. Oral terbutaline, 30 mg/day, has been shown to be superior to ritodrine, 120 mg/day, in preventing recurrent labor. [21]

The side effects associated with the parenteral use of terbutaline are similar to those seen with ritodrine. Many authors consider subcutaneous terbutaline preferable to ritodrine for the treatment of preterm labor because of terbutaline's lower cost, ease of administration, and comparable efficacy and side effects.

**Magnesium sulfate.**

Magnesium sulfate ($MgSO_4$ ) is not approved in the United States for use as a tocolytic agent. Nevertheless, many perinatal centers prefer $MgSO_4$ over the beta-mimetic agents owing to its comparable efficacy and low incidence of intolerable side effects. [7] [22] Although its effect is not fully understood, magnesium probably acts by competitively inhibiting calcium uptake into the muscle cell, thereby inhibiting the actin/myosin interaction.

When used as a tocolytic agent, 4 to 6 g of $MgSO_4$ is given IV over 20 to 30 minutes, followed by a maintenance IV infusion beginning at 2 g/hour and titrated to the cessation of uterine contractions or clinical evidence of magnesium toxicity. [17] [22] Infusion rates of 3 to 4 g/hour are usually required to maintain tocolysis. [18]

Intravenous infusion of $MgSO_4$ typically produces sweating, warmth, and flushing; and rapid parenteral administration may cause transient nausea, vomiting, headache, or

palpitations.Infrequently, pulmonary edema or chest pain has necessitated stopping the drug. [22] The major side effect of magnesium therapy is related to impairment of the muscles of respiration with subsequent respiratory arrest, an effect usually not seen until the serum magnesium level exceeds 10 mEq/L. The first sign of magnesium toxicity, decrease of the patellar reflex, typically occurs as serum magnesium levels exceed 4 mEq/L, with loss of the reflex as levels approach 10 mEq/L. Therefore, the patellar reflex should be monitored throughout therapy. Respiratory depression typically occurs when serum magnesium levels exceed 10 mEq/L; and at 12 mEq/L or greater, respiratory arrest may occur. Although high concentrations of magnesium (10 to 15 mEq/L) can increase cardiac conduction manifested by lengthened PR and QRS intervals on the electrocardiogram, the major cause of cardiac dysfunction in humans results from respiratory arrest.

Because magnesium is almost totally excreted by the kidney, magnesium is contraindicated in the presence of renal failure, and urinary output and renal function should be monitored throughout therapy. If respiratory depression develops, 10 mL of a 10% solution of calcium gluconate or calcium chloride injected over 3 minutes is an effective antidote. For severe respiratory depression and arrest, prompt endotracheal intubation may be lifesaving. MgSO$_4$ should be used with caution in patients with impaired renal function or heart disease and is contraindicated in patients with myasthenia gravis.

## VAGINAL BLEEDING DURING THE THIRD TRIMESTER

Bleeding during the third trimester should always be considered an emergency. Profound shock secondary to exsanguinating hemorrhage may occur within minutes. Although bleeding may result from local vaginal and cervical lesions, genital lacerations, circumvallate placenta, vasa previa, or rupture of the uterus, the most frequent causes are that due to placenta previa and that resulting from placental abruption. [3] *Placenta previa* refers to implantation of the placenta in the lower uterine segment with varying degrees of encroachment on the cervical os. Complicating 1 in 200 to 1 in 250 pregnancies that continue beyond the 28th week of gestation, [3] placenta previa is characterized clinically by vaginal bleeding with little or no abdominal or pelvic pain. Premature separation of the placenta, or *abruptio placentae*, refers to separation of the placenta from its site of implantation in the uterus before delivery of the fetus. Placental abruption occurs in 1 in 86 to 1 in 206 advanced pregnancies and is responsible for approximately 30% of all late pregnancy bleeding. [3] In contrast to placenta previa, abruptio placentae is associated with varying degrees of abdominal pain and uterine irritability. The degree of clinical shock may be out of proportion to the amount of apparent hemorrhage. Fetal distress is present in more than half the cases. [3]

As noted previously, third-trimester vaginal bleeding should always be considered an emergency. Stabilization should be initiated with at least 2 large-bore IV lines. In addition to routine laboratory work-up and the taking of blood for type and crossmatching, clotting studies, including a fibrinogen level, should be done. Vaginal examination is *contraindicated* in the ED because of the possibility of tearing or dislodging a placenta previa, which may result in profuse, potentially fatal hemorrhage. [1] The patient should be immediately transferred to the care of her obstetrician for

further evaluation. Definitive diagnosis by means of the "double set-up" examination has been replaced by localization of the placenta by ultrasound. The accuracy of placental localization and, therefore, the confirmation of placenta previa is between 93 and 98%. For unknown reasons, blood separating the placenta from its attachment is difficult to detect with ultrasound. *Ultrasonography, therefore, has limited value in excluding the presence of abruptio placentae* but is of great value in excluding the diagnosis of placenta previa.

## DELIVERY

Full dilation of the cervix signifies the second stage of labor, heralding delivery of the infant. Typically, the patient begins to bear down and, with descent of the presenting part, develops the urge to defecate. Uterine contractions may last 1.5 minutes and recur after a myometrial resting phase of <1 minute.

The mechanism of labor in vertex and breech presentations consists of engagement of the presenting part, flexion, descent, internal rotation, extension, external rotation or restitution, and expulsion (Fig. 60-8) (Figure Not Available) . The mechanism of labor is determined by the pelvic dimensions and configuration, the size of the fetus, and the strength of uterine contractions. Essentially, the fetus will follow the path of least resistance by adaptation of the smallest achievable diameters of the presenting part to the most favorable dimensions and contours of the birth canal.

The sequence of movements in vertex presentations is as follows:

1. *Engagement*. Usually occurring in the last 2 weeks of pregnancy in the primiparous patient and at the onset of labor in the multiparous patient, engagement refers to the mechanism by which the greatest transverse diameter of the head, the biparietal diameter in occiput presentations, passes through the pelvic inlet.
2. *Flexion*. Flexion of the head is necessary to minimize the presenting cross-sectional diameter of the head during passage through the smallest diameter of the bony pelvis. In most cases, flexion is necessary for both engagement and descent.
3. *Descent*. Descent is gradually progressive and is effected by uterine and abdominal contractions as well as by straightening and extension of the fetal body.
4. *Internal rotation*. Internal rotation occurs with descent and is necessary for the head or presenting part to traverse the ischial spines. This movement is essentially a turning of the head such that the occiput gradually moves from its original, more transverse position, anteriorly toward the symphysis pubis or, less commonly, posteriorly toward the hollow of the sacrum.
5. *Extension*. After internal rotation, the sharply flexed head reaches the anteriorly directed vulvar outlet, undergoing extension. With increasing distention of the perineum and vaginal opening, an increasingly larger portion of the occiput appears gradually. The head is born by further extensions as the occiput, bregma, forehead, nose, mouth, and finally chin pass successively over the anterior margin of the perineum. Immediately after its birth, the head drops downward such that the chin lies over the maternal anal region.

6. *External rotation.* External rotation or restitution follows delivery of the head as it rotates to the transverse position that it occupied at engagement. After this movement, the shoulders descend in a path similar to that traced by the head, rotating anteroposteriorly for delivery. First, the anterior shoulder is delivered beneath the symphysis pubis, followed by the posterior shoulder across the perineum. Expulsion of the remainder of the fetal body occurs with ease.

The mechanism of the labor for breech presentations varies (Fig. 60-9) (Figure Not Available) . Usually the hips engage in one of the oblique diameters of the pelvic inlet. As descent occurs, the anterior hip generally descends more rapidly than the posterior hip. Internal rotation occurs as the intertrochanteric diameter assumes the anteroposterior position. Lateral flexion occurs as the anterior hip catches beneath the symphysis pubis, allowing the posterior hip to be born first. The infant's body then rotates, allowing for engagement of the shoulders in an oblique orientation. There is gradual descent, with the anterior shoulder rotating to bring the shoulders into the anteroposterior diameter of the outlet. The anterior shoulder follows lateral flexion to appear beneath the symphysis, with the posterior shoulder delivered first as the body is supported. The head tends to engage in the same diameter as the shoulders. Subsequent flexion and descent of the head occurs, following the path of the shoulders. Internal rotation occurs toward the hollow of the sacrum.Delivery of the infant usually occurs spontaneously. The role of the physician or attendant is principally to provide control of the birth process, preventing forceful, sudden expulsion or extraction of the infant with resultant fetal and maternal injury.

## Equipment for Delivery

The following typical obstetric equipment pack should be available in the ED (Fig. 60-10) . The optional equipment may or may not be needed.

**Obstetric pack (sterile)**

   1 large basin (for placenta)

   1 pair of scissors

   2 medium Kelly clamps

   1 bulb syringe

   1 plastic umbilical cord clamp

   3 sterile towels

   1 package of gauze sponges

   1 baby blanket

   2 pairs of sterile gloves

Sterile tubes for placental blood collection

**Optional**

Infant resuscitation tray

Warm blankets

Name bands

Heated isolette

## Technique for Uncomplicated Delivery

Owing to the high bacterial content of the vagina and perineum, complete sterility is not a priority. [25] When time permits, however, sterile technique should be used. The hands should be cleansed and sterilely gloved. The perineum should be cleansed as described for vaginal examination and draped such that only the immediate area about the vulva is exposed. Care should be taken to avoid fecal contamination of the infant. Equipment in the obstetric pack should be sterile.

The patient should be positioned on a stretcher with her hips and knees partially flexed, her thighs abducted, and the soles of her feet placed firmly on the stretcher. The delivery position may be enhanced by placing the patient's buttocks on the underside of a sterile bedpan, providing up to 12 cm of additional space between the bed and the perineum.

**Vertex Delivery**

Spontaneous delivery of the vertex-presenting infant is divided into 3 phases: delivery of the head, delivery of the shoulders, and delivery of the body and legs.

Delivery should be anticipated when the presenting part reaches the pelvic floor. With each contraction, the perineum bulges increasingly and the vulvovaginal opening becomes more and more dilated by the fetal head. Just before delivery, "crowning" occurs; the head is visible at the vaginal introitus, and the widest portion, or biparietal diameter, of the head distends the vulva.

*Gentle, gradual, controlled delivery is desirable.* As the fetal head becomes progressively more visible, one palm of the physician's hand is placed over the occipital area, providing gentle pressure to control delivery of the head. *Explosive delivery of the head should be avoided.* The other hand, preferably draped with a sterile towel to protect it from the anus, may exert forward pressure on the chin of the fetus through the perineum just in front of the coccyx in a modified Ritgen maneuver (Fig. 60-11) (Figure Not Available) . This maneuver extends the neck at the proper time, thereby protecting the maternal perineal musculature.

The head is gently supported during subsequent delivery of the forehead, face, chin, and neck.

After the head has been delivered, the infant's face and mouth should be quickly wiped and the oral cavity and nares should be suctioned with a bulb syringe. This minimizes the chance of aspiration of amnionic fluid, debris, and blood, which may occur with inspiration during delivery of the thorax.

With delivery of the neck, a finger should be passed around the neck to determine whether it is encircled by one or more coils of the umbilical cord (Fig. 60-12) . If a cord is felt, it should cautiously be loosened and gently slipped over the infant's head. If this cannot be done easily, the cord should be doubly clamped and cut and the infant should be delivered promptly. In approximately 25% of deliveries, the umbilical cord is around the infant's neck but is rarely tight enough to cause fetal hypoxia. [1]

Just before external rotation, the head usually falls posteriorly, bringing it almost into contact with the mother's anus. As rotation occurs, the head assumes a transverse position and the transverse diameter of the thorax or bisacromial diameter rotates into the anteroposterior diameter of the pelvis. In most cases the shoulders are born spontaneously. Delivery may be aided by grasping the sides of the head and exerting *gentle* downward (posterior) traction until the anterior shoulder appears beneath the symphysis pubis. The head is then *gently* lifted upward to aid the delivery of the posterior shoulder (see Fig. 60-8) (Figure Not Available) . The remainder of the body usually follows without difficulty.

Delivery may be assisted by *gentle* traction on the head after the shoulders have been freed. Hooking the fingers in the axilla during delivery may result in brachial plexus injury, hematoma of the neck, or fracture of the clavicle; thus, it should be avoided. Furthermore, traction should always be exerted in the direction of the long axis of the child; if applied obliquely, traction may cause bending of the neck and excessive stretching of the brachial plexus.

Immediately after delivery the infant should be held with the head lower than the body, at an angle of *not* more than 15° to facilitate drainage of accumulated mucus and bronchial secretions in the airway. The infant's airway should be thoroughly suctioned. Although some controversy exists as to the optimal position of the infant in relation to the mother during this stage, most authorities recommend that the infant be placed at or slightly below the level of the vaginal introitus for 30 seconds before the cord is clamped. [1] [26] This allows up to 80 mL of blood to be transfused from the placental circulation into the infant. [4]

The umbilical cord should be cut 30 to 60 seconds after delivery. Blood samples from the placental end of the cord should be collected for determination of infant serology, including rhesus factor (Rh) studies. Two sterile clamps should be placed several inches apart, and the cord between the clamps should be cut with sterile scissors. A sterile cord clamp or cord tie of umbilical (cloth) tape is then placed around the cord, 2 to 3 cm

from the infant abdomen. [1]

Immediately after the cutting of the umbilical cord, the infant should briefly be evaluated and, if necessary, resuscitation should be initiated. Because of the relatively large surface area of the neonate, attention should be directed toward maintaining body temperature by drying the neonate and placing the baby in a heated isolette, under a radiant warmer, or in warm blankets. [1] [7]

*Meconium staining* of the amniotic fluid occurs in infants older than 34 weeks' gestation who have suffered intrauterine asphyxia and stress. [27] It is more common in post-term pregnancy and that complicated by fetal growth retardation. [1] Fetal aspiration of meconium may lead to meconium pneumonitis, which carries a mortality of 20 to 35%. [27] To minimize the risk of aspiration, all infants with meconium-stained amniotic fluid should have the nares and oropharynx thoroughly suctioned after delivery of the head but before delivery of the thorax and the first thoracic expansion. [1] [7] [28] As soon as possible after delivery, the traditional approach mandates direct visualization of the vocal cords with aspiration of supraglottic meconium followed by tracheal intubation and thorough suctioning of the trachea. [1] [7] The traditional approach has been questioned, and some authorities now recommend a selective approach to direct visualization of the glottis and tracheal suctioning, reserving this procedure for those infants with moderate to thick meconium staining and respiratory depression or distress at birth. [3] [28]

**Delivery of the Placenta**

Placental separation usually occurs within 5 minutes after delivery of the infant and may be recognized by the following signs:

1. The uterus becomes globular and firmer as it contracts.
2. The uterine fundus rises in the abdomen.
3. There is a sudden gush of blood.
4. The umbilical cord protrudes further out of the vagina, indicating placental descent.

The placenta usually delivers spontaneously within 20 to 30 minutes. [7] Intra-abdominal pressure produced by the mother's bearing down efforts may be enough to effect complete expulsion of the placenta. If maternal force alone is insufficient, delivery of the placenta may be aided by the physician. After ensuring that the uterus is firmly contracted, the physician uses one hand to exert gentle pressure through the abdominal wall to lift the uterine fundus cephalad while keeping the umbilical cord slightly taut with the other hand. This is repeated until the placenta reaches the introitus, at which time uterine pressure is stopped and the placenta is gently lifted upward out of the vagina (Fig. 60-13) (Figure Not Available) . Membranes that are adherent to the uterine lining should be grasped with a clamp or ring forceps and removed by gentle traction. Excessive traction should never be used to pull the placenta out of the uterus, because traction may result in uterine inversion with catastrophic hemodynamic consequences. The placenta should be examined for completeness and saved for later evaluation by the obstetrician. [1] [3] [7] The vulva, vagina, and cervix should be examined to assess for traumatic lacerations. Cervical lacerations most typically occur at the 9 or 3 o'clock

position; vaginal lacerations typically occur at the point of the ischial spines. If found, these injuries are best repaired in the operating room or delivery suite. [7] After delivery of the placenta the uterus should be palpated to ensure that it is well contracted. A normally contracted uterus will be firm with its upper margin just below the maternal umbilicus. If persistent bleeding occurs from a flaccid uterus, gentle uterine massage through the abdominal wall and oxytocic agents may be used as necessary. [1] Oxytocic agents should not be used before delivery of the placenta because the resultant uterine contraction may entrap the placenta within the uterus. Use of oxytocics before delivery of an undiagnosed second twin may prove fatal to the entrapped fetus.Oxytocin (Pitocin, Syntocinon) is the most commonly used oxytocic drug and is usually given by IV infusion. Twenty units of oxytocin is added to 1 L of normal saline and is given at a rate of 10 mL/min for several minutes until the uterus remains firmly contracted and bleeding is controlled. The infusion rate is then reduced to 1 to 2 mL/min. [1] [7] If bleeding persists, an ergot derivative, such as methylergonovine maleate (Methergine), 0.2 mg, may be given intramuscularly. [7] Because of their vasoconstrictive properties, ergot preparations are relatively contraindicated in patients with hypertension and preeclampsia. [16] Occasionally, the placenta may fail to separate completely, resulting in a retained placenta or placental fragments, with persistent uterine bleeding. Manual removal of the placenta, exploration of the uterine cavity for retained products, and, occasionally, hysterectomy are indicated.  These procedures are beyond the scope of ED care and should be left to the obstetrician. The patient should be supported with IV fluid and blood transfusion as indicated until definitive therapy is available. Constant firm uterine massage can lessen hemorrhage and may be life saving.

## Complex Deliveries

### Shoulder Dystocia

The term *shoulder dystocia* refers to impaction of the fetal shoulders in the pelvic outlet occurring after delivery of the head in vertex presentations. Shoulder dystocia complicates 0.15 to 0.6% of all vaginal deliveries and 1.7% of deliveries involving infants weighing >4000 g.Impaction of the fetal shoulders and thorax in the maternal pelvis prohibits adequate respiration, and compression of the umbilical cord frequently compromises fetal circulation, making shoulder dystocia a serious, and at times fatal, complication of delivery. Although shoulder dystocia occurs more commonly with large infants, it cannot be reliably predicted from any antepartum risk factors. Shoulder dystocia is associated with post-term pregnancy, fetal macrosomia, diabetes mellitus, maternal obesity, and multiparity.

**Management.**

General anesthesia is desirable but is seldom available in the ED. A wide episiotomy reduces the incidence of major perineal lacerations and provides additional space for manipulation. Because the techniques used to treat shoulder dystocia frequently require an assistant and delivery can result in fetal injury or hypoxia, assistance, including that of a pediatrician and obstetrician, should be emergently sought. Although reduction in the interval of time from delivery of the head to delivery of the body is of great importance to infant survival, overly vigorous traction on the fetal head or neck or

excessive rotation of the body may seriously damage the infant.

Most cases of shoulder dystocia can be resolved with 1 of 2 simple maneuvers. First, placing the mother in the extreme lithotomy position with her hips completely flexed, allowing the knees to rest on her chest (McRobert's maneuver), may cause the fetal shoulders to engage appropriately and enable delivery to progress. Alternatively, moderate suprapubic pressure applied to the maternal abdomen by an assistant while gentle downward traction is exerted on the fetal head may also result in delivery. [1] [32] If these simple maneuvers fail to effect delivery, several other techniques exist, the choice of which will depend on operator preference and experience. In the first maneuver, the operator places 2 fingers into the vagina and exerts pressure on the fetal scapula, rotating the posterior shoulder 180° in a corkscrew fashion (Wood's corkscrew maneuver). This may cause the impacted anterior shoulder to be released and delivery to progress (Fig. 60-14) (Figure Not Available) . Alternatively, delivery of the posterior shoulder may be attempted. Here, the physician's hand is inserted into the vagina along the hollow of the maternal sacrum. The posterior arm of the fetus is then carefully swept across its chest, followed by delivery of the arm. The shoulder girdle is then rotated into one of the oblique diameters of the pelvis with subsequent delivery of the anterior shoulder. Although this procedure may fracture the clavicle or humerus, these injuries are preferable to permanent brachial plexus or neurologic injury. [7] If all of these strategies fail, controlled destructive procedures such as fracture of the fetal clavicle may be necessary.

**Breech Delivery**

When compared with cephalic presentations, the breech delivery is associated with a greater incidence of prematurity, prolapsed cord, low implantation of the placenta, uterine and congenital abnormalities, multiple pregnancies, and increased perinatal morbidity and mortality rates. [1] [36] [37] The incidence of breech presentation varies inversely with gestational age and weight. At term, the incidence of breech presentation is 3 to 4%; from 28 to 38 weeks' gestation, 17%; and at <28 weeks' gestation, 40%. [38]

Increased rates of prematurity and congenital anomalies associated with breech presentation account for much of the perinatal loss. [36] [39] In addition, fetal distress also occurs more frequently. Whereas umbilical cord prolapse occurs in only 0.3 to 0.5% of vertex presentations, the incidence rate increases to 3.8 to 7.4% in breech presentations generally. [38] [39] Cord prolapse is more common among non-frank breech presentations, reaching an incidence of 8 to 16% and from 10 to 28.5% in double footling and single footling presentations, respectively. [39]

The increased use of cesarean section has greatly decreased the morbidity and mortality associated with breech delivery. Although cesarean section has been traditionally considered the standard of care, vaginal delivery may be the method of choice in carefully selected cases. The emergency physician seldom is called on to make the decision as to the most appropriate means of delivery but, rather, could be faced with the imminent vaginal delivery of the breech infant. Breech delivery is most appropriately performed with both a physician and an assistant present.

**Types.**

There are 3 types of vaginal breech delivery. *Spontaneous breech* is a breech delivery in which the infant is delivered spontaneously without any manipulation or traction other than supporting the infant. Although this form of delivery is rare with term infants, there is little associated traumatic morbidity. *Partial breech extraction* is when the infant is delivered spontaneously as far as the umbilicus and the remainder of the body is extracted. *Total breech extraction* is when the entire body of the infant is extracted by the physician.

Delivery is easier and perinatal morbidity and mortality are reduced when the breech is born spontaneously to the level of the umbilicus. [1] If fetal distress develops before this time, however, a decision must be made whether to perform a total breech extraction or prepare for cesarean section. Total breech extraction is indicated only if there is a definite diagnosis of fetal distress unresponsive to routine maneuvers and cesarean section cannot be performed promptly. To perform any vaginal breech delivery, the birth canal must be sufficiently large to allow passage of the fetus without trauma and the cervix must be completely effaced and dilated. If these conditions do not exist, a cesarean section is indicated. To ensure full cervical dilation in the footling or complete breech, it is important that the feet, legs, and buttocks advance through the introitus to the level of the fetal umbilicus before the physician intervenes in delivery and further extraction is attempted. The mere appearance of the feet through the vulva is not in itself an indication to proceed with delivery. This may be a footling presentation through a cervix that is not completely dilated. In this case there may be time to transfer the patient to the labor and delivery suite, preferably in the knee-chest position to minimize the risk of cord compression. [32]

**Technique.**

If fetal distress is documented and total extraction is deemed necessary, the following procedures are carried out. The physician's hand is introduced into the vagina, and both feet of the fetus are grasped, with the index finger placed between the fetal ankles. Gentle traction is applied until the feet are pulled through the vulva (Fig. 60-15) (Figure Not Available) . At this point, a wide episiotomy is usually made. Because the legs are slippery and difficult to hold due to vernix caseosa, they should be wrapped in a sterile towel as they emerge through the vulva. Downward gentle traction is continued as successively higher portions of the legs and thighs are grasped (Fig. 60-16) (Figure Not Available) . When the breech appears at the vulva, gentle traction is applied until the hips are

delivered. As the buttocks emerge, the fetal back usually rotates anteriorly. The thumbs of the physician are then placed over the sacrum while the fingers are placed over the hips, and gentle downward traction is continued (Fig. 60-17) (Figure Not Available) . As the scapulas emerge, the infant usually rotates back to its original position, with the back directed laterally.

If spontaneous rotation does not occur, slight rotation should be added to the traction to bring the bisacromial diameter of the fetus into the anteroposterior diameter of the pelvis (Fig. 60-18) (Figure Not Available) . Delivery of the shoulders should not be attempted until the lower halves of the scapula are delivered outside the vulva and the axilla becomes visible at the introitus. Two methods of shoulder delivery are commonly used. In the first method, with the scapulas visible, the trunk is rotated such that the anterior arm and shoulder appear at the vulva and can be easily released and delivered. The body of the fetus is then rotated in the reverse direction to deliver the other shoulder and arm beneath the symphysis pubis. In the second method, if trunk rotation is unsuccessful, the posterior shoulder must be delivered first. The feet are grasped in one hand and drawn upward over the mother's groin. In this manner, leverage is exerted on the posterior shoulder, which slides out over the perineal margin, usually followed by the arm and hand. The anterior shoulder, arm, and hand are then delivered beneath the symphysis pubis by downward traction on the fetal body (Fig. 60-19) (Figure Not Available) .

Occasionally, spontaneous delivery of the arm and hand does not follow delivery of the shoulder. If this occurs, upward traction of the fetal body should be continued after delivery of the posterior shoulder. Two fingers of the physician are then passed along the fetal humerus until the fetal elbow is reached. The fingers are used to splint the fetal arm, which is then swept downward and delivered. The anterior arm may then be delivered by depression of the fetal body alone. In some cases it may be necessary to sweep the anterior arm down over the thorax using 2 fingers as a splint.

After the shoulders appear, the head usually occupies one of the oblique diameters of the pelvis, with the chin directed posteriorly. The head may then be extracted using the Mauriceau maneuver. With the fetal body resting on the physician's palm and forearm, the index and middle finger of the hand are placed over the infant's maxilla, flexing the fetal head. Two fingers of the other hand are hooked over the fetal neck, and, grasping the shoulders, the physician applies downward traction until the suboccipital region appears under the symphysis pubis (Fig. 60-20) (Figure Not Available) . As the body of the fetus is then elevated toward the mother's abdomen, the fetal mouth, nose, brow, and eventually occiput successively emerge over the perineum. Suprapubic pressure applied by an assistant is helpful in delivery of the head. If delivery of the head is not effected by the Mauriceau maneuver, forceps delivery may be necessary. Forceps application is beyond the scope of this text.

At times, delivery of a frank breech may be necessary. Facilitated by an episiotomy, the breech should be allowed to deliver spontaneously as far as possible. Moderate traction may be exerted by a finger placed in each fetal groin (Fig. 60-21) (Figure Not Available) . Once the knees appear outside the birth canal, the legs may be slowly flexed to assist delivery, which usually occurs without trauma.

**Complications.**

Traumatic morbidity associated with breech presentations is approximately 12 times that of vertex presentations and is directly related to the manipulations used to effect

delivery and the relationship of fetal size to that of the maternal pelvis. [41] One of the most significant features of breech delivery is that progressively increasing diameters and less distensible fetal parts must traverse the maternal pelvis.

If cephalopelvic disproportion is not diagnosed until the fetal body has been delivered and if the fetal head will not descend, the prognosis is grave. In addition, whereas in vertex presentations, in which molding the fetal head is gradual, occurring over the course of hours, in breech presentation, molding is abrupt, subjecting the delicate supporting tissues of the aftercoming head to sudden and often violent stresses. Intracranial hemorrhage is the most frequent cause of death in breech delivery, with injury to the spinal cord, liver, adrenal glands, and spleen occurring in decreasing order of frequency. [1] [42]

Both assisted breech delivery and breech extraction involve a change in motive powers for delivery, substituting traction from below for pressure from above and increasing the probability of occurrence of unilateral or bilateral nuchal arms or hyperextension of the fetal head. Decomposition and extraction of a frank breech infant carry significantly increased fetal risks and impose additional maternal risks because of intrauterine manipulation. The fact that manipulation does indeed correlate with traumatic morbidity was illustrated by Rovinsky and coworkers, who found that, whereas spontaneous breech delivery was associated with no traumatic complications, increasing degrees of obstetric manipulation corresponded to progressive elevations of the traumatic morbidity rate. [41] The highest traumatic maternal morbidity rate, 8.3%, which is 10 times the rate for assisted breech delivery and 4 times the rate for breech extraction, occurred with breech decomposition and extraction.

## EPISIOTOMY

An episiotomy is an incision of the posterior vaginal wall and a portion of the pudenda, which is made to enlarge the vaginal introitus to permit easier passage of the fetus and theoretically to prevent perineal lacerations of the mother, preserving the structure and function of the vaginal introitus. In 1987, >60% of women in the United States received an episiotomy during childbirth. [43] The routine use of the procedure, however, has been questioned, with studies indicating a higher incidence of third- and fourth-degree perineal lacerations, a longer healing period, and increased perineal pain in women receiving episiotomies. ] When used appropriately, an episiotomy helps to minimize compression and trauma of the fetal head; facilitates the second stage of labor by removing the resistance of the pudendal musculature; and substitutes a straight surgical incision for the ragged laceration that may result from tearing of the musculature, making repair easier. [3] The traditional beliefs that episiotomy also results in less postoperative pain and may improve recovery of the pelvic floor musculature appear not to be true. Therefore, *the routine use of episiotomy, particularly in the primiparous patient, is no longer recommended, and a selective approach is now encouraged*. Indications for selective episiotomy include preterm or breech delivery, shoulder dystocia, occiput posterior presentations, and when perineal tear is imminent. [1] [3]

Two types of episiotomy are used: the median or midline episiotomy and the mediolateral episiotomy (Fig. 60-22) (Figure Not Available) .  The median incision is the

easiest type of episiotomy to perform and repair, results in the least amount of blood loss, and heals rapidly with minimal discomfort. The major disadvantage to the median incision is a 5 to 10% incidence of accidental extension of the incision into the anal sphincter or rectum, resulting in third- and fourth-degree lacerations, respectively. Although prompt recognition and proper repair of third-degree lacerations frequently have excellent results, [47] fourth-degree lacerations can result in significant morbidity. Although a mediolateral episiotomy seldom results in extension through the anal sphincter, blood loss is generally greater, repair is more difficult, and painful healing may result.

## Equipment

The following equipment is required for episiotomy and repair:

> Tissue scissors or scalpel (with tongue blade)
>
> 3-0 or 2-0 absorbable suture on atraumatic needle (e.g., chromic catgut or polyglycolic acid)
>
> Needle holder
>
> Suture scissors
>
> Gauze pack

## Technique

The episiotomy should be timed so that it precedes trauma to the maternal tissues and fetus but avoids excessive maternal blood loss before delivery. With vertex presentations, the episiotomy should be performed when the fetal head begins to distend the perineum and the caput becomes visible to a diameter of 3 to 4 cm during a contraction. [1] [49] With breech delivery, the episiotomy is usually performed just before breech extraction. [3] Anesthesia for episiotomy in the ED is usually limited to local infiltration of the perineum with 1 or 2% lidocaine.

The episiotomy is a simple incision that extends through the skin and subcutaneous tissues, the vaginal mucosa, the urogenital septum, the superior fascia of the pelvic diaphragm, and, if the episiotomy is mediolateral and deep, through the lowermost fibers of the puborectalis portion of the levator ani muscles. The incision may be made with either a scissors or a scalpel. When using a scalpel, a tongue blade is placed between the infant's head and the maternal perineum as the perineum is incised. For the median episiotomy, the incision is made through the median raphe of the perineum almost to the anal sphincter (Fig. 60-23) (Figure Not Available) . For the mediolateral episiotomy, the incision is directed downward and outward in the direction of the lateral margin of the anal sphincter and may be either to the right or to the left (see Fig. 60-22) (Figure Not Available) .

After delivery of the infant and placenta, the episiotomy is repaired. The goals of

episiotomy repair are to restore anatomy and achieve adequate hemostasis with a minimum of suture material. It is preferable to perform the closure after delivery of the placenta and after inspection and repair of the cervix and upper vaginal canal. The same principles of repair are followed for both the median (Fig. 60-24) (Figure Not Available) and mediolateral (Fig. 60-25) (Figure Not Available) episiotomies.

Because there is minimal tension on the closed wound, most authorities recommend the use of 2-0 or preferably 3-0 absorbable suture such as chromic catgut or polyglycolic acid on a large, atraumatic needle. The first step is to close the vaginal mucosa using a continuous suture from just above the apex of the incision to the mucocutaneous junction, reapproximating the margins of the hymenal ring. Burying the closing knot in the incision minimizes the amount of scar tissue and prevents tenderness and dyspareunia. All large actively bleeding vessels should be separately ligated during closure with separate absorbable suture ligatures. Next, the perineal musculature is reapproximated with 3 or 4 interrupted sutures. Closure of the superficial layers may be accomplished by 1 of 2 methods. In the first method, a continuous suture is used to close the superficial fascia from the mucocutaneous junction outward and is then continued upward as a subcuticular skin closure, returning to and ending at the mucocutaneous junction. Alternatively, several interrupted sutures may be placed through the skin and subcutaneous fascia and loosely tied. This last method of skin closure avoids burying 2 layers of suture in the more superficial layers of the perineum.

During episiotomy closure, it is helpful to maintain a dry field by inserting a large gauze pack in the vagina, leaving a tail or portion of the pack outside the vagina to aid in removal after the repair.

The most common complication of episiotomy is hematoma formation, owing to inadequate hemostasis; a hematoma is treated by evacuation and drainage. Occasionally, large bleeding vessels will require delayed ligation. Postpartum episiotomy pain can usually be controlled by analgesics and local heat or sitz baths. Infection is a rare complication and responds readily to adequate drainage and appropriate antibiotic therapy.

## IMMEDIATE POSTPARTUM HEMORRHAGE

Postpartum hemorrhage is traditionally defined as maternal blood loss >500 mL after delivery. Although this is the classic definition, ample evidence indicates that normal blood loss after vaginal delivery is frequently 500 mL. [1] [50] Therefore, in clinical practice the diagnosis of postpartum hemorrhage is usually made when the amount of bleeding exceeds the clinician's estimate of "normal." The most common cause of serious obstetric hemorrhage, postpartum hemorrhage accounts for a significant proportion of maternal deaths. [37] Postpartum hemorrhage is conventionally divided into immediate hemorrhage occurring within 24 hours of delivery and delayed hemorrhage occurring >24 hours after delivery.

Postpartum hemorrhage is frequently characterized by steady moderate bleeding that persists until serious hypovolemia develops rather than by sudden massive hemorrhage. Because of the relative hypervolemia that occurs during normal

pregnancy, blood loss may exceed 1500 mL before significant clinical changes in pulse and blood pressure become manifest. [51] Careful observation for blood loss, including evaluation of uterine size and consistency, is therefore mandatory during the early postpartum period.

The most common causes of immediate postpartum hemorrhage, in order of decreasing frequency, are uterine atony, lacerations of the vagina and cervix, and retained placenta or placental fragments. Less commonly, coagulation disorders, uterine rupture, uterine inversion, and paravaginal vessel laceration result in postpartum blood loss.

## Management

Management of postpartum hemorrhage consists of replacement of intravascular volume with crystalloid and blood products as needed, as well as therapy directed toward the cause of hemorrhage. The diagnosis of uterine atony, the most common cause of bleeding, is made when uterine palpation reveals a soft boggy uterine corpus. Although the diagnosis may be suspected on the basis of abdominal examination alone, bimanual pelvic examination is frequently necessary to confirm the diagnosis.

*Uterine atony* is managed by manual massage of the uterine fundus (Fig. 60-26) (Figure Not Available) . One hand of the physician is used to compress and massage the posterior aspect of the uterus through the abdominal wall while the knuckles of the other sterile gloved hand are used to gently massage the anterior aspect of the uterus through the vaginal wall. Care must be taken to avoid vigorous downward massage, which can result in acute uterine inversion. Oxytocic agents should be administered in conjunction with massage.

### Oxytocics

Oxytocin is ideally administered as an IV infusion, which is prepared by adding 20 to 40 units of oxytocin to 1 L of crystalloid and infused at a rate of 200 to 500 mL/hour, titrated to sustain uterine contractions and control uterine hemorrhage. Oxytocin should never be administered as an IV bolus because profound hypotension and myocardial arrhythmias may occur. If IV access is unavailable, 10 units of oxytocin may be given intramuscularly. [17] Because the onset of action of IV oxytocin is rapid, uterine contractions and therefore slowing of hemorrhage should be observed within minutes of administration. If bleeding persists and the uterus remains boggy despite oxytocin therapy, 0.2 mg of methylergonovine (Methergine) should be given intramuscularly to help stimulate uterine contractions. Typically, uterine contractions occur within minutes of ergot administration and last for several hours. Because of their tendency to cause vasoconstriction and severe hypertension in some patients, ergot preparations should be avoided in women who are known to be hypertensive [52] and should be used cautiously in women who have cardiac, hepatic, renal, or obliterative vascular disease. [17] Uterine atony that remains refractory to

these measures may respond to treatment with prostaglandins. Although intramyometrial injection or instillation of vaginal prostaglandin suppositories has been described, [53] most reports describing the successful management of uterine atony have

involved the intramuscular administration of 15-methyl prostaglandin F$_{2alpha}$ (carboprost tromethamine [Hemabate]).  Intramuscular carboprost is administered in a dose of 0.25 mg and may be repeated at intervals of 15 to 90 minutes as determined by the clinical course. The total dose should not exceed 2 mg. [17] The rate of successful control of uterine hemorrhage with this regimen exceeds 85%. Because nausea, vomiting, and diarrhea occur frequently in patients receiving prostaglandins, concurrent administration of antiemetic and antidiarrheal agents is recommended. [17]

**Procedures**

If vaginal bleeding persists despite uterine massage and a firmly contracted uterus, a cause other than uterine atony should be suspected. The labia, vagina, and cervix should be carefully inspected for lacerations. Bleeding from lacerations may be controlled by direct pressure or, in the case of cervical lacerations, by gentle application of the ring forceps to the bleeding point. Absorbable sutures may be used to control bleeding from easily accessible lacerations. Because adequate visualization of the cervix and upper vagina is difficult and repair of extensive lacerations frequently requires general anesthesia, repair of these lacerations is often better left to the obstetrician.

For the patient in extremis, *external abdominal aortic compression* has been recommended. This procedure is performed by pressing the operator's right fist firmly against the abdomen in the midline, just above the umbilicus with the palmar aspect of the hand directed caudad. [55] This technique compresses the aorta against the vertebral column and reduces perfusion of the uterus while the source of bleeding is identified and resuscitative measures are performed.

Although rare, occurring in approximately 1 in 4000 to 5000 deliveries, [56] *uterine inversion* is frequently the result of traction on the umbilical cord during the third stage of labor. [1] [52] Other risk factors include primiparity, fundal implantation of the uterus, delivery of a large fetus, the use of oxytocin, and placental anomalies such as placenta accreta.The principal signs and symptoms of the disorder are lancinating and often violent pelvic pain and excessive postpartum hemorrhage with up to 40% of patients developing shock. Diagnosis is made by visualization or palpation of the soft bluish-gray mass of the uterus filling the vaginal vault or protruding through the introitus. On abdominal examination, no mass representing the uterine corpus can be palpated above the symphysis pubis. Treatment is aimed at maintaining cardiovascular stability through the use of IV fluids and immediate repositioning of the uterine corpus. General anesthesia is often necessary, especially if the cervix has contracted. Tocolytic therapy, such as 0.25 mg SQ or IV terbutaline or 2 g IV MgSO$_4$ (administered over 10 minutes), has been used successfully to aid repositioning of the uterus.  Oxytocics should not be given until after the uterus is repositioned. Although timing of removal of an adherent placenta is controversial, removal is generally discouraged before repositioning of the uterus. [57] Early placental removal increases bleeding from friable myometrial vessels and may increase the risk of septic complications.

Repositioning of the uterus may be accomplished by inserting one hand into the vagina and extending the fingers to identify the margins of the cervix; the uterine corpus is

allowed to rest in the palm of the hand. Gentle pressure exerted with the fingers on the edges of the uterus closest to the cervix in the direction of the umbilicus is followed by gradual replacement of the corpus (Figs. 60-27 (Figure Not Available) and 60-28) (Figure Not Available) . Pressure should not initially be exerted centrally on the fundus, because this will cause the uterus to be compressed, forcing more "layers" of the uterus to simultaneously lie within the relatively tight cervical ring. Once the uterus has been repositioned, the placenta may be removed. Because traction on the cord of an adherent placenta is one of the principal causes of uterine inversion, this procedure may be deferred until the obstetrician arrives. Although replacement of the inverted uterus can usually be accomplished by vaginal manipulation, occasionally a dense cervical contraction ring is present, preventing repositioning. General anesthesia and laparotomy may be necessary for uterine repositioning.

## POSTMORTEM CESAREAN SECTION

Postmortem cesarean section, one of oldest and most dramatic surgical procedures known, has long been used as an attempt to preserve the life of the unborn child. [59] Earliest records trace its origin back to 715 B.C. when the legendary king of Rome, Numa Pompilious, decreed that the child be excised from the womb of any woman who died late in pregnancy. Under the emperors of Rome, the *caesars*, this law became known as the "lex caesarea," and hence the name "cesarean operation." [60]

Pliny the Elder described the first successful postmortem cesarean delivery in 237 B.C., that of Scipio Africanus who would later become one of Rome's greatest generals. In A.D. 1280 the Catholic Church at the Council of Cologne decreed that postmortem cesarean section must be performed to permit the unborn child to be baptized and undergo a proper burial. In 1500, a Swiss sow gelder, Jacob Nufer, performed the first reported successful cesarean section with maternal survival, delivering his wife of a live-born infant. His wife lived to bear 6 more children through vaginal delivery. [60]

Since 1879 there have been >188 reports of postmortem cesarean section resulting in the delivery of a live infant. [61] Because most of the literature on postmortem cesarean section involves only small numbers of cases with emphasis on those that are successful, accurate survival statistics are difficult to ascertain. When reported, infant survival rates range from 11 to 40%. [62] Because the potential for survival of a normal infant exists, cesarean delivery must be considered in any woman who suffers irreversible cardiopulmonary arrest during the third trimester of pregnancy. [61] Although the procedure is rare, the decision and its performance may fall to the emergency physician.

### Indications

Survival of the infant is directly related to the maturity of the fetus, the elapsed time from maternal death to delivery, the performance of cardiopulmonary resuscitation (CPR) on the mother, and, in certain circumstances, the availability of neonatal intensive care facilities. [61] Under the best circumstances the probability of infant survival is directly related to the neonatal birth weight and gestational age of the fetus. Although the lower limit of fetal viability varies among institutions, in general, performance of the procedure

before the point of fetal viability at 24 to 25 weeks is not indicated. [7] If the duration of gestation is not known from the history, fetal maturity may be quickly estimated by calculating gestational age on the basis of the date of the patient's last normal menstrual period or by measuring the height of the uterine fundus. Between 18 and 30 weeks' gestation, the age of the fetus in weeks will correspond to the distance in centimeters from the uterine fundus to the symphysis pubis, e.g., at 28 weeks' gestation the fundus is approximately 28 cm above the symphysis pubis or halfway between the umbilicus and the costal margin. [63] Criteria for intervention should be established prospectively at each institution and be in accordance with the institution's general neonatal policies.

The potential for infant survival decreases and the chance of neurologic damage increases as the time from maternal death (cessation of circulation) to cesarean section rises (Table 60-4) (Table Not Available) . When cesarean section is performed within 5 minutes of maternal death, neonatal outcome is generally considered excellent; from 5 to 10 minutes, good; from 10 to 15 minutes, fair; and from 15 to 20 minutes, poor. There have been no reported cases of fetal survival when cesarean delivery has been performed >25 minutes after maternal death.  Because even under optimal conditions CPR results in a cardiac output of 30 to 40% of normal and placental perfusion may be severely compromised, every attempt should be made to begin cesarean delivery within 4 minutes of the cardiopulmonary arrest, completing the procedure within 5 minutes of arrest.  The 5-minute time interval is so crucial to fetal survival that operative delivery within this period has been termed by Katz and colleagues as *perimortem* cesarean delivery. [61] Fetal prognosis is generally better after the sudden death of a previously healthy mother than after the death of a woman with a prolonged and debilitating illness.  Because volume losses incurred with perimortem cesarean section may precipitate maternal cardiac arrest, performance of the procedure in a patient who is hemodynamically unstable but not arrested is not warranted. [7]

CPR should, of course, be initiated immediately on arrest of the mother and continued until after delivery of the infant. The pregnant state produces certain physiologic changes that adversely affect the adequacy of standard CPR. Vena caval occlusion by the gravid uterus hampers venous return and thus compromises maternal cardiac output. A decreased functional residual capacity of the lung may impede ventilation. Manual displacement of the uterus away from the inferior vena cava may be attempted by an assistant. However, perimortem cesarean delivery in itself probably represents the most important variable for a successful maternal resuscitation.

**Legal and Ethical Considerations**

No physician has ever been found liable for performing a postmortem cesarean section. Indeed, it is thought that the physician has the legal right and responsibility to provide the unborn fetus with every possible chance of survival when there is no hope of maternal survival. [61] [63] Permission for the operation should be obtained from the family when possible but not at the expense of delaying the procedure. Failure to obtain permission should not preclude cesarean section.

Nonetheless, there is no standard of care relating to emergency physicians performing a

postmortem cesarean delivery. Each case must be individualized. Limited resources often place the physician in the difficult situation of deciding whether to continue efforts to resuscitate the mother or attempt to deliver the fetus in a difficult situation under less than ideal conditions. In the absence of obstetric backup immediately at hand, it is reasonable for the emergency physician to proceed with delivery of the child if the mother cannot be resuscitated. Prolonged attempts to resuscitate the mother are unlikely to benefit either the mother or the fetus.

## Equipment

The following equipment is needed for a postmortem cesarean section:

Scalpel with a No. 10 blade

Bandage scissors

Bladder retractor

Large retractors (2)

Forceps

Lap or gauze sponges

Hemostats (curved and straight)

Suction

Obstetric pack (as described earlier for vaginal delivery)

Because of the rarity of this procedure in the ED, it is unlikely that a specific instrument pack will be available. Minimally, a scalpel with a large blade and an obstetric pack are necessary.

## Technique

Postmortem cesarean section should be performed by the most experienced person present, preferably an obstetrician, and when possible a neonatologist should be in attendance. CPR should be initiated on the mother at the time of cardiac arrest and continued throughout the procedure. Although it is helpful if fetal heart tones are present premortem, time should not be wasted searching for them nor attempting to evaluate fetal viability with abdominal ultrasonography.

Rapid extraction of the infant while avoiding fetal and maternal injury is the goal of the procedure. Hence, time should not be wasted preparing a sterile operating field or transporting the patient to an operating suite outside the ED. Using a large (e.g., No. 10) scalpel, a midline vertical incision is made through the abdominal wall extending from the symphysis pubis to the umbilicus and carried through all abdominal layers to the

peritoneal cavity (Fig. 60-29) (Figure Not Available) . In most gravid women the hyperpigmented "linea nigra" is apparent and may serve as a guide for the incision. If available, retractors are placed in the abdominal wound and drawn laterally to expose the anterior surface of the uterus. The bladder is reflected inferiorly; if full it may be aspirated to evacuate it and permit better access to the uterus (Fig. 60-30) . While avoiding injury to fetal parts, a small, approximately 5-cm, vertical incision is made through the lower uterine segment until amniotic fluid is obtained or until the uterine cavity is clearly entered (Fig. 60-31 *A*). The index and long fingers are then inserted into the incision and used to lift the uterine wall away from the fetus. A bandage scissors is used to extend the incision vertically to the fundus until a wide exposure is obtained (see Fig. 60-31 *B*). The infant is then gently delivered, the mouth and nares suctioned, and the cord clamped and cut (Fig. 60-32) . Because the incision is relatively high in the uterus, the infant's head may not be readily accessible to the physician, in which case the infant's feet are grasped and the infant delivered through maneuvers similar to those of a breech delivery. Neonatal resuscitation should be carried out as necessary.

Because in rare instances relief of vena caval compression by the uterus improves maternal hemodynamics such that maternal survival is possible, maternal pulses should be checked and CPR continued after delivery of the infant.

### Conclusion

Postmortem cesarean section is a rarely performed but potentially life-saving procedure that should be considered in any woman in the third trimester of pregnancy who suffers irreversible cardiopulmonary arrest. Because neonatal survival is enhanced as the time from maternal death to delivery decreases while the irreversible nature of maternal cardiac arrest becomes more apparent as resuscitative efforts progress, the decision and timing of this procedure may be one of the most difficult that the emergency physician makes. Once the decision is made to perform a cesarean section, it should be done as quickly as possible by the most experienced person present. CPR should be continued until after delivery of the infant. Although rare, maternal survival has been reported after "postmortem" cesarean section.

## THE NEONATE

Evaluation of the neonate begins before delivery with assessment of maternal well-being, gestational age, ease and type of previous deliveries, and the recognition of fetal distress, as evidenced by meconium staining of the amniotic fluid, fetal bradycardia, or evidence of cord prolapse. Care of the newborn begins with delivery of the head while the mouth and nares are suctioned. After delivery and cutting of the umbilical cord, the infant should be placed in a supine and slight Trendelenburg position with the neck slightly extended (sniffing position). A 2.5-cm roll placed under the infant's shoulders may help in maintaining head position. Because of the relatively large surface area of the infant, temperature drops rapidly immediately after birth, with subsequent chilling, which produces shivering and increased $O_2$ demand. Care must be taken, therefore, to maintain body temperature by drying the infant with subsequent placement under a radiant warmer or, if a warmer is unavailable, in warm blankets.

**Evaluation**

Traditionally, the *Apgar scoring system*, applied at 1 and 5 minutes after birth, is the standard of neonatal evaluation (Table 60-5) . [1] [66] In general, the higher the score, the better the condition of the infant. The 1-minute Apgar score reflects the need for immediate resuscitation. A score of 7 to 10 indicates that the infant is in excellent condition, requiring no aid other than nasopharyngeal suctioning. A moderately depressed infant with depressed respirations, flaccidity, and pallor or cyanosis usually scores 4 to 6. A score of 0 to 3 indicates a severely depressed infant and mandates immediate resuscitation. Heart rate is slow and reflexes are depressed or absent. [1]

Although the Apgar score is the traditional standard for neonatal evaluation and low scores at 1 and 5 minutes are excellent indicators of the need for resuscitation, the decision to resuscitate and the infant's response to resuscitation can be more accurately assessed by evaluating the heart rate, respiratory effort, and color. [27]

Normally, the newborn takes a first breath within a few seconds of birth and cries within 30 seconds. [1] Apnea is the most common initial manifestation of depression in the neonate and unless reversed may lead to progressive hypoxemia, hypercarbia, and acidosis. Hypoventilation quickly leads to cardiovascular depression with subsequent slowing of the heart rate, the most sensitive indication of infant distress. A heart rate of <100 beats/min generally indicates the need for respiratory support.

**Equipment for Infant Stabilization**

The following equipment is required for infant stabilization:

Bulb syringe or DeLee suction trap

Oral airways (size 0, 00, and 000)

Suction catheters (size 5, 6, 8, and 10 Fr)

Endotracheal tubes (size 2.5 mm, 3.0 mm, and 3.5 mm)

Endotracheal tube stylet (optional)

Laryngoscope

Laryngoscope blade (straight; sizes 0 and 1)

Resuscitation bag

Face masks (sizes 0 and 1)

Wall suction

Wall oxygen

Radiant warmer

## Stabilization Technique

If neonatal respirations are infrequent or absent, suctioning the mouth and pharynx with a bulb syringe or DeLee suction trap and stimulating the infant by lightly slapping the soles of the feet and rubbing the back may serve to stimulate breathing. If necessary, the airway should be gently suctioned with an 8 or 10 Fr suction catheter. If wall suction is used, the pressure should be set at 60 to 80 mm Hg to prevent pharyngeal and esophageal trauma. Because deep suctioning of the oropharynx may produce a vagal response causing bradycardia or apnea, suctioning should continue for no longer than 10 seconds at a time, and heart rate should be continuously monitored. To minimize hypoxia, sufficient time should be allowed between suctioning for the lungs to be ventilated with 100% $O_2$ . [66] Because the neonate is an obligate nose breather, it is advisable to suction once through each nostril to ensure patency of the upper airway. Failure to establish effective respirations indicates either marked central nervous system depression, mechanical obstruction, or an intrinsic lung abnormality and demands active resuscitation.

If signs of airway obstruction, that is, decreased chest expansion and sternal and intercostal retractions, are present and persist after suctioning, the larynx should be directly visualized with a laryngoscope. Suctioning of the larynx should be done under direct vision. For obstruction distal to the glottic opening, it is advisable to intubate the infant and suction through the endotracheal tube. Appropriate size of the endotracheal tube varies with the size of the neonate from 2.5 mm for those weighing 1000 g or less to 3.5 mm for the term infant.

Because *meconium aspiration* is a major cause of neonatal morbidity and mortality, its prevention deserves special mention. Up to 60% of neonates with meconium staining of the amniotic fluid aspirate; approximately 20% of these neonates later develop pulmonary complications. [66] To prevent aspiration, neonates born with particulate meconium staining of the amniotic fluid require thorough suctioning of the hypopharynx before the initiation of respiration, that is, immediately after delivery of the head and before delivery of the thorax. If suctioning is inadequate and the hypopharynx has not been cleared of meconium before the onset of respiration, tracheal intubation should be performed to remove as much of the meconium as possible from the lower airway. Because

| TABLE 60-5 -- Apgar Scoring System | | | |
|---|---|---|---|
| **Sign** | **0** | **1** | **2** |

| | | | |
|---|---|---|---|
| Heart rate | Absent | Slow (<100) | >100 |
| Respiratory effort | Absent | Slow, irregular | Good, crying |
| Muscle tone | Flaccid | Some flexion of extremities | Active motion |
| Reflex irritability | No response | Grimace | Vigorous cry |
| Color | Blue, pale | Body pink, extremities blue | Completely pink |

meconium is viscous, suction should be applied directly to the endotracheal tube using the full caliber of the tube to evacuate the thick, tenacious material. The presence of watery or thin meconium does not require routine endotracheal intubation. [66] [67]

Bag and mask ventilation should be initiated as soon as it is recognized that tactile stimulation is not sufficient to establish spontaneous ventilation, that ventilation is not adequate to maintain a heart rate of >100 beats/min, or when central cyanosis persists despite a maximal oxygen environment.

| TABLE 60-6 -- Medications Commonly Used in Neonatal Resuscitations | | | |
|---|---|---|---|
| **Drug** | **Dose** | **Indications** | **Comments** |
| Epinephrine * | 0.01-0.03 mg/kg (0.1 mL/kg of 1:10,000 solution) | Bradycardia, asystole, EMD | May be repeated every 5 minutes as required. |

| Sodium bicarbonate | 1-2 mEq/kg | Correction of acidosis persisting after adequate ventilation | (1) Should not be used for brief episodes of arrest or to correct respiratory acidosis; |
| | | | (2) Because rapid infusion of hypertonic solutions may predispose to intracranial hemorrhage, each dose should be infused over 5-10 minutes in concentrations not to exceed 0.5 mEq/mL. |
| Atropine * | 0.02 mg/kg | Bradycardia, 2nd- and 3rd- degree atrioventricular block, perhaps asystole unresponsive to epinephrine | (1) Minimum initial dose is 0.1 mg; |
| | | | (2) May repeat mg/kg dose every 2-5 minutes to a total dose of 0.1 mg/kg; |
| | | | (3) Not recommended by current ACLS guidelines for acute phase of neonatal resuscitation. |
| Dextrose | 0.5-1.0 g/kg | Serum glucose < 40 mg/dL | (1) Monitor serum glucose (Dextrostix) frequently; |
| | | | (2) Administer as dilute solution, e.g., 10% dextrose solution; |
| | | | (3) Follow initial bolus with continuous infusion of 5-8 mg/kg/min. |

| | | | |
|---|---|---|---|
| Naloxone [*] | 0.01 mg/kg IV, IM, or SQ | Narcotic reversal as indicated | Duration of narcotic may be greater than that of naloxone; subsequent monitoring of infant required. |
| Calcium chloride | 5-7 mg/kg | Controversial, hypocalcemia and possibly for compromised myocardial dysfunction or cardiac arrest | Not recommended by current ACLS guidelines for acute phase of neonatal resuscitation. |

**Cardiovascular Drips**

| | | | |
|---|---|---|---|
| Epinephrine | 0.1-1.0 mug/kg/min | alpha-Adrenergic agent required to maintain systemic arterial pressure | Myocardial stimulation may cause pathologic arrhythmias; excessive dose may impair renal, splanchnic, or peripheral perfusion. |
| Isoproterenol | 0.1-1.0 mug/kg/min titrated to desired heart rate | Bradycardia, 2nd- and 3rd- degree atrioventricular block, asystole | May cause hypotension due to beta2 -adrenergic stimulation. |

**Other**

| | | | |
|---|---|---|---|
| Defibrillation | 1-2 J/kg | Ventricular fibrillation, ventricular tachycardia | Rarely indicated or effective. |

| | | | |
|---|---|---|---|
| Fluid (normal saline, lactated Ringer's solution) | 10-20 mL/kg | Hypovolemia | Rarely indicated. Hypovolemia most commonly occurs with placenta previa, abruption, twin-twin or fetomaternal transfusion. May require O-negative blood crossmatched with mother's blood or 5% albumin solution or other plasma substitute. |

ACLS, advanced cardiac life support; EMD, electrical mechanical dissociation.

\* May also be given via endotracheal tube.

A pulse oximeter strapped to the infant's Achilles tendon or thumb may provide a useful adjunct to assess neonatal well-being and the adequacy of resuscitation. [27] Intubation is indicated if prolonged positive-pressure ventilation is necessary, for the suctioning of thick meconium, or if bag-valve-mask ventilation is ineffective. [27] Perlman and Risser emphasize that optimization of ventilation is essential before administering chest compressions or medications. [68]

The heart rate should be monitored during the course of neonatal evaluation and stabilization with either direct auscultation over the chest or palpation of the pulse at the base of the umbilical cord or in the brachial or femoral areas. A readily discernible heartbeat of 100 beats/min is acceptable. If the heart rate is <60 beats/min or is between 60 and 80 beats/min and does not respond rapidly to effective ventilation and oxygenation, chest compression should be instituted while ventilation is continued. There are 2 techniques for performing chest compression in the neonate. In the two-handed method of chest compression the hands encircle the chest with the fingers placed over the back, and the thumbs are placed over the lower third of the sternum just below an imaginary line joining the 2 nipples. Because of the potential for injuring abdominal organs, the xiphoid portion of the sternum should not be compressed. If the infant is large or the resuscitator's hands are too small to encircle the chest, 2 finger compressions using the ring and middle fingers placed on the sternum one finger's breadth below the nipple line may be used. The sternum is compressed 1.2 to 2.0 cm at a rate of 120 compressions/min. Positive-pressure ventilation should be continued with 100% O2 at a rate of 40 to 60/min. Myocardial dysfunction and shock in the neonatal period are most commonly due to profound hypoxia. If these conditions persist despite adequate ventilation, an umbilical, IV, or interosseous line should be established with appropriate drug therapy. The medications most commonly used in neonatal resuscitation are found in Table 60-6 .

# Chapter 61 - Culdocentesis

**G. Richard Braen**

A number of conditions require sampling of the intraperitoneal fluid to confirm a diagnosis or to obtain material for microbial culturing. This fluid can be obtained from the peritoneal cavity in a number of ways. Culdocentesis involves the introduction of a hollow needle through the vaginal wall into the peritoneal space. Culdocentesis is a simple, rapid, and safe procedure. The technique has several indications, but it is used primarily for diagnosing ruptured ectopic pregnancies and ruptured ovarian cysts and for obtaining fluid to aid in the culture diagnosis of pelvic inflammatory disease (PID).

## ANATOMY

Before culdocentesis is attempted, the clinician must be familiar with the anatomy of the vaginal and rectouterine pouch (pouch of Douglas). In the adult female, the vagina is approximately 9 cm long. From its inferior to its superior aspect, the posterior wall of the vagina is related to the anal canal by way of the perineal body, the rectum, and the peritoneum of the rectouterine pouch. [1] The rectouterine pouch and the posterior wall of the vagina are adjacent only at the upper quarter (approximately 2 cm) of the posterior vaginal wall. The vaginal wall in this area is <5 mm thick. The uterus lies nearly at a right angle to the vagina.

The blood supply of the upper vagina comes from the uterine and vaginal arteries, which are branches of the internal iliac artery. The area is drained by a vaginal venous plexus that communicates with the uterine and vesical plexuses. The vagina has its greatest sensation near the introitus and little sensation in the area adjacent to the rectouterine pouch.

The rectouterine pouch is formed by reflections of the peritoneum, and it is the most dependent intraperitoneal space in both the upright and the supine positions. Blood, pus, and other free fluids in the peritoneal cavity pool in the pouch because of its dependent location. This pouch separates the upper portion of the rectum from the uterus and the upper part of the vagina. The pouch often contains small intestine and normally a small amount of peritoneal fluid.

## INDICATIONS

Culdocentesis is indicated in any adult female when fluid aspirated from the rectouterine pouch will help to confirm a clinical diagnosis. Ultrasound examination has largely replaced culdocentesis in the diagnosis of ruptured ectopic pregnancy and ruptured ovarian cysts, but the procedure still has an important role in emergency medicine. If ultrasound examination is not readily available in the emergency department (ED), or if the patient is too hemodynamically unstable to be transported to an off-site location for ultrasound, culdocentesis may be the fastest and most accurate diagnostic technique available to the emergency physician. [2] Analysis of peritoneal fluid is also a reliable

method of differentiating inflammatory from hemorrhagic pelvic pathologic conditions. Conditions in which culdocentesis may be of diagnostic value include a ruptured viscus (particularly an ectopic pregnancy or a corpus luteum cyst), PID, and other intra-abdominal infections (particularly appendicitis with rupture or diverticulitis with perforation), intra-abdominal injuries to the liver or the spleen, and ruptured aortic aneurysms. [3]

**Ectopic Pregnancy**

Ectopic pregnancy is often one of the most difficult gynecologic lesions to diagnose. [4] The incidence of ectopic pregnancy is on the rise, accounting for 1.6% of all pregnancies. Ectopic pregnancy is the most common obstetrical cause of maternal death in the first trimester. [4] In a series of 300 consecutive cases of ectopic pregnancy, 50% of patients received medical consultation at least 2 times before the correct diagnosis was made. [5] In 11% of the patients in this series, the diagnosis was not made until the third medical visit. Because of the severe consequences of a ruptured ectopic pregnancy, an early, accurate diagnosis is desired.

The clinical picture of ectopic pregnancy may include vascular collapse, pelvic pain, amenorrhea or abnormal menses, shoulder pain, syncope, cervical or adnexal tenderness, adnexal mass, anemia, and leukocytosis. There is often a history of salpingitis, use of an intrauterine contraceptive device, or tubal ligation; however, no combination of these signs, symptoms, or historical data is diagnostic for an ectopic pregnancy. To confuse the diagnosis further, a normal menstrual history is reported in approximately 50% of patients with ectopic pregnancy and the *urine* pregnancy test is occasionally negative. [6] Although rarely seen, the combination of a uterine decidual cast (Fig. 61-1) and a positive pregnancy test are virtually pathognomonic of an ectopic pregnancy. A uterine cast is decidua that has been hormonally stimulated by the ectopic pregnancy but is passed vaginally when the tissue can no longer be supported. The cast is an outline of the uterine cavity, but it can be mistaken for products of conception if not inspected carefully. Therefore, all tissue passed vaginally should be carefully inspected before it is sent to the laboratory for analysis for products of conception.

The greater sensitivity of the serum and urine human chorionic gonadotropin beta subunit (beta-hCG) radioreceptor assay, coupled with the proliferation of transvaginal ultrasound and laparoscopy, have greatly increased the chances for early diagnosis of unruptured and ruptured ectopic pregnancy. [7] A sensitive and specific beta-hCG test must be used. The newer urinary beta-hCG tests (enzyme-linked or solid-phase immunoassay) provide sensitivity to 20 to 50 mIU/ mL. Quantification of the serum test adds additional information being sensitive to >5 mIU/mL. Therefore, a negative *urine* beta-hCG test rules out pregnancy in >98% of cases, and pregnancy in any site can be ruled out in virtually all patients with a negative *serum* beta-hCG test. [8] A single quantitative beta-hCG is a poor predictor of size of the pregnancy or the risk of ectopic pregnancy, but serial testing is quite helpful. It is expected that the quantitative serum beta-hCG level should double approximately every 2 days in the first trimester. Serum progesterone determinations may also help to identify a normal or abnormal pregnancy. Although not infallible, a serum progesterone level of <10 ng/mL is usually associated with a nonviable intrauterine pregnancy or ectopic pregnancy, and a level >25 ng/mL is

usually associated with a viable intrauterine pregnancy.

To increase the accuracy of diagnosis, it is helpful to combine quantitative beta-hCG testing with ultrasound examination. An empty uterus by transvaginal or abdominal ultrasound combined with certain quantitative serum beta-hCG results can be quite helpful to the clinician. The quantitative range in which the ultrasonographer should detect an intrauterine pregnancy varies, but an intrauterine pregnancy should be detected if the serum beta-hCG level is in the range of 1200 to 1500 mIU/mL when using a transvaginal probe, and if the level is >6500 mIU/mL when using a transabdominal probe. It is important to note that the absence of an intrauterine pregnancy by ultrasound when the beta-hCG level is below the discriminatory zone is nondiagnostic and could represent an early viable normal pregnancy, a nonviable intrauterine pregnancy, or an ectopic pregnancy. When no intrauterine pregnancy is detected by ultrasound and the serum beta-hCG exceeds the discriminatory zone, the chance of an ectopic pregnancy ranges from 86 to 100%. [9]

Culdocentesis, for some patients, may play an important role in the diagnosis of ectopic pregnancy. The test has an accuracy rate of 85 to 95%. Romero et al. [12] reported that an ectopic pregnancy was found in 99% of cases when a positive pregnancy test and a positive culdocentesis were present. Although culdocentesis is most often positive in the presence of a frankly ruptured ectopic pregnancy, it may be diagnostic even in the nonruptured case when bleeding has been slow or intermittent. It is useful to note that many ectopic pregnancies leak varying amounts of blood for days or weeks before rupture. It is important that hemoperitoneum has been noted to occur in 45 to 60% of cases of *unruptured* ectopic pregnancy proven at surgery.

Hence, culdocentesis may be helpful in the stable patient whose ultrasound examination does not demonstrate an intrauterine pregnancy despite a quantitative serum beta-hCG level in the appropriate range. Although some clinicians opt for outpatient monitoring of serial beta-hCG levels in this setting, patients for whom the clinician has a high suspicion for ectopic pregnancy (e.g., the patient who has or has had significant discomfort) or for whom close follow-up cannot be ensured are candidates for culdocentesis. [2] Although a negative culdocentesis does not rule out an early ectopic pregnancy, patients with a nondiagnostic ultrasound and a negative culdocentesis generally represent patients at lower risk for "rupture" of an ectopic pregnancy during outpatient serum beta-hCG monitoring. Patients with a nondiagnostic ultrasound examination and a serum beta-hCG level below the threshold at which an intrauterine pregnancy should be visibile on the ultrasound examination also must be individualized. Those patients with significant pain, an unexplained low hematocrit reading, or postural vital sign changes (or near syncope) represent candidates for culdocentesis.

### Pelvic Infection

Acute PID has a polymicrobial etiology. [15] [16] [17] It has been common practice to define the etiology of PID by isolation of pathogens from the endocervix. The etiology is probably better defined by examination of the tubal flora. In fact, there is little correlation between cul-de-sac cultures and cervical cultures in PID. [18] Some medical centers routinely use aspirates obtained through culdocentesis to aid in determining the

causative microbial agents for the PID. [19] As the microbiology of PID becomes more complex and as the causative organisms develop resistance to antimicrobial agents, culdocentesis may evolve as one of the prime methods of obtaining meaningful microbiological cultures that will dictate appropriate therapy.

**Blunt Abdominal Trauma**

Although diagnostic peritoneal lavage, computed tomographic (CT) scanning, and ultrasound examination are popular and valuable techniques to detect hemoperitoneum, the use of culdocentesis also has been advocated. [3] [20] Because small amounts of blood tend to collect in the rectouterine pouch, the aspiration of clear peritoneal fluid is of great potential value in *excluding* hemoperitoneum. The procedure may be more advantageous than peritoneal lavage in some instances, because there is less risk of urinary bladder perforation or bowel injury. In addition, previous abdominal surgery is not a relative contraindication to culdocentesis, as it is with peritoneal lavage.

## CONTRAINDICATIONS

The contraindications to culdocentesis are relatively few and include an uncooperative patient, a pelvic mass detected on bimanual pelvic examination, a nonmobile retroverted uterus, and coagulopathies. Pelvic masses may include tubo-ovarian abscesses, appendiceal abscesses, ovarian masses, and pelvic kidneys. It has been suggested that the only major risk with the procedure is that of rupturing an unsuspected tubo-ovarian abscess into the peritoneal cavity. This can be avoided by careful bimanual pelvic examination to exclude patients with large masses in the cul-de-sac. [18] Although there are no data to guide the age at which culdocentesis may be safely performed, the procedure is generally limited to patients who are beyond puberty. This limitation is suggested on the basis of anatomy and with the consideration that the procedure is difficult to perform through a small, prepubertal vagina.

One should not forgo culdocentesis due to the absence of classic signs anticipated with ectopic pregnancy. It is important to note that a positive culdocentesis does not consistently correlate with peritoneal irritation, blood pressure, pulse rate, or the actual volume of hemoperitoneum. [13] In fact, bradycardia in the presence of significant intraperitoneal bleeding from a ruptured ectopic pregnancy is not unusual (Tables 61-1 (Table Not Available) and 61-2) (Table Not Available).

## EQUIPMENT

The equipment required for culdocentesis is listed in Table 61-3 . Either an 18-ga spinal needle or a 19-ga butterfly needle held by ring forceps is acceptable. It may be helpful to anesthetize the posterior vaginal wall at the site of the puncture with 1 to 2% lidocaine with epinephrine administered through a 27- or 25-ga needle. Some physicians use a cocaine-soaked cotton ball to anesthetize the mucosa before infiltration with a local anesthetic. Although local anesthesia is often unnecessary (because *puncture of the posterior vaginal wall at the upper one fourth of the vagina is generally no more painful than a venipuncture*), there is some advantage to use of a local anesthetic if multiple

attempts at culdocentesis are required, as is sometimes the case. In addition, the epinephrine may produce vasoconstriction and may reduce bleeding associated with the needle puncture. Furthermore, culdocentesis is often stressful to the patient, and all attempts should be made to render the procedure as painless as possible. Consideration of parenteral analgesia and sedation (see Chapter 35) should also be made when the patient is uncomfortable or anxious.

# TECHNIQUE

## Preparation

Culdocentesis is an invasive procedure that, in some hospitals, requires a written, witnessed, and signed consent form from the patient, parent, or guardian when the patient's condition permits. If verbal consent is obtained, this action should be witnessed and a notation in the medical record made documenting that the procedure was described, complications were discussed, and any alternatives--where appropriate--(e.g., sonography or immediate laparoscopy) were offered.

Once written or verbal consent is obtained, the patient is placed in a lithotomy position with the head of the table slightly elevated (reverse Trendelenburg position) so that intraperitoneal fluid gravitates into the rectouterine pouch. The patient's feet are placed in stirrups. In selected patients, some physicians premedicate with intravenous (IV) opioids or sedatives. The administration of nitrous oxide analgesia also is an accepted practice. When nitrous oxide is used during this procedure, it is important to document the presence of a chaperone, as some patients may develop sexual delusions under this agent. Although pain associated with culdocentesis needle passage is generally minor, the judicious use of analgesia and sedation makes the procedure easier for both physician and patient.

Radiographs, when indicated in the *stable* patient, are taken *prior* to culdocentesis, to avoid possible confusion if a pneumoperitoneum is detected following the procedure.

## Exposure

A bimanual pelvic examination must be performed before culdocentesis to rule out a fixed pelvic mass and to assess the position of the uterus. The examiner then inserts the bivalve vaginal speculum and opens it widely by adjusting both the height and the angle thumbscrews. The *posterior* lip of the cervix is grasped with the toothed uterine cervical tenaculum, and the cervix is elevated (Fig. 61-2) (Figure Not Available) . Grasping the cervix may produce minor discomfort, and the patient

---

**TABLE 61-3** -- Equipment for Culdocentesis

| |
|---|
| Adjustable examination table with stirrups |
| Bivalve vaginal speculum |
| Uterine cervical tenaculum |
| 19-ga butterfly needle or 18-ga spinal needle |
| 27- or 25-ga needle (for local anesthetic infiltration) |
| Ring sponge forceps |
| Syringes (20 mL) |
| Surgical preparation (iodinated, such as povidone-iodine) |
| Sterile water, cotton balls, 4 × 4 gauze sponges |
| Cocaine (10% solution) or benzocaine (20% solution) |
| Lidocaine (1%) with epinephrine |
| Culture media or test tube without anticoagulant |

should be warned in advance of a possible sharp pain during this part of the examination. Also, bleeding from the tenaculum puncture site and/or culdocentesis site

may produce postprocedure spotting, and the patient should similarly be informed.

Use of the tenaculum elevates a retroverted uterus from the pouch, exposes the puncture site, and stabilizes the posterior wall during the needle puncture. Some physicians prefer to use longitudinal traction on the cervix to produce the same result. The vaginal wall adjacent to the rectouterine pouch will be tightened somewhat between the inferior blade of the bivalve speculum and the elevated posterior lip of the cervix. This tightening of the vaginal wall exposes the puncture site and keeps it from moving away from the needle when the wall is punctured.

After the tenaculum is applied and the posterior lip of the cervix is elevated or traction is applied, the vaginal wall in the area of the rectouterine pouch should be swabbed with surgical preparation followed by a small amount of sterile water. Local anesthesia (1% lidocaine with epinephrine) may be administered at this point. Anesthesia may be injected with a separate 27- or 25-ga needle or by the spinal needle to be used for the culdocentesis. Also, a cotton ball soaked in cocaine or benzocaine solution can be used for topical anesthesia of the posterior vaginal wall before infiltration with a local anesthetic. The needles used for both the local anesthetic and the puncture should be attached to a 20-mL syringe. A smaller syringe may not be long enough to allow adequate control of the needle, and the physician's hand may block the view of the puncture site if a smaller syringe is used.

**Aspiration**

Following local anesthesia, the syringe and the spinal needle to be used for the culdocentesis are advanced parallel to the lower blade of the speculum. It is helpful to fill the syringe with 2 to 3 mL of saline (nonbacteriostatic) before puncture. Following needle puncture, the free flow of the fluid from the syringe expels tissue that may have clogged the needle and confirms that the needle tip is in the proper position and is not lodged in the uterine wall or the intestinal wall. Saline (rather than air) is preferred, because if air is used, one must be careful in interpreting the presence of free peritoneal air on subsequent radiographs. To avoid the need to change the syringe during the procedure, 1% lidocaine may be used for both anesthesia and confirmation of proper needle placement, but the bacteriostatic property of this agent precludes its use if the procedure is performed to obtain fluid for culture.

The vaginal wall should be penetrated in the midline 1 to 1.5 cm posteriorly (inferiorly) to the point at which the vaginal wall joins the cervix (Fig. 61-3) (Figure Not Available) . [22] The needle should penetrate a total of 2 to 2.5 cm. [22] [23] Gentle suction is then applied with the syringe while the needle is slowly withdrawn. It is important for the physician to avoid aspirating any blood that has accumulated in the vagina from previous needle punctures or from cervical bleeding, because this may give the false impression of a positive tap. Bleeding from the puncture site in the vaginal wall is minimized if epinephrine is added to the local anesthetic.

Blood or fluid may be obtained immediately but may also be obtained just before the needle is withdrawn from the peritoneal cavity. Therefore, it is important to aspirate throughout the gradual withdrawal procedure. If no fluid is aspirated, the needle should

be reintroduced and directed only slightly to the left or right of the midline. Directing the needle too far laterally may result in puncture of mesenteric or pelvic vessels. It is important to note that *if no fluid is obtained on the first attempt, the procedure should be repeated.*

Some physicians prefer the use of a 19-ga butterfly needle held with a ring forceps (Fig. 61-4) (Figure Not Available) . [22] This technique offers a built-in guide to needle depth and allows for good control of the needle during puncture. An assistant must aspirate the tubing while the physician controls positioning and withdrawal of the needle.

Fluid that is aspirated may be old, nonclotting blood; bright red blood; pus; exudate; or a straw-colored serous liquid. Any fluid that is not blood should be submitted for Gram staining, aerobic and anaerobic culture, and cell counts. Blood should be observed for clotting. Blood should also be sent for a hematocrit determination.

## INTERPRETATION OF RESULTS

An interpretation of the results of culdocentesis depends primarily on whether any fluid was obtained. In the absence of a pathologic condition, one will often aspirate 2 to 3 mL of clear, yellowish peritoneal fluid. When there is no return of fluid of any type (a so-called dry tap), the procedure has *no diagnostic value.* Because a dry tap is nondiagnostic, it should not be equated with normal peritoneal fluid. In addition, when <2 mL of clotting blood is obtained, this is also considered to be a nondiagnostic tap, because the source of this small amount of blood may be the puncture site on the vaginal wall. Such blood will usually clot. Over 2 mL of *nonclotting blood* is certainly suggestive of hemoperitoneum. However, some researchers interpret as little as 0.3 mL of *nonclotting* blood as a positive tap. [13] There is no particular significance to larger amounts of blood, because absolute volume may be related to the needle position or the rate of bleeding. Brenner and coworkers reported no blood from culdocentesis in 5% of patients with proven ectopic pregnancies, even when rupture had occurred. [5] In the series of 61 patients with surgically proven ectopic pregnancy reported by Cartwright and colleagues, culdocentesis performed within 4 hours of surgery was positive in 70%, negative in 10%, and inadequate in 20%. [13] "Positive" in their series was defined as obtaining at least 0.3 mL of nonclotting blood with a hematocrit of >3%. "Negative" was defined as obtaining 0.3 mL of fluid with a hematocrit of <3%. An "inadequate" tap was one in which no fluid was obtained. In the 252 surgically proven ectopic pregnancy patients having culdocentesis reported by Vermesh and others, 83% had a positive tap. [14] They defined a positive tap as nonclotting blood with a hematocrit >15%.

Because culdocentesis is usually used to diagnose an ectopic pregnancy, a "negative tap" is one that yields pus or clear, straw-colored peritoneal or cystic fluid. A large amount of clear fluid (>10 mL) indicates a probable ruptured ovarian cyst, aspiration of an intact corpus luteum cyst, ascites, or possibly carcinoma. The significance of these fluids and the interpretation of results are outlined in Tables 61-4 and 61-5 (Table Not Available) . Elliot and associates [24] caution that obtaining >10 mL of clear fluid should not automatically rule out an ectopic pregnancy, because the latter may coexist with other pathologic conditions.

A "positive tap" is one in which nonclotting blood is obtained, although the presence of nonclotted blood does not assure a tubal pregnancy. Intraperitoneal blood from any source (ectopic pregnancy, ovarian cyst, ruptured spleen) may remain unclotted after aspiration for days in the syringe as a result of the defibrination activity of the peritoneum. The return of a serosanguineous fluid also suggests a ruptured ovarian cyst. The hematocrit of blood from active intraperitoneal bleeding is >10%. In one series, the hematocrit of blood from a ruptured ectopic pregnancy was 15% in 97% of cases. [5]

It should be emphasized that a positive culdocentesis in the presence of a positive pregnancy test does not always prove an ectopic pregnancy. [14] A ruptured corpus luteum cyst in the presence of an intrauterine pregnancy test is probably the most common cause of a "false-positive" scenario. When possible, ultrasound may help corroborate the culdocentesis findings.

## COMPLICATIONS

Culdocentesis is one of the safest procedures performed in the emergency setting, and there are probably fewer complications with this technique than with peripheral venous cannulation. Complications have been reported, however, the most serious being rupture of an unsuspected tubo-ovarian abscess. [22] Other complications include perforation of the bowel, perforation of a pelvic kidney, and bleeding from the puncture site in patients with clotting disorders. Because the most common complications result from the puncture of a pelvic mass, careful bimanual examination of the patient should help prevent this problem. Puncture of the bowel and the uterine wall occurs relatively frequently, but this occurrence does not generally result in serious morbidity. Obviously, penetration of the gravid uterus has greater potential for harm. Occasionally, one will aspirate air or fecal matter, confirming inadvertent puncture of the rectum. Although this may be disconcerting, it is seldom of serious clinical concern and requires no immediate change in therapy.

| TABLE 61-4 -- Interpretation of Culdocentesis Fluid | |
|---|---|
| **Aspirated Fluid** | **Condition and Suggested Differential Diagnosis** |
| Clear, serous, straw-colored (usually only a few milliliters) | Normal peritoneal fluid |

| | |
|---|---|
| Large amount of clear fluid | Ruptured or large ovarian cyst (fluid may be serosanguineous); pregnancy may be coexistent |
| | Ascites |
| | Carcinoma |
| Exudate with polymorphonuclear leukocytes | Pelvic inflammatory disease |
| | Gonococcal salpingitis |
| | Chronic salpingitis |
| Purulent fluid | Bacterial infection |
| | Tubo-ovarian abscess with rupture |
| | Appendicitis with rupture |
| | Diverticulitis with perforation |

| | |
|---|---|
| Bright red blood * | Ruputured viscus or vascular injury |
| | Recently bleeding ectopic pregnancy * (ruptured or unruptured) |
| | Bleeding corpus luteum |
| | Intra-abdominal injury |
| | Liver |
| | Spleen |
| | Other organs |
| | Ruptured aortic aneurysm |
| Old, brown, nonclotting blood | Ruptured viscus |
| | Ectopic pregnancy with intraperitoneal bleeding over a few days or weeks |
| | Old (days) intra-abdominal injury (e.g., delayed splenic rupture) |

* *Note:* The hematocrit of blood from a ruptured ectopic pregnancy is usually >15% (97.5% of cases), [5]but some authors use >3% as positive.

## CONCLUSION

In the emergency setting, culdocentesis can be a helpful diagnostic procedure. In an unstable patient with a strong clinical scenario for a ruptured ectopic pregnancy, the procedure may facilitate life-saving surgery by confirming the diagnosis without the need for time-consuming ultrasound examinations. Although the procedure is mainly used in the evaluation of ectopic pregnancy, culdocentesis should also be considered as a diagnostic aid in the evaluation of PID and in abdominal trauma. This is a safe, simple procedure that every physician who deals with the emergency evaluation of women, *particularly women of childbearing age*, should know and use. It may be the most rapid way to confirm hemoperitoneum in the unstable patient with suspected ectopic pregnancy.

# Chapter 62 - Examination of the Sexual Assault Victim

**G. Richard Brae** n

Rape is reported to be the fastest-growing violent crime in the United States, [1] and it has been estimated that as many as 44% of women will be victims of a rape or an attempted rape in their lifetime, and that >50% of these women will be victims more than once. [2] The incidence of rape peaks between the ages of 16 to 19 years, but >60,000 rapes of women older than 50 years are reported annually. [3] The victims of rape can experience extensive immediate and delayed trauma (both physical and psychological), can be exposed to disease, and can become pregnant.

Society has held many misconceptions about the victims of sexual assault, particularly female victims. Included in these misconceptions are beliefs that the assault was encouraged by behavior or dress, that resistance by the victim was not sufficient, that the victim was promiscuous, or that there are ulterior motives for pressing charges. Variations on classic rape include the area of "date rape," in which *some sexual activity other than coitus* was voluntary, and spousal rape, defined as forced sexual activity between a married couple without consent by one party. [4] "Statutory rape" defines any form of coitus as criminal based solely on the young age of the victim, who is not deemed capable of consent. Many women do not report rape for fear of retaliation or embarrassment or simply because they do not know their legal rights.

Physicians and nurses dealing with an alleged sexual assault victim have a professional, ethical, and moral responsibility to provide the best medical and psychological care possible while simultaneously collecting and preserving the proper medicolegal evidence that is unique to the evaluation of alleged sexual assault cases.

Ideally, rape victims should be evaluated in a designated rape evaluation center, usually a designated hospital setting (often a designated emergency department [ED]) staffed with informed physicians, dedicated social workers, and trained counselors. However, victims may be brought to an ED that does not routinely provide this service. This may happen for several reasons, but it is often a matter of logistics--the peak hours for this crime are from 8:00 P.M. to 2:00 A.M., [5] and the most common days on which it occurs are weekends. In many localities, the only available physician at these times is the emergency physician, and it is often his or her responsibility to perform the evaluation and treatment. Emergency personnel can help change the psychological and physical impact of sexual assault. Through proper care of the victim, careful and thorough acquisition of evidence, and cooperation with the law and the legal process, ED staff can help the victim to recover from the assault and can aid society in improving the prosecution and conviction rates of rapists.

## MANAGEMENT OF THE ADULT FEMALE SEXUAL ASSAULT VICTIM

An important aspect of performing a sexual assault evaluation is preparation. This includes the establishment of a protocol and the assembly of appropriate forms and equipment. All of this must be accomplished through a cooperative effort with the police,

crime laboratory, hospital laboratory, crisis volunteers, and the ED clerical, social service, nursing, and physician staffs. Careful step-by-step planning concerning the way in which a victim is handled in the ED and in follow-up helps both to ensure the best care for the victim and to aid in the prosecution and conviction of assailants (Table 62-1) .

Major provisions in the ED protocol should include patient privacy and the designation of a separate area for the care of the victims. Emergency personnel should know the appropriate steps for evaluation and treatment of the victim, follow-up care, and maintenance of evidence. Examination kits should be available in the ED, and the staff should be familiar with them. A list of the contents of the kits should be kept in the department (Table 62-2) (Table Not Available) . The kits save a tremendous amount of nursing and physician time when a

| TABLE 62-1 -- Physicians' Responsibilities for Victims of Sexual Assault |
|---|
| **Medical** |
| Provide a safe and compassionate environment for the victim |
| Obtain a focused and nonjudgmental history of the assault |
| Obtain an accurate gynecologic history |
| Assess and treat physical injuries |
| Obtain appropriate cultures and treat existing infections |
| Provide therapy to prevent unwanted pregnancy |
| Provide prophylaxis for sexually transmitted diseases |

| |
|---|
| Provide for immediate and follow-up counseling |
| Arrange for follow-up medical care |
| Offer shelter and coordinate social services for the immediate discharge period |
| **Legal** |
| Provide accurate, objective, nonjudgmental recording of events |
| Document injuries |
| Collect forensic samples and maintain the proper chain of evidence |
| Report to authorities as required |
| Provide testimony at trial if required |

victim comes to the department. A checklist for "sexual assault examinations" (Table 62-3) should be included in the kits. This serves as a reminder of all of the medicolegal procedures to be completed.

Even though this chapter is primarily devoted to the evaluation of the adult *female* sexual assault victim, a guideline to the evaluation of the adult male sexual assault victim, the female child victim, the male child victim, and the accused assailant is provided in Table 62-4 . Each of these groups has special needs, and separate protocols should be developed for them in the ED.

**Consent**

Consent for treatment of a victim of sexual assault is mandatory. The victim has

undergone an experience in which her right to grant or deny consent was taken from her, [7] and obtaining consent for medical treatment and for the gathering of evidence has important psychological and legal implications. The victim has the right to refuse medicolegal examination and even medical treatment. She should, however, be encouraged to have physical evidence collected in the event that she later decides to seek prosecution. Witnessed, written, informed consent should therefore be obtained before evaluation and treatment are begun. If the victim refuses any part of the examination, her wishes should be honored, and the refusal should be noted in the hospital record.

When the court orders an examination but the victim does not want to be examined, the physician must realize

I .A., If appropriate.

* Indicated.

*Note 1:* Collection of salvia for secretor status is appropriate only if samples from the body, clothing, or crime scene potentially containing antigens that could link the victim with the suspect or suspects have been or will be obtained.

*Note 2:* The beta-hCG serum pregnancy test is more sensitive and quantitative.

*Chlamydia* screening tests may also be used.

that an uncooperative victim (who indeed has the right to refuse examination) can make a thorough examination impossible. Pursuing an examination that is unwanted by the victim can add to the victim's psychological trauma; the examining physician should discuss the situation with the authority that issued the court order and resolve the conflict before proceeding with the examination.

**History**

It should be emphasized that the sexual assault victim is actually a patient whose physical stability takes priority over all else (e.g., if she is in physical danger from hemorrhage, shock, or respiratory insufficiency, treatment of these conditions takes precedence).

The history appropriate to a sexual assault case basically is divided into 3 categories: history of the event, gynecologic history, and medical history (Table 62-5) . The history of the event should include only those elements necessary for the physician to complete a thorough physical examination and to collect evidence. Questions beyond this, such as a description of the assailant, should be left to the police investigators. Limiting the history not only shortens the evaluation in the ED, but it also helps to prevent discrepancies between the

ED history and the official police investigation report, which could weaken the victim's case if it comes to trial. For the sake of time, the medical history may be obtained by a nurse and expedited by the use of a checklist, which is then reviewed by the physician.

The history of the event should include the time, date, and place of the alleged assault and a description of the use of force or threats of force and the type of assault. Elements of force include the type of violence used, threats of violence, the use of restraints, the number of assailants, the use of alcohol or drugs (forcibly or willingly) by the victim, and any loss of consciousness experienced by the victim. Elements of the type of assault include fondling; vaginal, oral, or anal penetration or attempted penetration; ejaculation on or in the body; the use of a condom; and the insertion of foreign bodies into the vagina or the anus. The use of force or violence is partly a police matter, but from a medical standpoint it is desirable to correlate the physical examination with a description of any force, restraint, or violence.

A basic gynecologic history should be obtained in preparation for treatment plans regarding venereal disease and pregnancy. For example, it might be important from a medicolegal standpoint to know of any recent gynecologic surgical procedure that could be misinterpreted as local trauma. The gynecologic history therefore includes the use of birth control before the attack (with information regarding any missed birth control pills), last normal menstrual period, last voluntary intercourse, gravidity and parity, recent gynecologic surgery, and recent venereal disease.

The medical history should include current medications, tetanus immunization status, and allergies. One should note whether the victim douched, bathed, urinated, defecated, used a mouthwash, or brushed her teeth following the rape. These can alter the recovery of seminal specimens and other sexual assault evidence. In addition, any nonperineal or nonoral trauma should be reassessed when the medical history is taken.

Several elements of the history taken together can help the physician decide which samples to obtain. For example, sperm remain motile in the cervix for up to 5 days and remain motile in the vagina for 6 to 12 hours. [8] If the victim had voluntary intercourse 48 hours before examination and was raped 3 hours before examination, the physician should obtain samples from both the vagina and the cervix, keeping the 2 specimens separate. [9] By taking a careful history, the physician is able to perform an appropriate examination given these 2 events.

While taking the history, the examiner should observe the patient's ability to understand and respond appropriately to questions. Some victims of sexual assault are not capable of consenting to intercourse because of mental retardation, immaturity, or intoxication with drugs or alcohol. If intoxication is suspected, appropriate testing should be undertaken. If mental retardation is suspected, formal examination of the patient's mental status should be planned for a later date.

**Physical Examination**

The physical examination of the sexual assault victim is an extension of the history. The purpose of the examination is twofold: to aid in the proper medical evaluation of the patient and to gather samples and observations that might serve as evidence. The findings on physical examination help the physician and the court to answer the following questions: (1) Is or was the victim capable of consenting to intercourse? (2) Was force used? (3) Did vulvar, oral, or anal penetration occur? (4) Is there collectible physical evidence from the assailant in or on the victim's body?

A number of standardized examination kits have been developed to assist the physician in gathering evidence in a systematic fashion. Each kit should be reviewed for completeness as it applies to the local legal protocol.

Photographs should be considered, particularly if the victim is still wearing the clothing worn during the attack. Some institutions take their own photographs; others use police photographers. Patient consent should be obtained for photographs taken by hospital personnel, and a chain of evidence should be maintained. Self-developing film that can be permanently labeled (e.g., subject, date, details of pictured injury) should be used. The photographs should be labeled immediately and may be added to the legal evidence. These photographs may serve as evidence or may simply refresh the examiner's memory at the time of the trial. After the victim has been photographed, she should remove her own clothing, piece by piece, placing each item in a separate *paper* bag. If semen, blood, or other foreign material is present, it will dry in a paper bag,

whereas it could become moldy if placed in a plastic bag.

At this time the entirety of the patient's body, excepting the pelvic, anal, and oral areas, should be examined for signs of trauma and foreign bodies. Important areas for evaluation are the back, the thighs, the breasts, the wrists, and the ankles (particularly if restraints were used). Even in the absence of ecchymoses, tender contusions should be reported. Leaves, grass, sand, and other materials can occasionally be found in the hair or on the skin and should be retained as evidence. Areas of trauma should be documented and further evaluated (e.g., with radiographs) as indicated by the type and extent of injury. Up to 30% of rape victims show external evidence of trauma. [5] This evidence may range from abrasions to multiple major blunt and penetrating trauma. In addition, dried semen stains may be visible on the hair or the skin of the victim. These appear as lightly crusted, flaking areas that can be removed by saline-moistened swabs; the swabs are then air-dried and preserved as evidence. In addition to the skin, the fingernails can contain hidden bits of evidence. Rape victims may have bits of the assailant's skin, blood, or facial hair or other foreign material from the rape site beneath their fingernails; fingernail scrapings should be obtained routinely.

Following this initial examination, the patient should be placed in a lithotomy position for the pelvic examination. The thighs and the perineum should be inspected for signs of trauma and for foreign materials, such as seminal stains. An ultraviolet light used in a darkened room can aid in the search for external seminal stains. Any such stains should be removed and preserved as previously described.

The pelvic examination includes careful evaluation of the vulva and the introitus for signs of trauma, foreign material, and degree of maturity or senility. The internal examination should be done with a water-lubricated speculum. [10] The hymen should be inspected and one of the 4 following conditions noted: (1) that the hymen is present, intact, and free of evidence of trauma; (2) that the hymen is present and intact and shows old scarring; (3) that the hymen is present and recently ruptured; or (4) that the hymen is absent. A recently ruptured hymen is associated with bleeding or fresh clots. The breadth of perineal findings in normal and assaulted children has recently been reviewed. [11]

The vaginal wall should be inspected for lacerations. These appear near the introitus in younger, sexually inexperienced females; in older, sexually active females they appear higher, particularly in the right fornix. [12] [13] The cervix should be inspected for signs of pregnancy, menstruation, trauma, and preexisting infection.

**General Evidence Collection**

Protocols for evidence collection vary in different jurisdictions. Many rape evaluation centers have abandoned the cumbersome rape kits that have been used in the past, substituting simple collection methods that concentrate on important and usable legal evidence. The following discussion is patterned after the model protocol suggested by Young and associates. [14] As more sophisticated techniques using DNA analysis become legally accepted and more widely available, further modification in this

approach will undoubtedly evolve.

After inspection of the introitus, the vagina, and the cervix, specimens should be obtained. If at all possible, the speculum should be lubricated with water rather than a water-soluble lubricant to avoid contamination of specimens with the commercial lubricant. Generally, the specimens collected will be determined by local protocol, but they often include the following:

1. Any vaginal tampon that may have been inserted before or after the assault.
2. Any foreign body. Items identified have included condoms, soap bars, and handkerchiefs.
3. Vaginal swabs from pooled secretions in the posterior fornix (these may contain acid phosphatase or sperm) using a *dry* sterile cotton-tipped swab. A wet mount of one swab may reveal motile sperm if the examiner has ready access to a microscope. One swab can be used to make a dry mount for the crime laboratory, and 1 or 2 swabs can be air-dried for submission to the crime laboratory. These swabs are placed in a labeled envelope or red-topped tube for submission to the crime laboratory. If no pooled secretions are seen, a vaginal washing using 5 mL of sterile (but not bacteriostatic) water can be obtained with a syringe. The washing can be collected on a swab or placed in a sealed container for later examination for sperm and acid phosphatase.
4. Swabbing the oral cavity when oral penetration is stated or suspected. It may be helpful to obtain swabs along the gum line. Some examiners prefer to have the victim also swish or gargle with sterile water and collect those washings as samples. However, seminal fluid is rapidly destroyed by salivary enzymes, making identification difficult after a few hours. Similarly, swabbing the rectum should be performed if anal penetration is stated or suspected.
5. Consider a cervical, rectal, and/or oral culture or polymerase chain reaction (PCR) specimen(s) for *Chlamydia* and for *Neisseria gonorrhoeae.* Some clinicians treat empirically and forgo the culture or PCR testing. One series found gonorrhea cultures to be rarely positive in

   children<12 years of age and always associated with either a vaginal or a urethral discharge. [17] Each sample should be labeled separately; the label should include mention of the area from which the specimen was collected.After these samples have been obtained, a bimanual pelvic examination should be performed to assess uterine size and to identify adnexal masses and tenderness.

**Collection of Hair**

The victim's pubic hair can be combed for foreign material (particularly pubic hair belonging to the assailant) prior to the pelvic examination. These combings can be placed directly into a large paper envelope; the samples are submitted along with the comb. Foreign pubic hairs can help identify race and hair color, but hair does not generally possess enough individual characteristics to enable one to state positively that a hair of unknown source came from a particular person to the exclusion of all others. [18] In the future, crime laboratories may be able to perform enzyme typing of hair roots. Currently, sufficient phosphoglucomutase activity can be found in plucked hair roots to

enable typing of individual roots by starch-gel electrophoresis. [19] This capability may eventually be extended to hair roots collected by brushing.

Unfortunately, significant hair transfer occurs in <5% of assaults. Although the routine pulling of the patient's hair from the roots provides the best sample, the act of pulling the victim's hair is considered insensitive and unnecessary during the initial evaluation. The victim can provide the hairs at a later time--often the victim is willing to pluck the hairs herself at that time. Cutting locks of hair from the victim is essentially useless because this portion of the hair has no forensic value.

**Perineal Toluidine Dye Staining**

Another test that can be performed for sexual assault victims is the toluidine blue dye test for traumatic intercourse. Genital lacerations are corroborating evidence that rape has occurred, but without specialized staining techniques the majority of small lacerations go undetected. Toluidine blue greatly increases the detection of genital lacerations by highlighting lacerations with clear, linear marks easily distinguishable from episiotomy scars, rugae, and vulvitis. This test is highly sensitive, and small toluidine blue-highlighted lacerations may occur in vigorous non-rape intercourse, especially in adolescents. [20] This test involves the application of toluidine blue to the vaginal mucosa. Tears in the mucosa expose superficial nuclei of underlying cells. These nuclei have an affinity for the toluidine blue, and lacerations (small and large) become stained. In one study, 70% of nulliparous patients and 40% of the total number of patients examined within 48 hours after complaint of sexual assault demonstrated toluidine blue-positive lacerations. [21] McCauley and coworkers demonstrated that the use of toluidine blue increased the detection of vaginal lacerations in reported rape victims from 1 in 24 (4%) to 14 in 24 (58%). [20] Toluidine blue is primarily used in gynecology for outlining cervical neoplasia. [22]

The dye is applied with cotton-tipped applicators; all excess is wiped off with cotton balls until no further dye can be removed. Lacerations retain the dye (Fig. 62-1) (Figure Not Available) . Toluidine blue should be applied to the external genitalia before the insertion of a speculum, because the speculum itself may cause small lacerations. [21] Because of the potential spermicidal activity of toluidine blue, the examiner must decide on a case-by-case basis when to perform this test. The dye is not absorbed systemically, so it is considered safe in pregnant women. Note that the dye is not used intravaginally but only on external areas. If seminal stains are noted on the perineum, samples should be collected before toluidine blue application.

**Anal Evaluation**

The anorectal area should be examined for traces of foreign material (particularly lubricants) and trauma. Because of a reluctance of some victims to admit to anal or oral sodomy, some clinicians recommend an examination of these areas in all cases. When done, anorectal swabs can be obtained for sperm and acid phosphatase testing. Culture or PCR studies also may be desired as noted above. If the patient admits to anal penetration, one can perform a rectal washing by injecting 5 to 10 mL of normal saline with a syringe and a small plastic IV catheter, aspirating and preserving the fluid as

evidence. This washing can be examined for sperm and acid phosphatase, even though acid phosphatase determination has been of little value from samples taken from the anal canal and the rectum. [23]

**Oral Evaluation**

The mouth, particularly if oral sodomy is reported, should be inspected for signs of trauma. These can include bruises about the mouth, a torn frenulum of the lower lip, a torn frenulum beneath the tongue, and contusions or lacerations of the tonsillar pillars or the posterior pharyngeal wall. The examiner can test for acid phosphatase and sperm in the oral cavity by swabbing between the teeth with cotton-tipped applicators. The acid phosphatase test is seldom positive, but spermatozoa have been identified in oral smears up to 6 hours after the attack despite toothbrushing, using mouthwash, and drinking various fluids. [23] In addition, saliva samples (2 to 3 saliva-soaked swabs) may be obtained to assess the victim's secretor status of blood group antigens if foreign blood group antigens are found in the vagina. Most people (80%) secrete blood group antigens in saliva, semen, and other bodily fluids. However, determining the victim's secretor status can be done at a later time by the local crime laboratory. Consideration of pharyngeal gonorrhea culture or PCR testing should be made.

**Blood Tests**

Blood tests in sexual assault victims may include the following: drug and alcohol testing, blood typing, serologic test for syphilis, and, if appropriate, a pregnancy test using the beta-subunit of human chorionic gonadotropin (beta-hCG). [24] [25] If a serum pregnancy test is positive within a few hours or days of the assault, the victim was probably already pregnant at the time of the assault. If the test is negative at the initial examination but positive at a 2-week follow-up visit, it can be assumed that the victim became pregnant at or near the time of the assault. [9] Given the availability of sensitive and rapid bedside urine beta-hCG tests, many EDs are using this rapid assay to document pregnancy prior to consideration of pregnancy prophylaxis.

**Spermatozoa and Semen Testing**

Motile and immotile sperm may be found microscopically in wet mounts of vaginal aspirates and in vaginal, oral, and rectal swabs. Some examiners microscopically evaluate the slide immediately after the physical examination, because the forensic pathologist may not be able to examine the samples for several hours, days, weeks, or months after they are collected. At that time, sperm motility (a good sign of recent intercourse) has been lost. However, the absence of sperm does not rule out sexual assault. The assault may have been without penetration, there may have been coitus interruptus, or the assailant may have used a condom or have had a vasectomy. However, *some recommend that only the forensic pathologist examine the specimen for sperm,* so as to avoid potential conflicting evidence should later review identify the presence of sperm. [14]

Seminal plasma components (P30 and acid phosphatase) can be sought in the dried swab specimens at the crime lab. P30 is a glycoprotein specific to the prostate [26] and is

regarded as conclusive evidence of semen (i.e., ejaculation within 48 hours), whereas acid phosphatase is presumptive only because it can occur in other body fluids, such as vaginal secretions. Furthermore, low to intermediate levels of acid phosphatase do not rule out sexual assault. [27]

### Chain of Evidence

Samples and other evidence must be given to the police, a crime laboratory, or a forensic pathologist. Each sample must be labeled with the patient's name, the hospital number, the date and time of collection, the area from which the specimen was collected, and the collector's name. These specimens should then be packaged and transferred to the next appropriate official (police officer, pathologist, or other individual) along with a written "chain of evidence" that includes a list of the specimens, the signature of each person who provided them, and the signature of each person who received them. If this chain is broken, important evidence may be considered worthless in the courtroom.

## Treatment

### Sexually Transmitted Disease (STD) Prophylaxis

The factors of venereal disease, pregnancy, psychological distress, and follow-up should be considered in the treatment of a sexual assault victim. The risk of contracting a sexually transmitted disease (STD) as a consequence of a sexual assault has been difficult to determine, and estimates are tentative or nonexistent. One report of postassault STDs found a 3% chance of development of gonorrhea and a 0.1% chance of development of syphilis. [5] Others suggest that the risk for these STDs may be as high as 12% and 3%, respectively. [28] Jenny and colleagues found the postassault incidence of STDs to be 2% for *Chlamydia*, 4% for gonorrhea, 12% for *Trichomonas*, and 19% for bacterial vaginosis. [29] It is interesting to note that the latter group of women had a high rate (43%) of preexisting STDs at the time of initial examination. Glaser and others found similar STD infection rates. [30] The risk of developing herpes, cytomegalovirus, hepatitis B, or human immunodeficiency virus (HIV) infection from being raped has not been determined. However, HIV transmission has been noted. [31]

Depending on patient reliability and other factors, the examiner may choose to treat a victim as if she had been exposed to a known case of gonorrhea or *Chlamydia*; alternatively, the examiner may choose to rely on cultures. When cultures are obtained from the cervix, the pharynx, and the rectum, 90% of established gonorrhea cases can be diagnosed at a single visit. [32] Gonorrhea resulting from a rape may possibly be culturable within hours of the attack, but it should be almost always culturable at a 2-week follow-up visit.

Because victims tend to have a relatively low compliance with keeping follow-up visits, many physicians offer gonorrhea and *Chlamydia* prophylaxis at the time of the initial examination. If this course of treatment is chosen, the patient is essentially treated as if she had been exposed to a man known to have gonorrhea and/or *Chlamydia*. With the increasing prevalence of *Neisseria gonorrhoeae* strains resistant to penicillin and

tetracycline, ceftriaxone has become the antibiotic of choice in treating gonorrhea. Ceftriaxone also treats incubating syphilis. Intramuscular spectinomycin (2 g IM) and oral ciprofloxacin (250 to 500 mg PO) are single-dose alternatives for penicillin- and cephalosporin-allergic patients, but neither of these has been shown to be effective against incubating syphilis. No single-dose regimen for gonorrhea is effective against coexisting *Chlamydia trachomatis* infection, and patients should be given either a single dose of azithromycin (1 g PO) or a 7-day course of doxycycline (100 mg PO BID) or tetracycline (500 mg PO QID); a negative pregnancy test is a prerequisite for using either of the latter 2 antibiotics. [33] Erythromycin is a second alternative for *Chlamydia* prophylaxis in the pregnant patient.

One author has recommended consideration of hepatitis B prophylaxis, but this is not standard therapy. [4] Some recommend prophylaxis for *Trichomonas* with a single 2 g oral dose of metronidazole; again, this is not standard practice.

**Pregnancy Prophylaxis**

Pregnancy occurs in approximately 2 to 4% of sexual assault victims. The examiner must be careful to determine that pregnancy did not exist before the attack, and pregnancy tests should be obtained before any postcoital therapy is offered. The greater sensitivity of the serum beta-hCG test makes it the optimal evaluation. This test is sensitive at 5 days after implantation of the products of conception. However, newer urine tests with a detection threshold approaching 20 to 25 mIU/mL provide a reasonable alternative. These urine pregnancy tests should not be relied on if the patient's urine is quite dilute (specific gravity <1.010).

Sexual assault victims should be offered pregnancy prevention as outlined in Table 62-6. Diethylstilbestrol was once approved by the U.S. Food and Drug Administration (FDA), but it currently is not approved as a morning-after contraceptive. Ovral (50 mug of ethinyl estradiol and 0.5 mg

| **TABLE 62-6** -- Alternative Drug Regimens for Pregnancy Prevention in Female Sexual Assault Victims [*] |
|---|
| Oral diethylstilbestrol in a dose of 25 mg twice daily for 5 days |
| Intravenous conjugated estrogen (Premarin) in a dose of 50 mg once daily for 2 days |
| Oral conjugated estrogen (Premarin) in a dose of 30 mg once daily for 5 days |

| |
|---|
| Oral ethinyl estradiol in a dose of 5 mg once daily for 5 days |
| Oral ethinyl estradiol and norgestrel (Ovral), 4 tablets total; 2 at a time taken 12 hr apart |

* All should be begun within 24 hours of the sexual assault. Regimens may be effective for up to 72 hours post coitus. All of these preparations may cause nausea and vomiting. Note that treatment is started only after pregnancy has been ruled out.

of norgestrel) is approved for pregnancy prevention, but it has an unknown mechanism of action as a morning-after contraceptive. [34] Ovral works best if begun within 12 to 24 hours following the deposit of semen in the vagina but not >72 hours. A total of 4 tablets are taken orally, 2 tablets at a time, 12 hours apart. Adverse effects are nausea, vomiting, and breast tenderness. If the patient vomits within 1 hour of taking a dose, the dose should be repeated. Some routinely offer prophylactic antiemetic therapy; others reserve such treatment for patients who vomit. The failure rate of this regimen is reported to be 1.8%. [34] [35] Outside of the United States, RU 486 (mifepristone) is often used for postassault pregnancy prophylaxis. [36]

**Psychological Support**

Sexual assault precipitates a psychological crisis for the patient, and psychological care should begin when the patient first arrives in the ED. [37] [38] The victim often develops a posttraumatic stress disorder, manifested by numbed responsiveness to the external world, sleep disturbances, guilt feelings, memory impairment, avoidance of activities, and other symptoms. [39] The victim is particularly vulnerable to this stress disorder because of the following characteristics of sexual assault: (1) it is sudden, and the victim is unable to develop adequate defenses; (2) it involves intentional cruelty or inhumanity; (3) it makes the victim feel trapped and unable to fight back; and (4) it often involves physical injury. [40] The initial psychological care of the rape victim in the ED is fundamental (Table 62-7) (Table Not Available) . One can learn the methods for proper psychological care with a minimum of training.

**Post-examination Follow-up**

Follow-up for rape victims is essential. A 2-week follow-up examination conducted by a physician should be arranged; medical (venereal disease and pregnancy) and psychological reevaluation is performed at this time. Further evaluations can be performed at 4 and 6 weeks at the discretion of the physician following the patient. In addition, local volunteer support groups can be of immense assistance to a rape victim, and contact with such a group should be offered to each victim of sexual assault. Determining the victim's HIV status represents a complex issue. [41] Directing the patient to obtain anonymous HIV testing at a follow-up visit will keep the test results from the

defense counsel. HIV testing of the accused also is controversial and will depend on the willingness of the accused, local legal precedent, and other special circumstances (e.g., early pregnancy in the victim, in which case antiviral therapy may be beneficial to the fetus). [41]

**Legal Issues**

It is uncommon for the examiner to be called to court to testify in cases of sexual assault; if called, however, it is best to work with the prosecuting attorney to prepare testimony. However, *all chart notes should be written with the expectation that the ED evaluation and evidence collection will have to be explained and defended in court*. In some jurisdictions it is possible to minimize the time spent away from work by arranging to be called to the courtroom just before the time of testimony or by giving a deposition before the court date. Once on the witness stand, remember that one is called as the examining physician and not necessarily as an expert witness. The law requires that one testify only to one's best recollection and to what is indicated in the chart. Factual information in answer to questions should be given only if one knows the facts, and assumptions should be avoided. One should not be afraid to acknowledge the limits of one's knowledge or expertise. Statements such as "There were marks on the body that were consistent with bite marks" are preferable to statements such as "There were bite marks." It is the court's decision whether or not a person was raped, and the clinician is there to give information about the patient's presentation, statements, what was found, and what was done for treatment. Stick to the facts and avoid interpretation.

# Chapter 63 - Removal of an Intrauterine Device

**Robin R. Hemphill, J. Alan Morgan**

In 1987 it was estimated that 84.5 million women worldwide used an intrauterine device (IUD). [1] Of these, 59 million women were in China, where the IUD was the birth control method of choice. The IUD was introduced in the 1960s and has been the object of considerable controversy. Problems with the infamous Dalkon shield in the late 1970s resulted in 2 major IUD manufacturers withdrawing from the U.S. market. As a result, use of the IUD in the United States dropped by two thirds between 1982 and 1988, from 2.2 million women in 1982 to 0.7 million in 1988. [2]

Currently, while there are several models available for worldwide use, only 2 models have recently been available for use in the United States: Progestasert and ParaGard T 380A (Figs. 63-1 (Figure Not Available) and 63-2) (Figure Not Available) . The Progestasert is a T-shaped ethylene vinyl acetate copolymer with a vertical stem containing 38 mg of progesterone and barium sulfate in a silicone base. The device is 36 mm long and 32 mm wide and has 2 dark blue-black monofilament strings attached to the base. The contained progesterone supplies approximately 65 mug/day into the uterine cavity. The ParaGard T 380A is also a T-shaped device made up of polyethylene and barium sulfate. The exposed surface areas of copper are 380 ± 23 mm2 . Two off-white strings are attached to the base. The "A" designation identifies this model as having an enlarged bulbous stem base. This device is 36 mm long and 32 mm wide. Correct placement of an IUD within the uterus is shown in Figure 63-3 .

Multiple theories have been proposed for the contraceptive action of IUDs. One of the most widely studied theories suggests that the IUD inhibits implantation of the blastocyst through a variety of endometrial effects. Specifically, the IUD itself may mechanically interfere with implantation; the IUD may cause a local inflammatory response (particularly the copper-containing devices, which appear to cause significant inflammation) or release of prostaglandin that makes the endometrium unsuitable for implantation. The progesterone-releasing device may additionally disrupt endometrial maturation. Studies also indicate that IUDs are spermicidal. This may result from the induction of an inflammatory response at the endometrium that may cause sperm to be phagocytosed. Other suggested mechanisms of contraception are interference with normal development of unfertilized oocytes, reversal of ciliary action in the fallopian tubes, and changes in cervical mucus. Even a missing IUD tail has been reported to be the source of infertility. [6] Whatever the exact mechanism, the net effect is a highly effective form of reversible birth control. When the IUD is removed, the contraceptive effects rapidly disappear, and normal fertility returns in the majority of patients. There remains some concern that young nulliparous women may have an increased rate of infertility after IUD use, and this point is still controversial.

IUDs have 1-year and long-term contraception rates second only to implantable hormonal contraceptives and are at least as effective as oral contraceptives in preventing pregnancy. The Progestasert has a failure rate of 1.8 to 2.5 pregnancies per 100 women-years, and the Copper T 380A demonstrates a pregnancy rate of 0.5 to 1.0

per 100 women-years. After the IUD is placed, the rate of spontaneous expulsion is up to 15%, although this usually occurs during menses and within the first few months of being placed. This is more common in young nulliparous women. Bleeding and pain are the most common side effects reported by users of IUDs, and 5% to 15% of patients will have the IUD removed for these problems. [3] [5] The copper-containing devices are associated with more severe bleeding problems, and the Progestasert may be better tolerated.

## COMPLICATIONS OF IUD USE

There are several complications of IUD use that are of ongoing concern and continue to be debated. Multiple published studies suggest that the rate of pelvic inflammatory disease (PID) is increased substantially in women using IUDs. The Women's Health Study, published in 1981, concluded that the relative risk of PID in IUD users was 1.6. Other studies seemed to support these data and showed particularly high risk in women using the Dalkon shield. Since that time the original data have been reanalyzed, and many investigators currently believe that the original study was markedly flawed, and there is little increased risk of PID in IUD users. Still others argue that the original data were sound and believe that there is still a marked risk of PID. What seems clear is that the greatest risk of PID occurs within the first month of insertion and is likely related to the insertion process; PID after the first few months is more likely to be related to the patient's background risk of getting a sexually transmitted disease than to the simple fact that an IUD is in place. Whether the string that passes through the uterine cavity and cervix increases the risk of PID is debatable, as is the use of prophylactic antibiotics during IUD insertion.

There also is concern regarding an increased risk of ectopic pregnancy should the IUD wearer get pregnant. Because the IUD prevents pregnancy, overall the risk of ectopic pregnancy is decreased in IUD users (specifically, IUD wearers have 40% less chance of ectopic pregnancy than those using no contraception). [23] However, should a women become pregnant while using an IUD, there is a several-fold increased risk of ectopic pregnancy; the Progestasert appears to have a higher risk than the Copper T 380A. Women who have used an IUD in the past appear to have the same risk of ectopic pregnancy as women who have never used one.

The woman who becomes pregnant with an intrauterine pregnancy while the IUD is in place may experience several complications. A higher than normal percentage of IUD-failure pregnancies result in spontaneous abortion, and with the IUD left in place, the chance of a live birth is significantly reduced. [26] The type of IUD does not affect the risk of spontaneous abortion. Should the pregnancy proceed to term, the risks of premature delivery, stillbirth, and low birth rate are much higher than in a pregnancy without an IUD in place. [5] There is no known association with birth defects. Not only is the risk of spontaneous abortion higher (50%), but a number of those abortions may be septic in nature (2- to 13-fold increased risk), resulting in significant morbidity and mortality to the mother. Removing the IUD in the first trimester when the string is visible decreases the rate of spontaneous abortion to approximately 25%, and essentially eliminates the risk of subsequent septic abortion. This 25% rate of spontaneous abortion in women who have their IUD removed in the first trimester is not too dissimilar

from the 17% incidence of spontaneous second trimester abortion seen in women who conceive with no IUD in place. [27] In recent years there has generally been agreement that IUDs should be removed from the pregnant uterus when the string is visible.  When the string is not visible, the best management is controversial. Certainly, termination of pregnancy may be offered. For those for whom this is a difficult choice, ultrasound-guided IUD removal may be a possibility. [28] When such a patient is encountered in the emergency department, prompt follow-up should be arranged with an obstetrician to discuss the options available to the patient. However, any pregnant patient released from the emergency department with an IUD still in place must be given detailed instructions advising her to return for care if she should develop flu-like symptoms, purulent vaginal discharge, abdominal pain, pelvic pain, temperature elevation, or back pain. Septic abortion can proceed rapidly to fulminate septicemia and death.

Those patients who have been using an IUD for a prolonged time will sometimes have *Actinomyces*-like structures identified in Papanicolaou smears. This may occur in an average of 12% of women (range, 1% to 35%), but there does not appear to be an increased rate of gynecologic symptoms in those patients with the organisms. [23] Once the smear becomes positive for these organisms, subsequent smears will remain positive until the device is removed. Most experts agree that if signs or symptoms of infection develop in women who harbor *Actinomyces* bodies, the IUD should be removed and antibiotic therapy started. Asymptomatic patients with positive smears can probably be followed clinically. Concern that an inflammatory stimulus that remains within the uterus for a prolonged period might increase the risk of cervical or endometrial carcinoma has not been borne out. In fact, there is some evidence to suggest that IUD wearers may have a decreased risk of endometrial and cervical cancer.

Any time a foreign object is inserted blindly into a closed cavity, there is a risk of perforation, and the use of the IUD is no exception. Perforation of the uterus is among the more serious of the complications that occur with the use of the IUD. When perforation occurs, it is usually at the time that the IUD is inserted. While an experienced operator generally avoids this complication, there is a nearly ten-fold increase in the risk of uterine perforation if the IUD is placed while a woman is lactating. [1] [3] The overall risk of perforation is from 0.5 to 2 per 1000 insertions. [1] Perforation may be complete or partial, with the IUD embedded within the uterine wall. The IUD may never move from this position, or the normal uterine contractions could cause the IUD to gradually migrate through the uterine wall. The literature is replete with cases of contiguous organs that have become involved with the migrating IUD.  Given these different mechanisms of perforation, it should be clear that the patient could present with problems any time between shortly after insertion to years after insertion of the IUD.

Most commonly, unless rare complications develop, uterine perforation by an IUD is completely asymptomatic. It is usually suspected when (1) disappearance of the string is discovered during routine examination or by the patient herself during self-examination, (2) pregnancy develops and the IUD is discovered to have migrated, or (3) symptoms of abdominal pain with or without vaginal bleeding develop in a patient with a known IUD. [34] The loss of a string does not necessarily indicate a perforation (although most studies report a 5% to 10% perforation rate in missing strings), [37] nor

does the presence of a string mean that there is not a uterine perforation. However, when the string is missing, further evaluation is indicated.

In general, IUDs have a low risk of death, with IUD-related mortality ranging from 1 to 10 deaths per 1 million women-years. This makes the IUD one of the safest methods of contraception and far safer than pregnancy. These statistics are consistent, regardless of patient age, for the child-bearing years. The IUD also is a cost-effective means of birth control; the ParaGard T 380A can be left in place for 5 years (with some studies suggesting up to 10 years), and the Progestasert has a life span of 1 year. The IUD appears to be safe and effective for birth control in a well-chosen population. [40] Certainly, neither the IUD nor oral contraceptive pills alone should be advised for young nonmonogamous women, as these forms of birth control offer no barrier protection against acquired immunodeficiency syndrome (AIDS) and other sexually transmissible diseases. Given the ongoing debate about the increased risk of tubal infertility in nulliparous women, this group may not be the best population for use of the IUD. However, in older, monogamous, parous women who desire a safe, simple, and effective means of contraception, the IUD appears to be a reasonable choice.

## INDICATIONS FOR IUD REMOVAL

The most common reasons for removal of an IUD are as follows:

1. Severe uterine cramps or lower abdominal pain
2. Excessive and persistent uterine bleeding, either with the menstrual period or between periods
3. Perforation of the uterus, with passage of the device to extrauterine sites
4. Downward displacement of the device into or partially through the cervical canal
5. Intrauterine pregnancy
6. Pelvic inflammatory disease

Increased uterine cramping and bleeding are common and expected side effects of IUD use and are the most common reasons that IUDs become unacceptable to the user. [1] [3] A patient may present with this type of complaint, asking that the IUD be removed because the pain or bleeding has become unbearable. It is important to rule out infection or pregnancy as the source of the increased pain or bleeding, after which the device can be removed.

Displacement of the IUD is another indication for removal of the device. This can present as a partially extruded IUD or as a missing string in a patient with a known history of past IUD placement. If the IUD is partially extruded from the uterus, it can cause pain or bleeding and possibly penile lacerations during coitus. For these reasons, the device should be removed if it is found to be out of place during the pelvic examination.

In the case of a missing IUD string, there are a number of possible explanations. In some cases the patient may simply be unable or unwilling to examine herself for the presence of the string and may mistakenly lead the physician to believe the string is missing; in such cases a complete examination will reveal the string to be in the

appropriate position (extending 2 cm from the external os). Another cause of a missing string is spontaneous expulsion. Up to 20% of patients with spontaneous expulsion may not be aware that they passed the device, and in this case the evaluation should continue until the device is proven to no longer be present in the woman. [34] The string may also have simply retracted up into the cervical or uterine canal, or the IUD may have turned within the uterus. Again, the important issue to address is whether the IUD is still in the appropriate position. Finally, the 2 most concerning causes of a missing IUD string are pregnancy (in which the enlarging uterus pulls the string into the uterus) and perforation of the uterus by the IUD. [5] The incidence of uterine perforation in patients with missing strings varies from 3% to 22%, with most series reporting an incidence of 5% to 10%. [34]

The final indication for IUD removal is the presence of PID. Although this is controversial, most experts recommend removing the IUD in the presence of pelvic inflammatory disease, even mild cases, as its continued presence may make antibiotics less effective in eradicating the infection. [42] In the presence of infection, broad-spectrum antibiotics should be started and continued for 10 to 14 days; these are generally administered intravenously. In the patient with a complaint of pain and bleeding, it is difficult to ensure that infection is not a contributing factor. If there is doubt about the presence of infection, it is safer to administer antibiotics. Some authors advocate administration of antibiotic 30 minutes prior to the actual IUD removal. Durack and Phil reviewed endocarditis prevention and noted that in the absence of infection, antibiotics were not needed prior to IUD removal, except in certain high-risk patients such as those with severe native valve disease or prosthetic valves. [43] Antibiotics are not required if the IUD is being removed and there is no infection present.

## EQUIPMENT

Equipment useful in IUD removal is shown in Figure 63-4 . The items include 2 different vaginal specula (the Graves speculum is broad, and the Pederson speculum is narrow), Bozeman forceps, ring forceps, a tenaculum, and a uterine sound. Sponges; large, cotton-tipped applicators; and an antiseptic solution should also be available.

## PROCEDURE

Prior to removal of the IUD, the patient should have the procedure explained carefully, with the indication for IUD removal discussed, as well as the risks and benefits. This is particularly true of the pregnant patient, who must understand that any manipulation of the cervix and uterine cavity, no matter how uncomplicated and minor, may be associated with a spontaneous abortion. The complications of the procedure, which include cramping, bleeding, infection, and uterine perforation, must be explained. Preferably, a consent form listing these risks and complications should be signed by the patient and a witness and kept with the patient's medical record.

In any patient who desires IUD removal, a pregnancy test should be done prior to any manipulation. If pregnancy is ruled out, the patient may be placed in the lithotomy position and the cervix swabbed with povidone-iodine or a soap solution. If the IUD string is visible, it may be grasped with a Bozeman forceps and pulled out using slow,

gentle traction. Stabilizing the uterus with a tenaculum may occasionally be helpful. A jerking motion should never be used as the motion may cause the string to break, or cause uterine perforation if the IUD is imbedded within the uterine wall. If the string breaks when removal is attempted, partial or complete perforation must be presumed, and the patient should be appropriately referred. [34] If the IUD does not easily come free with steady, firm traction, the device should be left in place and gynecologic consultation obtained. Excessive manipulation of the IUD or probing of the uterus to free the device increases the risk of hemorrhage, infection, and perforation.

If the patient presents with a history of IUD placement and the string is not visible at the cervical os, several scenarios are possible: the IUD may have shifted within the uterus, the IUD may have fallen out unnoticed, the IUD may have perforated the uterus, or the patient may be pregnant. After determining that the patient is not pregnant, it is important to determine the IUD location. The IUD location often can be determined with a radiograph. A uterine sound may be positioned gently at the cervical os to determine where the IUD is in relation to the uterus and cervix on posterior and lateral radiographs of the pelvis. Alternatively, sonography may help localize the missing IUD. If the IUD is found to be outside the uterus, it can usually be removed as an elective operative procedure unless there is concern regarding an acute infection or other severe complication. The device should be removed to reduce the risk of adhesions and bowel obstruction.

In the nonpregnant patient, gentle probing of the external os with Bozeman forceps can often determine whether the string has retracted slightly from view. When the string is located in this manner, the string can be advanced into the vaginal canal until resistance is met. This maneuver may be sufficient when the patient presents solely because of concern regarding a "missing" IUD. Should the patient request removal, the IUD can then be removed as discussed above. There are several methods described in the literature for locating and removing a "missing" IUD believed to remain within the uterus. These include ultrasound-guided retrieval,  as well as techniques using a Lamicel, [46] the Mi-Mark Helix, [47] the Rocket retrieval forceps from London, or a uterine sound. These techniques are beyond the scope of this text.

If the patient is found to be pregnant and the string is not visible, retrieval should not be attempted by the emergency physician. The patient should be informed that if she maintains the pregnancy, she is at high risk for a second trimester spontaneous abortion, and it may be septic. Some centers attempt ultrasound-guided intrauterine removal of the IUD in early pregnancy, but this approach is beyond the scope of this text. [28] Some obstetricians may recommend elective abortion in those women who do not feel strongly about maintaining the pregnancy.

## AFTERCARE INSTRUCTIONS AND COMPLICATIONS

Patients usually tolerate uncomplicated removal of the IUD with no difficulty. It is reasonable to give the patient a mild analgesic to take home in case of cramping. The patient should be told to return to the emergency department for severe pain, bleeding, or fever. If the uterus is believed to be perforated, the patient should be given broad-spectrum antibiotics, and a gynecologist should be consulted for admission.

When the IUD is removed, the patient should be notified that she no longer has a contraceptive device and should use another form of contraception from that point on.

Removal of the IUD should be a careful and gentle procedure. Multiple forceful attempts at removal should be avoided. Prior to a removal attempt, the patient should be counseled that the removal attempt may be unsuccessful. In this case the patient will need referral to a gynecologist for further attempts at removal. An expected complication of removal is mild bleeding and uterine cramping. Patients who develop severe, unrelenting bleeding; pain; or evidence of sepsis may have a uterine perforation as a result of removal or attempted removal. These patients need resuscitation, broad-spectrum antibiotics, and urgent admission to a gynecologist.

For the patient found to be pregnant and with a history of IUD placement, the first step is to ensure that the patient has an intrauterine pregnancy. As mentioned previously, the IUD user who becomes pregnant has an increased risk of ectopic pregnancy. It is critical to verify that the pregnancy is intrauterine so that this complication of IUD use is not missed. After confirming an intrauterine pregnancy, it is appropriate to attempt IUD removal if the IUD string is visible. However, the patient must be fully informed that any manipulation of the pregnant uterus may result in spontaneous abortion.

## CONCLUSION

In the patient with a visible IUD string and appropriate indications, IUD removal is usually a simple and safe procedure, as long as the IUD is in the proper intrauterine position. Removal of the IUD is clearly indicated and beneficial in the first trimester of pregnancy and can be done in the emergency department. However, the risk of spontaneous abortion must be understood by the patient. If the IUD string is not visible, it is important to ensure that the patient is not pregnant and then to locate the IUD. This is best done using radiographs or ultrasound. Blind attempts at uterine explorations are best left to the gynecologist. If there is a suggestion of uterine perforation, the patient should receive timely referral to a gynecologist for further evaluation.

# Chapter 64 - Management of Increased Intracranial Pressure and Intracranial Shunts

**Alan B. Storrow**

Increased intracranial pressure (ICP) has multiple causes, but its pathophysiologic consequences are similar for all of them. Increased ICP impairs cerebral perfusion and causes ischemic damage to the brain. Mass lesions lead to intracranial shifts and directly damage brain tissue. Whatever its cause, increased ICP carries a high morbidity rate and may be rapidly fatal if not recognized and treated. Hence, recognition and management of this condition are important skills for emergency physicians.

In addition, many hydrocephalus patients with the potential for long-standing increases in ICP are being treated with indwelling cerebrospinal fluid (CSF) shunts and may present with shunt-related complications. Unfortunately, the emergent management of shunt-related problems is complicated by the great variety of shunts and the variability of their emergent presentations. Key issues in the management of CSF shunt problems include device identification, physical examination, radiographic examination, and access.

## PROCEDURES TO LOWER INCREASED ICP

Normal ICP (5 to 15 mm Hg) is maintained by regulation of three compartments: brain tissue volume, cerebral blood volume, and CSF volume. Tissue volume may be increased by diseases affecting the blood-brain barrier, such as cytotoxic or vasogenic edema secondary to head trauma or anoxia. Tissue volume also may be affected by mass effect from hematoma or tumor. Cerebral blood volume is regulated by brain tissue blood flow and is affected by hypoxia, hypercapnia, vasoactive medications, and ICP. The CSF compartment is the most dynamic of the three compartments. CSF is produced by the choroid plexus, located in the lateral and fourth ventricles; flows out around the brainstem; and is reabsorbed in the brain tissue, sagittal sinus, and spinal nerve roots.

The emergency physician must become adept at identifying the symptoms, signs, and conditions associated with increased ICP. Although some patients may present with subtle symptoms and a gradual rise in ICP, others may deteriorate within minutes. It is prudent to understand the emergent nonoperative treatments available for lowering ICP.

**Intracranial Anatomy and Pathophysiology**

The cranial cavity is surrounded by the skull, a rigid nondistensible structure, and is divided into compartments by the semirigid, densely fibrous folds of the dura mater: the falx cerebri and tentorium cerebelli. There are 3 primary components within the cranial cavity: CSF, blood, and semigelatinous brain. If the volume of one of the cranial components is increased as a result of hematoma, pus, edema, or tumor, there must be a corresponding decrease in the volume of one or more of the three primary

components; otherwise, pressure within the compartment rises. Compensation can occur: (1) by expressing CSF from the ventricles and subarachnoid cisterns; (2) by expressing blood from the collapsible cerebral veins; or (3) in cases of slow-growing tumors, by expressing interstitial fluid from the brain itself. Once the volume of the mass exceeds the compensating capacity of the compartmental components, pressure rises rapidly, often within minutes, and brain shift occurs from one compartment toward another. Because of the attachment of cranial nerves and delicate blood vessels, the brain tolerates shift poorly. Progressive lateral displacement of the pineal gland on computed tomography (CT) scan is associated with progressive impairment of consciousness (e.g., 3 to 4 mm of displacement produces drowsiness, and 8 to 13 mm of displacement produces coma). [1]

In the case of an expanding temporal epidural hematoma, the most medial part of the brain, the temporal lobe uncus, will begin to pass into the tentorial notch (uncal herniation), and the cingulate gyrus will pass under the falx (subfalcine herniation) (Fig. 64-1) (Figure Not Available) . The herniating uncus commonly exerts pressure on the oculomotor nerve in the tentorial notch, resulting in pupillary dilation on the side of the hematoma (Fig. 64-2) (Figure Not Available) . Pupillary dilation is the most reliable sign for determining the side of the hematoma but is correct in only 80% of cases. [2] When pupillary dysfunction does occur contralateral to the mass lesion, it is often due to direct pressure of the tentorium cerebelli on the displaced oculomotor nerve contralateral to the mass. As brain shift continues, the opposite cerebral peduncle also can be forced against the free edge of the tentorium, producing extremity paralysis on the same side as the hematoma (Kernohan's notch; see Fig. 64-1) (Figure Not Available) . Direct pressure on the ipsilateral cerebral peduncle or, in the case of a posterior frontal hematoma, the motor cortex itself can produce a contralateral paralysis. Thus, paralysis is not as accurate a localizing sign as is pupillary dilation and can be present on the same or opposite side of the hematoma. Further herniation and shift of the midbrain will result in tearing of delicate perforating vessels. At this point, irreversible damage has occurred. Damage to the midbrain reticular formation results in deep unconsciousness and cessation of eye movements, and the pupils become fixed at midposition.

The infratentorial compartment is much smaller than the 2 supratentorial compartments; compensatory mechanisms are exhausted much more quickly, and the volume increases that can be tolerated are much smaller. Patients with initial symptoms of drowsiness, incoordination, ataxia, and nystagmus may suddenly become deeply unconscious and apneic. Bradycardia and wide pulse pressure from direct brainstem pressure are more common with infratentorial masses. There can be upward herniation through the tentorial notch or downward herniation of cerebellar tonsils through the foramen magnum (tonsillar herniation) (Fig. 64-3) (Figure Not Available) . Infratentorial hematomas are difficult to diagnose without CT. In the setting of trauma, a fracture on plain films extending through the occipital bone to the foramen magnum suggests an infratentorial hematoma.

While the relationship between increased ICP and brain shift is one mechanism for impairment of brain function, Miller also implicates the influence of ICP on cerebral blood flow. [3] A constant blood flow to the brain is normally maintained by automatic changes in cerebrovascular resistance at the arteriole level, despite fluctuations in systemic blood pressure. This is known as *cerebral autoregulation,* and it continues to

function in the presence of moderate elevations of ICP. Repeated elevations of ICP, however, are believed to damage cerebral autoregulation. [3] When autoregulation is lost, increased ICP reduces cerebral blood flow. As ICP approaches mean arterial blood pressure, blood flow ceases. This quickly leads to cerebral ischemia and infarction.

**Indications and Contraindications**

Intervention begins with identification of the symptoms and signs likely to indicate increases in ICP and the acute syndromes necessitating urgent diagnosis and treatment. [4] While the emergent nature of a comatose patient with an isolated closed head injury is easy to ascertain, the more subtle symptoms suggesting a rising ICP may be difficult to recognize.

Classic symptoms associated with increasing ICP include headache, a change in mental status, and vomiting. Headaches are more worrisome when they are nocturnal, occur on arising, worsen with cough or head motion, are new in middle age, are associated with an altered mental state, or occur before the age of 10. Early changes in mental status include lethargy, irritability, slow decision making, and loss of normal social behavior. If the condition remains untreated, mental status will deteriorate to stupor, coma, and death. Vomiting may occur without nausea early, and then can progress to projectile as ICP rises.

Examination of the pupils, fundi, extraocular movements, motor ability, arterial pressure, and pulse may reveal classic signs of increased ICP. Pupil changes include unilateral irregularity or dilation. Fundi may reveal blurring of the disc margins, loss of venous pulsations, disc hyperemia, and flame-shaped hemorrhages. Later, the disc margins become obscured, and retinal hemorrhages may be seen. Extraocular muscle examination may reveal unilateral ptosis or unilateral third and sixth nerve palsies. Later, ophthalmoplegia and loss of vestibulo-ocular reflexes may occur. Motor changes occur late and include hemiparesis, followed by bilateral hemiparesis. Late changes in vital signs include arterial pressure elevation; widened pulse pressure; and a slow, irregular pulse (the Cushing response).

Acute syndromes of increased ICP include head injury and obtundation; syncope, headache, and meningismus; focal deficit followed by obtundation; and seizures. [4] Even mild trauma may lead to hematoma formation and a rapidly expanding mass lesion. A delay in treatment may allow ICP to rise precipitously within minutes to hours. Abrupt onset of headache, especially when associated with syncope or meningismus, suggests a ruptured cerebral aneurysm or vascular lesion. Mass lesions can be associated with an initial focal deficit. When this is associated with edema formation or hemorrhage, intracranial compartment shift and increased ICP may result within minutes or hours. Seizures may be associated with mass lesions. Status epilepticus may cause a decompensation of cerebral volume regulation.

A further subset of patients who "talk and deteriorate" has been defined. Such patients utter recognizable words at some time after head injury, then deteriorate to coma within 48 hours.Although they represent a small group of patients, most have intracranial

hematomas, and outcome depends on early recognition.

A cranial CT scan should be obtained, if possible, on all patients with increased ICP. It may reveal mass lesions, hemorrhages, or enlarged ventricles. Direct measurement of ICP is desired for all high-risk patients, although this is rarely available in the emergency department. Lumbar puncture should not be performed prior to CT and has no role in the trauma patient.

Optimal treatment of increased ICP begins with airway management and maintenance of normal oxygenation. The first priority is to get oxygen to the brain. Since both hypoxia and hypercapnia produce cerebral vasodilation and increased ICP, intubation for maintenance of normal $Pa_{O2}$ and $Pa_{CO2}$ is indicated for all unconscious patients. Other nonoperative techniques, discussed below, include positioning, body temperature and seizure control, medications, anesthesia, and special techniques for patients with intracranial shunts (Table 64-1) . Operative techniques include craniotomy, shunt placement, and infant hematoma aspiration. Only infant hematoma aspiration will be discussed here.

## Equipment

Most of the procedures below do not require special equipment. Hematoma aspiration in the infant requires sterile prep and drape, gloves, razor, appropriate spinal needle (20 ga, 1½ or 2½ inch), manometer, CSF collection tubes, and local anesthesia (if desired).

## Technique

### Mechanical Ventilation

IV lidocaine (1.5 mg/kg) has been suggested to blunt the rise in ICP associated with intubation, [9] [10] perhaps by preventing the cough reflex. However, this belief has been refuted in a randomized trial that suggested that paralyzing agents were the only sure mechanism to prevent ICP increase during intubation. [11] Nonetheless, a lidocaine dose of 1.5 to 2 mg/kg IV is commonly recommended.

After intubation, mechanical oxygenation and hyperventilation can optimize $Pa_{O2}$ and $Pa_{CO2}$ to produce cerebral vasoconstriction and a lower ICP. A target $Pa_{CO2}$ of 25 to 30 mm Hg was originally suggested. [13] However, more recent work  suggests that the physician must balance the degree of cerebral vasoconstriction with the potential to cause cerebral hypoxia and impaired cerebral extraction of oxygen. For

**TABLE 64-1** -- Initial Emergent Procedures to Lower Increased ICP

| Pathway | Procedure | Initial Quantity | Time To Effect |
|---|---|---|---|
| Respiratory | Hyperventilation | $Pa_{CO2}$ 30 torr | 1-5 min |
| | Oxygenation | $Fi_{O2}$ , 100%, PEEP | 1-5 min |
| Medications | Mannitol | 0.5-2 g/kg IV | 5-60 min |
| | Furosemide | 0.5 mg/kg IV | 5-30 min |
| | Dexamethasone | 10 mg IV, IM | Hours to days |
| Seizure control | Benzodiazepine | | 1-5 min |
| Surgical | Craniotomy | Hematoma removal | Immediate |
| | Ventricle catheterization | Burr hole and catheter | Immediate |
| | Infant hematoma aspiration | | Immediate |

| | | | |
|---|---|---|---|
| Shunt patients | Chamber pumping | | 1-5 min |
| | Aspiration | | 1-5 min |
| | Proximal catheter puncture | | Immediate |
| Anesthesia | Pentobarbital | 20-35 mg/kg IV bolus | 30-60 min |
| | | 3-5 mg/kg/hr IV infusion | |

$Pa_{CO2}$, partial pressure of carbon dioxide in the arterial blood; $Fi_{O2}$, inspired oxygen content; PEEP, positive end-expiratory pressure.

the emergent management of these patients, it seems prudent to suggest a target $Pa_{CO2}$ of 30 to 35 mm Hg. After admission, more invasive monitoring of cerebral perfusion pressure, cerebral blood flow, and cerebral oxygen extraction may be undertaken to optimize this balance. An additional beneficial effect of hyperventilation may be optimization of global cerebral glucose extraction. [16]

Mechanical ventilation and positive end-expiratory pressure (PEEP) should be used to maintain a $Pa_{O2}$ of 80 to 100 mm Hg. [4] This level produces at least a 90% hemoglobin saturation, adequate to attenuate $Pa_{O2}$-mediated cerebral vasodilation.

**Positioning**

Placing the patient in a head-upright posture has been suggested to lower increased ICP. Despite concerns about the deleterious effects of an upright position on cerebral perfusion pressure and cerebral blood flow, 2 reports support moderate elevation, between 15° to 30°. This degree of elevation significantly reduced ICP and, in general, did not impair the perfusion pressure or blood flow. In addition, neck flexion or rotation to either side has been shown to significantly increase ICP. [21]

**Body Temperature and Seizures**

A rise in body temperature increases the brain's metabolic demands and should be treated with antipyretics or cooling. A recent investigation concluded that

acetaminophen was the single most effective method to lower brain temperature, performing better than isolated head cooling or nasopharyngeal cooling. [22]

Similarly, seizures markedly increase the brain's metabolic needs and cause a rise in ICP. They should be terminated with a rapidly acting benzodiazepine or barbiturate. Longer term seizure prevention may be initiated with phenytoin or phenobarbital.

**Medications**

Osmotic diuretics favor the passage of water from the brain to the systemic circulation by producing an osmolar gradient. Mannitol should be administered IV for signs of increased ICP, especially herniation. One gram per kilogram is given as a 20% solution (100 g mannitol in 500 mL 5% dextrose in water) over 10 to 20 minutes. Its therapeutic effect begins within minutes and may last several hours. It can be repeated at the same dose every 4 to 6 hours. The mechanisms of mannitol are not clearly elucidated, although animal studies suggest it decreases ICP by decreasing CSF formation rate and brain tissue water content. [23]

Loop diuretics are sometimes used in conjunction with mannitol to decrease brain water content and therefore assist in production of a negative free water balance. [4] The standard dosage is 0.5 mg/kg of furosemide IV. Use of loop diuretics is not as accepted as use of mannitol; therefore, consultation with a neurosurgeon is advised.

Corticosteroids are thought to stabilize the blood-brain barrier and reduce brain swelling. Their clear benefit in improving neurologic symptoms for patients with brain tumors has led to widespread use for this indication. The standard dosage is 10 mg dexamethasone given IV or IM, followed by 4 mg every 6 hours. The pediatric dose is 1.5 mg/kg initially (up to 10 mg), followed by 1.0 mg/kg/day. The benefits of steroid use in trauma have not been well demonstrated.

If ICP is not controlled with the above measures and surgical decompression is not imminent, many practitioners would add barbiturates in anesthetic dosages (e.g., pentobarbital 20 to 35 mg/kg bolus IV, followed by 3 to 5 mg/kg/hour IV infusion).

Newer experimental approaches to lower ICP include hypertonic saline [24] and superoxide dismutase. [25] Hypertonic saline performed as well as mannitol in a preliminary trial [24] and has the added benefit of assisting with hemorrhagic shock resuscitation. Superoxide dismutase scavenges the oxygen radical superoxide. Formation of this radical is one of the last steps leading to neuronal death after traumatic or ischemic brain injury.

**Intracranial Shunts**

Intracranial shunts are discussed in detail below. Acute shunt obstruction in the rapidly deteriorating patient is a neurosurgical emergency. Rarely, forced shunt pumping may provide temporary relief. Emergency reservoir puncture may help with distal obstructions, although unfortunately, most obstructions are proximal. As a last measure,

puncture of the entire length of the ventricular catheter may relieve the obstruction, but it will also destroy the shunt. Definitive treatment is operative shunt replacement.

**Infant Hematoma Aspiration**

Head trauma at time of delivery or within the first 6 months of life is a frequent cause of infant subdural hematoma. It likely results from disruption of the bridging veins that course to the sagittal sinus. In the majority of cases, the bleeding is bilateral and located over the dorsolateral surfaces of the frontal and parietal lobes. The bleeding may be chronic, well tolerated, and diagnosed by an excessive rate of cranial enlargement. However, bleeding may also be acute and require emergent neurosurgical intervention. In addition to the typical signs and symptoms of increased ICP, the infant may present with a bulging, tense, pulseless anterior fontanelle. If untreated, the infant may progress to transtentorial herniation. [26]

The anterior fontanelle becomes effectively closed between 9 and 18 months. Until this time it may be possible to lower increased ICP caused by a subdural hematoma in the rapidly deteriorating infant by the following tap procedure: The infant is placed supine, and excessive flexion of the neck is avoided. The scalp is shaved over the lateral margins of the anterior fontanelle. The skin is scrubbed with povidone-iodine for 10 minutes, if time allows, and then draped with sterile towels. Local anesthetic is not required but may be used. A 20-ga, 1½- or 2½-inch spinal needle is inserted through the skin at the extreme lateral limit of the anterior fontanelle where it meets the coronal suture (Fig. 64-4) (Figure Not Available) .

A zigzag puncture is used to prevent later leakage of subdural fluid. The needle is first inserted through the skin, and then the skin is moved with the needle in place before the pericranium is penetrated. The needle is then pushed through the pericranium into the subdural space. The subdural fluid is allowed to drain spontaneously, pressure is measured with a manometer, and specimens are collected for Gram staining, culture, cells, glucose, and protein. The fluid is never aspirated for fear of drawing pial vessels into the point of the needle. If a pial vessel is punctured, bleeding will usually cease spontaneously. The procedure is then repeated on the opposite side. A firm sterile dressing should then be applied. If continued leakage occurs from the puncture site, applying a collodium-impregnated cotton fluff over the puncture wound and elevating the head 20° to 30° will usually stop it.

### Complications

The use of mechanical ventilation and PEEP can increase intrathoracic pressure and cause ICP to rise. The use of mannitol requires attention to serum osmolality, which should not rise above 315 mOsm. [4] Discontinuation of mannitol may result in a rebound increase in ICP.  Infant subdural aspiration may be complicated by bleeding, infection, or intracranial vessel rupture.

## INTRACRANIAL SHUNT ASSESSMENT

**Physiology**

CSF is continuously produced by the choroid plexus and cerebral ventricles. It is partially reabsorbed by the surface of the brain and drains through the central nervous system. Hydrocephalus, which means "water head," results from an excess accumulation of CSF, usually in the ventricular system.

A wide variety of terms have been developed to describe the anatomic cause of this problem. *Communicating hydrocephalus* indicates continuity between the ventricular system and the subarachnoid spaces of the brain and spinal cord. In *noncommunicating hydrocephalus* the ventricular system or its outlets to the subarachnoid space are blocked. *Obstructive hydrocephalus* implies CSF flow blockage at any point. Since CSF overproduction is virtually never a cause of hydrocephalus, most hydrocephalus is obstructive. Furthermore, hydrocephalus can be described as acute, subacute, or chronic, indicating a time course of days, weeks, or months, respectively. [27]

Congenital and acquired disorders are most often responsible for hydrocephalus. Examples include myelomeningoceles, encephaloceles, meningitis, atriovenous malformations, traumatic hemorrhage, cysts, and calcifications. [28]

The long-term management of hydrocephalus has been revolutionized by the use of CSF shunts. Kausch first described CSF diversion to the peritoneal cavity in 1905. [29] CSF shunting has been described to such unusual sites as the bowel, thoracic duct, gallbladder, retroperitoneal space, ureter, mastoid, Stenson duct, and fallopian tube. However, ventriculovenous (VV) and ventriculoatrial (VA) shunts were the commonly used early shunts. Problems with thrombosis and obstruction due to backflow of blood in these shunts were largely overcome with the development of a one-way valve in 1952. [30] However, complications with septicemia, endocarditis, glomerulonephritis, pulmonary embolism, and a high revision rate led to the current preference for ventriculoperitoneal (VP) shunts. [31]

Early VP shunts used polyethylene tubing and were plagued by a high incidence of breakage, kinking, and obstruction secondary to foreign body reaction. [32] Silicon polymer shunts, developed in the 1960s, were more pliable, caused less tissue reaction, and were less likely to become obstructed. Most of the shunts currently encountered and used are made from this material. VP shunts also need fewer revisions for growth, since excess shunt tubing can be placed in the peritoneal cavity.

**Indications and Contraindications**

A shunt assessment, which includes physical and radiographic examination, is warranted for a myriad of patient presentations. The leading cause of shunt malfunction is mechanical failure resulting in obstructed CSF outflow. Closed fontanelles associated with sudden CSF obstruction may lead to rapid deterioration, herniation, and death. More commonly, patients have partial CSF obstruction with less dramatic symptoms. Signs and symptoms include headache; vomiting; increase in seizure frequency;

lethargy; ataxia; coma; and, for young children or infants, a change in level of activity, head size, feeding, consolability, or the presence of a full fontanelle. Presence of papilledema has been reported to occur in less than 2% of patients. [33] These symptoms may be slowly progressive over several days.

Unfortunately, these presentations are often vague and similar to many less serious conditions. The emergency physician must be aggressive in considering a shunt-related problem in any shunted patient. An understanding of the variety of shunt types and mechanisms is necessary for a safe evaluation. Shunt malfunction may be due to obstruction, disconnection, migration, equipment failure, or a variety of complications unique to the distal or proximal catheter.

## Technique

Identification of the shunt type and its components is a necessary and often difficult step in assessment. A great number of shunting systems are in use; the VP shunt is the most common encountered in clinical practice (Fig. 64-5) (Figure Not Available) . The similarity of different shunt systems should prompt a review of the patient's past medical record, operative note, and the patient's or parent's knowledge of the shunt implanted.

### Radiographic Survey: Plain Films and CT

Assessment includes a radiographic survey of the entire shunt length and may aid in shunt identification. One film may be sufficient for small children, but older patients and adults require an anteroposterior (AP)/lateral skull, chest, and supine abdominal radiographs (Figs. 64-6 through 64-9 ). Catheters are made of silicon, have a 2- to 3-mm outside diameter, and have at least 1 type of radiopaque component. Some are barium impregnated throughout, and some have radiopaque tantalum dots a fixed distance apart. Less common are catheters with metal springs fixed throughout their length and catheters with tantalum dots only at their end points (Fig. 64-10) . The ventricular catheter has multiple tip perforations to allow flow of CSF and may have flanges to decrease obstruction (Fig. 64-11) (Figure Not Available) . The distal catheter may be open or closed with slit valves (Fig. 64-12) . The slit valves are used as the sole device for flow regulation in simple systems and as adjuncts in systems with other unidirectional components. They are classified as low, medium, and high pressure to describe their variable opening pressures. The metal parts of some systems will also be visible on radiographic assessment.

Radiographic assessment of shunt malfunction includes attention to disconnection, which may occur at any point in the system. Sites of connection (Fig. 64-13) and mobility, such as the lateral neck, are at increased risk. Some portions of shunts, such as certain valves, connectors, or parts of the tubing itself, may be radiolucent and appear as disconnections. Comparison with older radiographs and a thorough knowledge of the shunt components will help avoid this erroneous conclusion. [34] Older shunts may undergo mineralization and biodegradation and become fixed by fibrous tissue. They are at greater risk for breakage. [35] The distal catheter may migrate to a wide variety of sites, [36] generally into the peritoneal cavity (Figs. 64-14 through 64-17 ). Distal catheter retraction from out of the peritoneal cavity may occur due to patient

growth.

Cranial CT scans are an important component of shunt assessment. The ventricular tips of most shunts are placed in the frontal horn of a lateral ventricle, anterior to the foramen of Monro. They generally exit through a posterior parietal burr hole, although a frontal approach is sometimes used. [37] CT may confirm appropriate shunt placement and help rule out hematoma or enlarging tumor. An increase in ventricular size (Figs. 64-18 and 64-19) or blurring of the ventricular margins suggests obstruction, although older scans from the patient may be necessary to determine a baseline ventricular size. In 1 series, 87% of patients with ventricles that were enlarged compared with prior scans had shunt malfunction, while 93% of patients with small or normal ventricles had normal shunt function. [38] However, this implies that a CT scan can sometimes appear normal or unchanged in the presence of shunt malfunction and high ICP. If a baseline CT scan is unavailable, a bicaudate distance of greater than one sixth of the brain diameter is suggestive of enlargement. [38] Other serious signs include mass effect and obliteration of the perimesencephalic cistern.

Slit-ventricle syndrome is the association of episodic signs and symptoms of raised ICP with small or slit-like ventricles. It is uncommon and occurs in only 1% to 3% of shunted children. [39]

**Shunt Identification**

Identification and further assessment may be simplified by considering the shunt as a 3-component system: a ventricular catheter, a shunting device, and a distal catheter leading to the receiving site. [31] The shunting device may consist of 1 or more components, including a reservoir, valve, filter, anti-siphon device, and pump. Older systems likely consist of a distal flow valve only. The need for cerebral flushing and instillation of drugs prompted the addition of reservoirs and double-lumen domes. These components may be attached together by nylon or metal connectors or come integrated in a single device.

A *reservoir* is a device that allows physician access to CSF or the injection of medications. [40] *Valves* are unidirectional components that regulate flow and prevent reflux. *Filters* are less common; they are used to prevent the transfer of cells to the ventricles when neoplasm is suspected or known. An *anti-siphon device* closes under negative distal pressure to negate the siphon effect and possible overdrainage associated with the upright position. The *pump* describes any shunt part that can be used to determine shunt patency or to manually move CSF through the catheter. The shunt may be a separate component with bidirectional flow or a function of the reservoir or valve unit. An easy way of classifying shunts is to consider whether the pumping chamber is a "dome" or "cylinder." [42]

**Dome devices.**

Dome devices are manufactured in many configurations and may serve as a pumping chamber, access chamber, valve, or a combination of these functions. They may lie partially over or in a burr hole, or they may be placed in close proximity to it. Some may

be used as a ventriculostomy only and have no palpable distal catheter. Most, however, are an integral part of a complete shunt system.

A classic dome device is the Pudenz flushing valve (American Heyer-Schulte, Santa Barbara). It has a valve diaphragm over the ventricular end of the catheter and can be used as a pump and a reservoir. It is surgically placed into a burr hole so that only the reservoir protrudes above the skin and can be palpated (Fig. 64-20) (Figure Not Available) .

Dome-shaped reservoirs without valves can be placed separately for a simple ventriculostomy or combined with a cylindrical valve device for use as a shunt. They were originally developed to allow drug instillation and for periodic relief of increased ICP. [40] Examples are the Rickham reservoir, the cerebral catheter reservoir, and the Ommaya reservoir (American Heyer-Schulte, Santa Barbara). The Rickham reservoir (Fig. 64-21) has a stainless steel funnel that protrudes into the burr hole and is covered with a silicon dome. It may be used alone or, more commonly, in combination with a palpable cylindrical shunt valve placed distal to the reservoir. The cerebral catheter reservoir is a 1-piece silicon reservoir and catheter (Fig. 64-22) . It can serve as a simple ventriculostomy, or it can be used in combination with a distal valve and serve as the proximal portion of a shunt. The larger Ommaya (Fig. 64-23) (Figure Not Available) is a 1-piece silicon device used as a ventriculostomy, or, with a side arm, for continuous shunting. All 3 of these reservoirs may be confused with the Pudenz valve.

Other dome devices may be placed near, but not over, the burr hole. Examples include Delta valves and CSF flow control valves (Pudenz-Schulte Medical Corporation, Goleta, Calif). The tantalum markings on these domes (Figs. 64-24 (Figure Not Available) and 64-25) (Figure Not Available) indicate flow direction and opening pressures. The Delta valve serves to maintain a near-constant pressure gradient, regardless of patient position. It incorporates a device that automatically adjusts for the hydrostatic pressure difference between the ventricles and the peritoneal cavity. [43]

The Accu-Flo system (Codman and Shurtleff, Inc., Randolph, Mass) includes 4 types of reservoirs made from 1-piece silicon with polypropylene bases. It includes both single domes and double domes (Fig. 64-26) .

One of the least complex systems is the Uni-Shunt (Codman and Shurtleff, Inc., Randolph, Mass), which is a continuous catheter from the ventricular end to the distal slit valve (Fig. 64-27) . Since it has no connectors, it is less prone to disconnection. It is barium impregnated throughout. The Uni-Shunt is manufactured with or without a double-dome reservoir for pumping and CSF access (Fig. 64-28) . The catheter's distal slit valves serve to regulate flow.

The Multi-Purpose Valve (American Heyer-Schulte) incorporates an on-off device that is controlled percutaneously. [42] Its single unit includes a proximal occluder, dome reservoir, on-off switch, and an anti-siphon device.

Anti-siphon devices (Fig. 64-29) (Figure Not Available) may also be found as separate units. [44] They have both flat and round components and have a thin membrane

covering their dome. Shunt filters (see Fig. 64-22) are silicon cased and designed to prevent transfer of cells. They may be used when malignancy is known or suspected. In this case, they are commonly placed just behind the mastoid air cells in order to be exposed to radiotherapy.

**Cylinder devices.**

Cylinders are of variable sizes and since 1970 have been placed distal to a reservoir. Prior to this, reservoirs were rarely attached. [42]

The Holter valve system (Codman and Shurtleff, Inc., Randolph, Mass) incorporates 2 silicone slit valves encased in stainless steel bodies. The bodies are connected by a silicone tube that serves as the pumping chamber (see Fig. 64-21 and Fig. 64-30) (Figure Not Available) . It is commonly placed just distal to a Rickham reservoir.

The Denver shunt (Codman and Shurtleff, Inc., Randolph, Mass) incorporates a Rickham reservoir with a valved cylindrical pump. It is manufactured as 1 inseparable unit (Fig. 64-31) or with the reservoir and pump as separate units.

The Hakim shunt (Cordis Corporation, Miami) incorporates a cylindrical valve unit with a rectangular reservoir (Fig. 64-32) (Figure Not Available) . The reservoir includes a metal plate visible on radiographs. It is longer and thinner than the Holter.

**Shunt Palpation**

Continuity of a shunt may be assessed by palpation throughout its length. Most shunts are placed through posterior parietal burr holes, although a few are placed in the frontal area. The feel of the reservoir or pump may assist in identifying the shunt type.

Disconnections may be suspected by palpation. However, fibrous tracts may feel, and even perform, like shunt tubing. Single-dome devices may be difficult to palpate due to fibrous or bony encasement. Hardening of the plastic after placement has also been described. [45]

**Assessing Shunt Patency**

Patency of a single-dome device may be determined with transcutaneous digital pressure. An understanding of how CSF may flow through a particular system is necessary to interpret the results.

A valveless dome (e.g., Ommaya or Rickham without an attached Holter valve) is usually attached to a distal catheter with slit valves. Easy depression of the dome while occluding the distal catheter suggests proximal patency, whereas difficult depression suggests a proximal obstruction. Lack of prompt refilling suggests poor CSF flow toward the dome. If distal occlusion is not held, CSF will flow both proximally and distally through the path of least resistance. [42] In this case, a firm, noncompressible dome

suggests both proximal and distal occlusion.

For a dome with a valve (e.g., Pudenz), lack of easy depression suggests distal obstruction, and lack of prompt refilling suggests proximal obstruction. For double domes (e.g., Uni-Shunt with reservoir, Accu-Flo), while digital occlusive pressure is held over the proximal dome, easy distal dome pumping implies distal patency. After applying digital occlusive pressure over the distal dome, prompt refilling of the proximal dome when pressure is released implies proximal patency. The multipurpose valve contains an on-off switch composed of a silicon dome containing a tantalum-impregnated ball. Digital pressure over the dome forces the ball into a cup at the dome's base and prevents distal flow. The valve can be reopened by applying pressure over the proximal occluder and pumping the reservoir. Patency is determined by applying pressure over the proximal occluder and then pressing on the reservoir. Prompt emptying suggests distal patency. When releasing pressure off the occluder, prompt refilling suggests proximal patency.

Cylinder devices (e.g., Holter, Hakim) are tested by digital pressure on the tube. Difficult depression suggests distal obstruction, while delayed filling suggests proximal obstruction.

Acute obstruction with deterioration is a neurosurgical emergency. The role of the emergency physician consists of diagnosis, supportive care, and consultation. Forced pumping may be attempted but provides only temporary relief in a minority of cases. [31] [37]

Anti-siphon devices and filters are not designed for pumping or determination of shunt patency.

### Complications

Pumping of the shunt should not be done repeatedly unless forward flow of CSF is desired for therapeutic purposes. Repeated pumping may lead to breakage of the shunt or shunt mechanism, as well as the possibility of pumping CSF retrograde into the ventricle. Not all shunt obstructions may be determined by simple digital pressure or a normally functioning pumping chamber. However, information on this maneuver is an important component of overall shunt assessment.

## CULTURING INTRACRANIAL SHUNTS

The second most common cause of shunt malfunction is infection, which unfortunately carries a 30% to 40% mortality rate. [46] Reported incidence rates vary widely, from 2.6% to 38%, with an average of 8% to 10%. VA shunts have a slightly higher rate of infection, approximately 15%. [51]

Shunt infection is generally considered a complication of surgery, since 70% are diagnosed within the first month after surgery and 90% within 6 months. Because of this, there may be reluctance to associate minor signs and symptoms of shunt infection

with actual infection after 6 months. A variety of operative antibiotic regimens, accessory equipment, and surgical techniques have been explored to prevent shunt infection. [52]

Increased infection rates have been reported for patients with Dandy-Walker syndrome, aqueductal stenosis, or encephaloceles [46] ; premature infants [53] ; newborns, as compared with adults [54] ; patients with successive shunt revisions or taps; and those who have undergone laparotomy. Transient bacteremia has not been shown to cause shunt infection. [55]

Shunt infections may be internal, describing colonization on the inner surface of the shunt with or without ventriculitis. External shunt infections describe wound infections around the shunt secondary to the operation or erosion of the overlying skin. Infection may follow perforation of the abdominal contents by the distal catheter.

Coagulase-negative staphylococci are responsible for the majority of internal shunt infections; *Staphylococcus epidermidis* is the most common organism. Almost every other bacterial species has reportedly caused infection at one time, although *Staphylococcus aureus*, diphtheroids, gram-negative enterics, and *Candida* are more frequently noted. Infections resulting from *Haemophilus, Streptococcus pneumoniae* (pneumococcus), and *Neisseria meningitidis* (meningococcus) typically present late. It has been suggested that these infections often are not shunt related but probably represent meningitis in a patient who happens to have a shunt. [56]

**Indications and Contraindications**

Unfortunately, the clinical presentation of a shunt infection is nonspecific. Fever, change in sensorium, emesis, abdominal pain, diarrhea, peritonitis, irritability, and signs of shunt malfunction predominate. Meningeal signs are present in only 25% to 33% of patients. Local shunt tract inflammation may occasionally occur. [58] VA shunts may be complicated by septic emboli or shunt nephritis. [59] In addition, patients with infected VA shunts may remain apparently well for months before symptoms of septicemia become apparent. In contrast, VP shunt infections rarely present after 6 months. Often patients with VP shunt infections present with symptoms attributable to distal shunt obstruction caused by infected CSF being discharged into the peritoneal cavity and forming a cyst or adhering to omentum. [60] One series described 23 patients with gram-negative VP shunt infections as appearing relatively well at presentation. [61] Of these infections, 87% occurred within 4 weeks of shunt placement or revision, and the most common symptoms were fever, lethargy, and irritability.

In the unfortunate event that a shunt needs to be tapped but has no reservoir for access (e.g., Uni-Shunt), a lumbar puncture can be performed. However, this procedure may not be diagnostic for ventriculitis or infection confined to the shunt--that is, CSF from a lumbar puncture is frequently normal in the early stages. [50] The patient without a shunt access site is rarely encountered in current practice.

Because shunt tapping may introduce organisms into the central nervous system, contraindications include inexperience with the procedure and infection overlying the tap site. It is prudent to discuss the indications for the procedure with the patient's

neurosurgeon before initiating the procedure.

## Equipment

All equipment should be set up and sterilely prepared before initiating the procedure. A 25-ga needle, commonly a butterfly, is used to perform the actual puncture. Other equipment needed includes gloves, preparation and drape, anesthesia, an 18-ga needle to nick the scalp, a CSF manometer, and CSF collection tubes. The standard lumbar puncture tray could be used, with the addition of the appropriate needles.

## Technique

After the procedure is discussed with the patient (and parents, when appropriate), written informed consent is desirable. The procedure should not be particularly painful, although the sting of local anesthesia needs to be addressed.

Determine the appropriate reservoir site by palpation and radiographic assessment. *Do not puncture anti-siphon devices, filters, and Holter or Hakim valves.*

Place the patient prone and restrain him or her, if needed. Shave the scalp, if necessary, overlying the device. Meticulous attention should be paid to a standard sterile preparation and drape technique. When povidone-iodine is used for skin preparation, give the solution time to fully dry (1 to 2 minutes) to maximize its bactericidal effect. Provide anesthesia at the site with an appropriate local anesthetic. Some may elect to omit anesthesia, since its application may be as uncomfortable as the actual tap.

Nick the scalp with an 18-ga sterile needle. Puncture the reservoir with a short 25-ga butterfly needle (Fig. 64-33) . The angle of puncture should be approximately 25° to 30° to avoid placing the needle too deep and potentially damaging the reservoir floor. Many reservoirs have silicon or metal needle guards to avoid this problem. An exception is the Hakim reservoir, which may be entered at almost any angle. [31]

Watch for passive appearance of fluid, attach the manometer, and record the pressure obtained. Allow only passive withdrawal of 4 to 6 mL of CSF. Place the CSF in sterile tubes, and send for standard CSF analysis. Cell count with differential, protein and glucose levels, culture, and Gram stain are routinely desired. Other studies may be appropriate in specific clinical circumstances (see Chapter 65) .

## Complications

Puncturing anti-siphon devices, filters, and Holter or Hakim valves may result in damage to or leakage of the shunt; these structures are not designed for sampling. Infection may be introduced by the tap itself. Since this may result in increased morbidity or mortality, a thorough sterile preparation and drape is emphasized.

**Interpretation**

Assessment of CSF studies should follow standard practice (see Chapter 65) . Shunt-aspirated CSF has a reported culture sensitivity that ranges from 62% to nearly 100%.  Data on the sensitivity of the Gram stain are lacking, although generally the association with infection is considered high. [63] In 1 study, shunt-obtained CSF glucose and protein were abnormal in 18% and 66% of cases, respectively. [63] Abnormal cell counts, defined as >2 neutrophils or >10 total white blood cells per milliliter, were present in 65% of infected cases. [63] Administration of antibiotics prior to the procedure will decrease culture sensitivity.

## CONCLUSION

Increased ICP may be manifested in many ways. If unrecognized and untreated, it may lead to brain death through cerebral hypoxia or direct tissue damage. The emergency physician has several techniques to combat this problem while awaiting definitive neurosurgical treatment.

Intracranial shunts and care of shunt patients continue to improve. Emergency physicians can expect more of these patients to present with problems possibly attributable to this life-saving device. The treating physician needs to be adept at basic shunt identification, assessment of patency, and CSF sampling.

# Chapter 65 - Spinal Puncture and Cerebrospinal Fluid Examination

**Jon C. Kooiker**

Cerebrospinal fluid (CSF) examination is performed in an emergency setting for the purpose of obtaining information relevant to the diagnosis and treatment of specific disease entities. Many urgent and life-threatening conditions require immediate and accurate knowledge of the nature of the CSF. However, certain harmful consequences may result from a spinal puncture. The procedure should follow a careful neurologic examination with thought given to the risks and merits of the procedure in each given situation.

In 1885, Corning punctured the subarachnoid space to introduce cocaine anesthesia into a living patient. [1] Quincke (1891) first removed CSF in a diagnostic study and introduced the use of a stylet. [2] He studied cellular contents and measured protein and glucose levels. Quincke was also the first to record pressure with a manometer. Subsequently, increasingly sophisticated bacteriologic, biochemical, cytologic, and serologic techniques were introduced. In 1918, Dandy replaced CSF with air to determine normal brain anatomy and changes that would indicate disease. [3] Water-soluble contrast media have been used to delineate the spinal subarachnoid space and cerebral cisterns. Other uses of the spinal puncture include injection of anesthetic agents, chemotherapeutic agents, and antibiotics and drainage of fluids.

## ANATOMY OF CSF FORMATION AND CIRCULATION

In the adult, approximately 140 mL of the spinal and cranial cavities is occupied by CSF, with approximately 30 mL in the spinal canal. This volume is the result of a balance between continuous secretion (primarily by the ventricular choroid plexus) and absorption into the venous system (chiefly by way of the arachnoid villi). After formation, the fluid passes out of the ventricles by way of the midline dorsal foramen of Luschka and the lateral ventral foramina of Magendie. The fluid then flows into the spinal subarachnoid space, the basilar cisterns, and the cerebral subarachnoid space. Production is approximately 0.35 mL/min, and CSF ventricular production is such that there is a net flow out of the ventricles of 50 to 100 mL/day. Thus the usual volume of CSF removed at lumbar puncture is regenerated in 1 hour.

Cerebrospinal fluid may have an embryologic nutritive function; at maturity the CSF most likely acts as a mechanical barrier between the soft brain and the rigid fibro-osseous dura, skull, and vertebral column. It also appears to support the weight of the brain. [4] When buoyed by CSF, the functional brain weight is reduced from 1400 to 50 g. Contraction and expansion of the CSF may accommodate changes in brain volume. Additional functions, including intracerebral transport and maintenance of a stable chemical environment of the central nervous system (CNS), have been reviewed by Fishman.

## INDICATIONS FOR SPINAL PUNCTURE

In recent years, the indications for spinal puncture have been reduced with the introduction of new noninvasive diagnostic procedures--magnetic resonance imaging (MRI) and computed transaxial tomography (CT). A few clinical situations require an early, or even an emergent, spinal puncture. The primary indication for an emergent spinal tap is the possibility of CNS infection, with the exception of brain abscess or a parameningeal process. The need for early detection of meningitis results in performance of many more lumbar punctures than ultimate diagnoses of infection. [6] No other method can be used to completely exclude the diagnosis of meningitis.

CSF generally should be examined for evidence of an infection in patients with a fever of unknown origin, especially if an alteration of consciousness or impaired immune system is present, even in the absence of meningeal irritation. *Meningeal signs need not be present in patients who are old, debilitated, immunosuppressed, or receiving anti-inflammatory drugs or who have had partial treatment with antibiotics.* In a newborn, even a fever is not a dependable sign; temperatures may be normal or even subnormal. A high index of suspicion is required when evaluating infants younger than 12 months of age. Approximately 25% of infants with meningitis will not have nuchal rigidity, but most will usually appear toxic or moribund. A tense and bulging fontanel is somewhat more reliable, although this sign may be absent in a dehydrated child. Neonatal meningitis occurs in 25% of sepsis cases. In addition, 15 to 20% of infants with meningitis will have negative blood cultures. [9] [10] In a child between the ages of 1 month and 3 years, fever, irritability, and vomiting are the most common symptoms of meningitis. Typically, handling is painful for the child, and the child cannot be comforted. In addition, the older child may complain of a headache. In all ages, the patient generally looks unusually ill and appears drowsy with a dulled sensorium.

Physical signs become more useful in diagnosing meningitis in children older than 3 years of age. [11] These include nuchal rigidity, Kernig's sign (efforts to extend the knee are resisted), and Brudzinski's sign (passive flexion of one hip causes the other leg to rise, and efforts to flex the neck make the knees come up). A useful aid in distinguishing neck rigidity of meningeal origin from that caused by primary pain in the cervical muscles and the soft tissues is the usual preservation of lateral movement in meningeal irritation. A petechial rash in a febrile child should also raise the possibility of *Neisseria* meningitis. [12] Prior use of antimicrobial agents may modify the clinical presentation and alter CSF findings; partially treated children are less likely to be febrile or exhibit an altered mental status.

The second indication for an emergent spinal puncture is a suspected spontaneous subarachnoid hemorrhage. The diagnosis will usually be made by head CT scan or by the finding of blood in the CSF. [13] CT sensitivity drops in patients presenting later than 24 hours after the event to 76% after 48 hours. From 20 to 60% of aneurysmal subarachnoid hemorrhage will have "sentinel thunderclap" or "warning leak" headache before a major hemorrhage. This consists of an unusual sudden headache without nuchal rigidity caused by a "minor" leak of blood from the aneurysm and may precede major rupture by 10 to 320 days. [14] [15] Surgical treatment before a major hemorrhage is

the goal of early clinical recognition. After a "warning leak," the head CT scan is usually negative, giving added importance to the performance of a lumbar puncture. Migraine or "vascular" headache is a common misdiagnosis in patients with a subarachnoid hemorrhage who have an initially negative head CT scan.

The usual clinical picture of a subarachnoid hemorrhage is a severe and instantaneous excruciating headache. Patients will usually recall the exact moment the headache occurred. The location of the headache is variable and does not give a clue as to the site of hemorrhage. Nausea, vomiting, and prostration are common symptoms, with approximately one third of patients becoming unconscious at the onset. Examination shows an acutely ill patient with irritability or overt altered mental status. Meningeal signs are commonly present at the time of the initial examination and usually develop in all cases within 2 to 3 days. Meningeal signs may become more severe during the first week after hemorrhage and correspond to the breakdown of blood in the CSF. During the first week, many patients are febrile, reflecting a chemical hemic meningitis. [16] Failure to detect blood radiographically in an awake patient may indicate a small hemorrhage or a predominant basal accumulation of blood. If a patient is seen several days after the hemorrhage, the blood may have become isodense with brain and may no longer be visible on a CT scan. The proper diagnosis would then require spinal puncture. Because 2 to 10% of acute subarachnoid hemorrhages will not be detected by the initial CT scan (even with modern third generation scanners), a lumbar puncture is appropriate to rule out the diagnosis with certainty. In theory, a small subarachnoid hemorrhage may take several hours to reach the lumbar region. Thus, it is possible that such a patient might have normal lumbar CSF if examined soon after rupture. A second, delayed lumbar puncture may occasionally be required for diagnosis in such a situation. If the neurologic picture demonstrates localizing findings, the presence of a large intracranial hematoma should be suspected, and spinal puncture is contraindicated until CT (or arteriography) delineates the nature of the lesion.

In a patient with suspected cerebral embolus or evolving infarction, either a negative CT scan or clear CSF should be obtained before the use of anticoagulants. This seems particularly applicable if neurologic deficits or an altered mental state persists. [21]

The emergency physician may be called on to perform a therapeutic lumbar puncture in the patient with known pseudotumor cerebri (idiopathic intracranial hypertension). The patient has elevated intracranial pressure (ICP), headache, and papilledema. The headache worsens with maneuvers that increase the ICP (e.g., Valsalva, squatting, bending, coughing). The symptomatic patient may have an ICP of 250 to 400 mm $H_2O$.

Other nonemergent reasons for CSF examination include evaluation of CNS syphilis, unexplained seizures, instillation of chemotherapy and positive contrast agents, evaluation of suspected demyelinating or inflammatory CNS process, and treatment of headache from subarachnoid hemorrhage or benign intracranial hypertension. [22] Carcinomatous meningitis and suspected spinal cord compression from metastatic disease may require spinal puncture for myelography and cytologic examination. The availability of MRI is a suitable alternative for identifying compressive myelopathies.

# CONTRAINDICATIONS FOR SPINAL PUNCTURE

Spinal puncture is absolutely contraindicated in the presence of infection in the tissues near the puncture site. [4] [5] Spinal puncture is relatively contraindicated in the presence of increased ICP from a space-occupying lesion. Caution is particularly advised when lateralizing signs (hemiparesis) or signs of uncal herniation (unilateral third nerve palsy with altered level of consciousness) are present. In such cases, a tentorial or cerebellar pressure cone may be precipitated or aggravated by the spinal puncture. Cardiorespiratory collapse, stupor, seizures, and sudden death may occur when pressure is reduced in the spinal canal. [22]

The risk of herniation seems to be particularly pronounced in patients with brain abscess. Brain abscesses frequently occur as expanding intracranial lesions with headache, mental disturbances, and focal neurologic signs rather than as infectious processes with signs of meningeal irritation. In 75% of cases, a primary source of chronic suppuration is present. Common predisposing causes of brain abscess include craniofacial trauma, craniocerebral trauma, penetrating injuries with bone fragments in brain, transmitted foreign objects or large animal bites of infant skulls, postneurosurgical procedures, cardiovascular disorders with right to left shunts, bacterial endocarditis, gram-negative sepsis in neonates, dental infections, chronic sinusitis, otitis, mastoiditis, chronic abdominal pulmonary or pelvic infections, bacterial meningitis, and immunosuppression. Infarcted brain tissue may develop abscesses in the presence of sepsis because of a compromised blood-brain barrier. [25] Although the CSF is usually abnormal (elevated pressure, elevated white blood cell count, and elevated protein concentration), spinal puncture in patients with a possible abscess is contraindicated in most cases. Five of Samson and Clark's 22 patients exhibited signs of midbrain compression within 2 hours of lumbar puncture. [24] Evidence of herniation markedly reduces the patient's chances for survival.

Brain abscess may spontaneously rupture into the ventricular system producing ventriculitis and meningitis. If the history suggests possible brain abscess, CT can rapidly diagnose and localize the lesion. [26] Because the appearance of brain abscesses on CT is similar to that of neoplastic and vascular lesions, false-positive reports of brain abscess may be encountered. [27]

Trauma to the dural or arachnoid vessels may create minor hemorrhage into the CSF. This generally is of little consequence. However, the number of patients with hemophilia and human immunodeficiency virus (HIV) infection who require lumbar puncture has increased in the past decade. Spinal epidural hematomas may occur but are rare complications of lumbar puncture in individuals receiving anticoagulant therapy or in patients with disease associated with abnormal clotting mechanisms, especially thrombocytopenia. Edelson and colleagues reviewed over 100 cases of spinal epidural hematoma; approximately one third were associated with anticoagulant therapy. [28] Most articles describe isolated cases. Spinal subdural hematomas after lumbar puncture are even more rare than epidural hematomas. When a patient is anticoagulated or has a coagulopathy, the tap should be performed by experienced physicians, who are less likely to traumatize the dura. The patient should be carefully

followed for progressive back pain, lower extremity motor and sensory deficits, and sphincter impairment after the procedure. *Complaints of motor weakness, sensory loss, or incontinence after lumbar puncture should be thoroughly investigated.* Lumbar puncture may be performed in the presence of a coagulation defect if the procedure is expected to provide essential information, such as in the diagnosis of meningitis. In cases of severe thrombocytopenia, the infusion of platelets before the lumbar puncture may be desirable.

The infusion of clotting factors in the hemophiliac patient and normalization of the prothrombin time with fresh frozen plasma in the anticoagulated patient are desirable if the clinical situation permits such delay before performing a lumbar puncture. Because as many as 90% of patients with severe hemophilia are seropositive for HIV, the issue of performing a lumbar puncture in patients with coagulopathies is an increasingly common phenomenon. Silverman and colleagues [31] have demonstrated the safety of lumbar puncture in patients with hemophilia A or B who had their deficit clotting factor replaced before the procedure. In their series of 33 patients (30 with <1% normal factor level) who underwent a total of 52 spinal taps after specific factor replacement, no serious procedure-related complications were identified. Their protocol was to attain an immediate postinfusion factor level between 5% and 100%. Use of additional factor replacement after lumbar puncture is of unknown value.

If the history and physical examination suggest a treatable illness, such as meningitis or subarachnoid hemorrhage, then the physician may perform a spinal puncture after careful consideration of the entire clinical picture. In all cases, the study should be undertaken after careful thought regarding how the results will assist in patient evaluation and treatment. It is unlikely that the spinal puncture will beneficially alter management in the presence of a neoplasm, a cranial hematoma, an abscess, a completed nonembolic infarction, or cranial trauma.

## EQUIPMENT

Standard equipment to be assembled before a spinal puncture include spinal needles (generally 22 ga or smaller bore and up to 32 in. in length--longer needles may be needed for some obese patients); three-way stopcock; manometer; connecting tubing (optional, to connect needle with stopcock and manometer); 4 specimen tubes; local anesthetic; syringes and needles for local anesthesia (appropriate for both skin and subcutaneous tissue infiltration); sterile drapes, gauze, sponges, and gloves; and an antiseptic solution for skin preparation (e.g., 0.5% chlorhexidine in alcohol or 1% povidone-iodine). [32]

Some operators prefer to use an "atraumatic standard Sprotte needle" to minimize the dural injury associated with needle passage. These styletted needles (Havel's Inc., Cincinnati) have a side port for fluid withdrawal and theoretically are more likely to *separate* rather than core the dural tissue.

Although commercial kits provide most of the items (Fig. 65-1) (Figure Not Available) , it is important for the operator to bring additional supplies, including supplemental spinal needles, gauze and antiseptic solution, additional local anesthesia and

needles/syringes, and extra sterile gloves of the appropriate size. Following this advice will minimize procedural interruptions when material on the commercial kit must be supplemented.

## TECHNIQUE

Lumbar puncture is carried out with the patient in the lateral recumbent position. A line connecting the posterior-superior iliac crests will intersect the midline at approximately the L4 spinous process (Fig. 65-2) (Figure Not Available) . Spinal needles entering the subarachnoid space at this point are well below the termination of the spinal cord, and the only important neurologic structure is the cauda equina. Generally, the needle will push isolated nerves to the side during advancement. The adjacent interspace above or below may be used, depending on which area appears to be most open to palpation. The space between lumbar vertebrae is relatively wide. In the thoracic region, the spinous processes overlap and are directed caudad, and therefore there is no midline area free of overlying bone. In the adult, the spinal cord extends to the lower level of L1 or the body of L2 in 31% of persons, thus eliminating higher levels as sites for puncture. The puncture in adults and in older children may be performed from the L2 to L3 interspace to the L5 to S1 interspace. Developmentally, the spinal canal and the spinal cord are of equal length in the fetus. Growth of the cord does not keep pace with longitudinal growth of the spinal canal. At birth, the cord ends at the level of the L3 vertebra. The needle in infants should be placed at the L4 to L5 or L5 to S1 interspaces. The subarachnoid space extends to an S2 vertebral level; however, the overlying bony mass prevents entry into this lowermost portion of the subarachnoid space.

Almost all patients are afraid of a spinal puncture because they have heard stories of severe complications. Explaining the procedure in advance and discussing each step during the course of the test aids in reducing patient tension and helps the physician. The physician should inquire about history of allergies to local anesthetic agents and topical antiseptics. A standard informed consent form or detailed procedural note is recommended to document the process of patient/guardian education regarding the indications, procedural techniques, risks/benefits and alternatives to the procedure, and the patient/guardian's assent to the procedure.  This step may need to be abridged when the patient is critically ill or eliminated when the patient is mentally incapacitated and no guardian is present. In anxious patients, a benzodiazepine agent (orally or parenterally; e.g., midazolam, 0.05 to 0.075 mg/kg IV) will facilitate the procedure.

The next important step is positioning of the patient. Generally the procedure is performed in the lateral decubitus position in older children and adults. The patient is given a pillow to keep the head in the same plane as the vertebral axis. The shoulders and the hips are positioned perpendicular with the table. A firm table or bed is desirable whenever possible. Flexion of the neck does *not* facilitate the procedure to any great extent; and because severe flexion may add to the patient's discomfort, this step may be omitted. The patient's lower back should be arched toward the physician. Some physicians place the patient in an upright sitting position, because the midline is more easily identified when the patient is sitting. The higher CSF hydrostatic pressure in a sitting, dehydrated patient may aid CSF flow. Caution regarding orthostatic blood pressure changes and airway maintenance must be observed when the patient is sitting

for the procedure. Generally the sitting patient is allowed to lean onto a bedside stand using a pillow to rest the head and arms. An assistant also must help support the patient during the procedure.

Sterile gloves must be used. The examiner should wash the patient's back with an antiseptic solution applied in a circular motion. The circumference of the cleansed area should increase with each motion. A povidone-iodine solution will decrease skin flora to a bacterial count of 0 to 2 bacteria/sq in. [33] Friction during skin preparation helps remove loose debris. The patient should be warned that the solution will be cold. The excess fluid is removed with a dry sterile gauze pad. A sterile towel is placed between the patient's hip and the bed. Commercial trays have a second sterile drape with a hole that may be centered over the site selected for the tap.

The skin and deeper subcutaneous tissue are infiltrated with local anesthetic (1% lidocaine). Buffered or warmed lidocaine is preferred (see Chapter 31) . The patient should be warned about transient discomfort from the anesthetic. Anesthetizing the deeper subcutaneous tissue significantly reduces the procedural discomfort. Merely raising a skin wheal is insufficient anesthesia. Some operators not only anesthetize the interspinous ligament but also apply local anesthesia in a vertically fanning distribution on both sides of the spinous processes near the lamina. This field block on each side of the spinous processes anesthetizes the recurrent spinal nerves that innervate the interspinous ligaments and muscles.

While waiting for the anesthetic to take effect, the physician should attach the stopcock and manometer and see that the valve is working. A 3.5-in., 20-ga needle should be used in adults, and a 2.5-in., 22-ga needle should be used in children (a 1.5-in., 22-ga needle is available for infants). A needle of this size has enough rigidity to allow the procedure to be accomplished easily but makes less of a dural tear than do larger instruments. The patient should be told to report any pain and should be informed that he or she will feel some pressure.

The needle is placed into the skin in the midline parallel to the bed. The needle is held between both thumbs and index fingers. After the subcutaneous tissue has been penetrated, the needle is angled toward the umbilicus. The bevel of the needle should be facing laterally. It has been speculated that pointing the bevel laterally may allow the needle to separate the transverse fibers of the dura rather than cut through them, allowing for less CSF leakage after the needle has been withdrawn.

The supraspinal ligament connects the spinous process; the interspinal ligaments join the inferior and superior borders of adjacent spinous processes. The ligamentum flavum is a strong, elastic, yellow membrane that may reach a thickness of 1 cm in the lumbar region. The ligamentum flavum covers the interlaminar space between the vertebrae and functions to assist the paraspinous muscles in maintaining an upright posture (Fig. 65-3) (Figure Not Available) . The ligaments are stretched in a flexed position and are more easily crossed by the needle. The ligaments offer resistance to the needle, and a "pop" is often felt as they are penetrated. One should remove the stylet frequently to see if the subarachnoid space has been reached. The "pop" is occasionally not felt with the

very sharp needles contained in disposable trays.

If bone is encountered, the needle must be partially withdrawn to the subcutaneous tissue. The physician should repalpate the back and ascertain that the needle is in the midline. If bone is again encountered, the needle should be slightly withdrawn and re-angled, with the point placed so that it angles more sharply cephalad. This should avoid hitting the inferior spinous process.

Clear fluid will flow from the needle when the subarachnoid space has been penetrated. The physician should attach the manometer and record the opening pressure. Pressure readings are only valid if taken with the patient in the lateral decubitus position. A three-way stopcock is supplied in disposable trays; this allows both collection and pressure to be measured by a single needle (Fig. 65-4) (Figure Not Available) . Positioning of the manometer is often more convenient if an extension tube (provided with most disposable trays) connects the needle hub to the stopcock, which is in turn attached to the manometer. The manometer should be positioned so that the "zero" mark is at the level of the spinal needle. The patient is then asked to relax and to extend his or her legs to decrease intra-abdominal pressure. The fluid column is observed for phasic changes with respirations and arterial pulsations. This ensures placement in the subarachnoid space. If the needle is against a nerve root or is only partially within the dura, the pressure may be falsely low, and respiratory excursions will not be seen in the manometer. Minor rotation of the needle may solve these problems. Hyperventilation to relax the patient should not be attempted, because this will reduce the pressure readings owing to hypocapnia and resultant cerebral vasoconstriction.

After measuring the pressure, the physician should turn the stopcock and collect enough fluid to perform all desired studies. Even if the pressure is elevated, sufficient fluid should be removed for performance of all indicated studies, because the risk of the procedure involves the dural rent and not the amount of fluid initially removed. Presumably, more fluid will be lost subsequently through the hole in the dura. A dressing is placed over the puncture site. Commercial trays supply 4 specimen tubes. Tube 1 is used for determining protein and glucose levels and for electrophoretic studies; tube 2 is used for microbiologic and cytologic studies; tube 3 is for cell counts and serologic tests for syphilis. In the presence of bloody CSF, cell counts should be performed in tubes 1 and 3 to help differentiate traumatic taps. One may compare water placed in tube 4 with CSF in tube 3 to detect cloudiness or discoloration. Alternatively, tube 4 can be stored under refrigeration in the laboratory for subsequent studies.

Traumatic taps can be avoided by proper patient and needle positioning. A traumatic tap most commonly occurs when the subarachnoid space is transfixed at the entrance of the ventral epidural space, where the venous plexus is heavier. A plexus of veins forms a ring around the cord, and these veins may be entered if the needle is advanced too far ventrally or is directed laterally (Fig. 65-5) (Figure Not Available) . If blood is encountered and the fluid does not clear, the procedure should be repeated at a higher interspace with a fresh needle. A traumatic tap, per se, is not a particularly dangerous problem in the patient with normal coagulation, and no specific precautions are needed if blood-tinged fluid is obtained. However, observation for signs of cord or spinal nerve

compression from a developing hematoma should be routine for these patients.

**Lateral Approach in Lumbar Puncture**

The supraspinal ligament may be calcified in older persons, making a midline perforation difficult. A calcified ligament may deflect the needle. In this case, a slightly lateral approach may be used. As the lower lamina rises upward from the midline, the needle is directed slightly cephalad to miss the lamina and slightly medially to compensate for the lateral approach. The needle passes through the skin, superficial fascia, fat, the dense posterior layer of thoracolumbar fascia, and the erector spinae muscles. The needle then penetrates the ligamentum flavum (bypassing the supraspinal and interspinal ligaments), the epidural space, and the dura before CSF is obtained (Fig. 65-6) (Figure Not Available) .

**Cisternal Puncture**

In situations in which lumbar puncture is contraindicated (such as local infection or acute trauma to the lumbar spine), cisternal, or suboccipital, puncture is the usual alternative. Technical problems, such as morbid obesity, cord tumor, arachnoiditis, bony deformities, or prior spinal surgery (fusion), may make lumbar puncture impossible. Contrast material may be injected into the cisterna magna to identify the rostral extent of an obstructing lesion identified by lumbar myelography.

The patient is cleaned and anesthetized in a manner similar to that for a lumbar puncture after the neck has been shaved from the external occipital protuberance to the mastoid process laterally. The patient is preferably placed in a lateral decubitus position, but a sitting position can be used. A pillow is placed under the head to keep the neck and the vertebral axis in the same plane. The patient's neck is flexed to the chest. The spinal needle is placed in the midline halfway between the spinous process of C2 and the inferior occiput. The needle is angled cephalad through the subcutaneous tissue until it comes in contact with the bony occiput. The needle is then withdrawn and subsequently advanced at a less acute angle with the horizontal plane of the cervical spine. This is repeated until the dural "pop" is felt. As in the lumbar region, the stylet should be removed frequently so that the dura is not punctured unknowingly. Fluid is removed in the usual manner. Dural veins are less extensive, and bloody taps are less common. Low-pressure headaches are less common, presumably because the subarachnoid pressure is lower and the dural tear can heal faster.

**Lateral Cervical Puncture**

The patient is placed in a supine position and fully sterilized and anesthetized. A 20-ga lumbar puncture needle is inserted perpendicular to the neck and parallel to the bed. The landmark for insertion is a point 1 cm inferior and 1 cm dorsal to the mastoid process. The physician frequently removes the stylet to check for fluid return and, as at other sites, advances the needle slowly. If the needle goes too deeply and encounters paraspinous muscles, it is probably too deep posteriorly and should be repositioned more anteriorly. If bone is encountered, more dorsal placement is needed. Pressure and

fluid samples are collected, as in other sites. [34]

The contraindications to cisternal and cervical punctures are the same as those to lumbar puncture. Both techniques are easily mastered, but prior demonstration of the procedure by an experienced neurologist or neurosurgeon is advised. When lumbar puncture cannot be performed for technical reasons and meningitis is suspected, then placement of the needle under fluoroscopy may help obtain CSF.

**Lumbar Puncture in Infants**

Lumbar puncture in infants is usually performed to exclude meningitis. The sitting position may allow the midline to be more easily identified. Some authors use a nonstyleted needle in small infants, because this device allows the pressure to be estimated as the needle punctures the dura. [35] However, the failure to use a stylet may be the source of later development of an intraspinal epidermoid tumor. [36] A technique of lumbar puncture in the neonate using a butterfly infusion set needle has been described as a simplified procedure that may be useful in the squirming or hyperactive patient. [35]

If the child's neck is very tightly flexed, CSF may not be obtained. However, if the head is held in midflexion, CSF usually flows briskly. Prolonged severe flexion of the neck in an infant should be avoided because it may produce dangerous airway obstruction; the airway should be checked if the infant suddenly stops crying. [37] Incorrect positioning usually results in multiple punctures and a bloody tap. If CSF fails to flow, gentle suction with a 1.0-mL syringe may be used to exclude a low-pressure syndrome. Pressure readings are inaccurate in the struggling child and hence not commonly measured in infants or young children. Positioning is very important in the infant and is best accomplished by an assistant, who maintains the spine maximally flexed by partially overlying the child and holding him or her behind the shoulders and the knees. The infant has poor neck control; hence, the assistant must also ensure that the child maintains an open airway.

Newborn and preterm infants may experience significant hypoxia during lumbar puncture with clinical deterioration; a sitting position appears preferable. [38] Lumbar puncture in infants with respiratory distress syndrome may cause greater risk than benefit. [39] This is a problem primarily in neonates but may occur in younger infants with sepsis. Gleason and coworkers [40] demonstrated that performing a lumbar puncture in the ill preterm infant using the traditional lateral recumbent position with full neck flexion resulted in significant respiratory abnormalities, presumably due to a ventilation-perfusion mismatch. All infants with serious cardiopulmonary disease should be closely monitored during the procedure. Preoxygenation with or without oxygen saturation monitoring may be used as a precaution. Particular attention should be given to avoiding marked neck and trunk flexion.

Although local anesthesia or sedation has not been a routine practice during lumbar puncture in the infant or child, it is being reconsidered. Pain is perceived in the neonate, and local anesthesia neither produces physiologic instability nor makes the procedure more difficult.  Sedation in the anxious child may be considered as an adjunct as for the

adult, although these agents are relatively contraindicated in the obtunded infant or child without a protected airway or with hemodynamic instability.

## COMPLICATIONS

### Implantation of Epidermoid Tumors

An epidermoid tumor or cyst is a mass of desquamated cells containing keratin within a capsule of well-differentiated stratified squamous epithelium. Congenital lesions are rare and arise from epithelial tissue that becomes sequestered at the time of closure of the neural groove between the third and fifth weeks of embryonic life. Acquired intraspinal epidermoid tumors result from implantation of epidermoid tissue into the spinal canal at the time of lumbar puncture performed with needles without stylets or with ill-fitting needles. [36] The clinical syndrome consists of pain in the back and the lower extremities developing years after spinal puncture. Failure to use a stylet may also result in aspiration of a nerve root into the epidural space.

### Headache After Lumbar Puncture

A number of complications from lumbar puncture have been reported. By far the most common is the post-lumbar puncture headache. This occurs after 5 to 30% of spinal taps. [5] [43] The syndrome starts up to 48 hours after the procedure and usually lasts for 1 to 2 days and occasionally up to 14 days. Exceptional cases lasting months have been described. The headache usually begins within minutes after the patient arises and characteristically ceases as soon as he or she assumes a recumbent position. The pain is mild to incapacitating and is usually cervical and suboccipital but may involve the shoulders and the entire cranium. Exceptional cases include nausea, vomiting, vertigo, blurred vision, ear pressure, tinnitus, and stiff neck. The headache may improve and change to a positional backache or neckache. The headache appears in the first 1 to 3 days and may last for weeks or rarely months to years. The syndrome is caused by leakage of fluid through the dural puncture site. This results in an absolute reduction of CSF volume below the cisterna magna and a downward movement of brain tissue with displacement and stretching of pain-sensitive structures, such as meninges and vessels, which, in turn, causes a traction headache. In the recumbent position there is relief, because the weight of the brain is shifted cephalad. Dural leakage has been confirmed at surgery for disk disease and by at least one isotope myelographic study; the size of the dural rent seems to correlate with the frequency of post-lumbar puncture headaches.

The incidence of headache in normal volunteers has been found to be 1 case per 9 subjects with the use of a 26-ga needle and 1 case per 3 subjects with a 22-ga needle. [45] The headache was reported to be milder when the smaller needle was used. Technically, a 26-ga needle is difficult to place and to manipulate into a position in which it does not become intermittently obstructed by nerve roots. In addition, a syringe is needed to withdraw fluid, and pressure cannot be easily recorded. Theoretically, the incidence of headache is greater with an 18-ga needle.

Other factors claimed to influence the incidence of postspinal headache have been reviewed by Fishman. [5] The incidence is higher in young patients than in older patients and is also increased in females and individuals with a prior headache history. Psychologic factors, quantity and rapidity of CSF removal, forced bedrest, post-lumbar puncture hydration, and position during lumbar puncture have not been found to be relevant in the incidence of headache. [46] Some reports suggest a lower incidence with the lateral approach resulting from the production of holes in the dura and the arachnoid that do not overlap.

The influence of activity on postspinal puncture headache has been studied with contradicting results, including worsening of, improvement in, and no effect on the incidence of headaches when patients were mobilized. [5] [47] Brocker studied 1094 patients and reported a reduction of headache from 36.5 to 0.5% by having the patients lie prone instead of supine for 3 hours after puncture with an 18-ga needle. [47] He concluded that the prone position caused hyperextension of the spine and disrupted alignment of the holes in the dura and the arachnoid, making a leak less likely. Others have failed to show a decrease in duration, severity, or incidence of spinal headache with 24 hours of bedrest. [48] Interestingly, Vilming and colleagues noted a slight reduction in post-lumbar puncture headache if immediate mobilization was undertaken. [49]

Many medications have been advocated for treatment of post-lumbar puncture headache: barbiturates, codeine, neostigmine, ergots, diphenhydramine (Benadryl), dimenhydrinate (Dramamine), amphetamine sulfate (Benzedrine), ephedrine, intravenous fluids, magnesium sulfate, and vitamins. [5] Sechzer and Abel, [50] in a double-blind demand method, found caffeine sodium benzoate (500 mg in 2 mL normal saline given by IV push) to be effective in 75% of patients. Additional patients responded to a second injection 1 to 2 hours later. Other clinicians prefer to put 500 mg of caffeine sodium benzoate in 1 L of saline and infuse the fluid over 1 hour. [51] This approach is contraindicated in the patient at risk for xanthine toxicity (e.g., supratherapeutic theophylline level, history of cardiac dysrhythmias). Aminophylline, 5 to 6 mg/kg by IV infusion over 20 minutes, is also reported to be useful.

Most clinicians generally follow the practice of using a styleted needle that is as small as possible. A 20- to 22-ga needle is often used for adults because of its stiffness and ease of fluid flow. Multiple punctures should be avoided. There is no certainty about activity and position immediately after the procedure. Most post-spinal puncture headaches can be managed with bedrest with the head in the horizontal position. Dehydration should be avoided, because it lowers CSF pressure and might aggravate the headache. Although simple analgesics are commonly prescribed, they have no apparent advantage over bedrest and fluid intake. In the absence of a postural headache it is not necessary to stress immobilization or bedrest after lumbar puncture. [52] A patient with a prolonged headache after spinal puncture should be reassessed to rule out other structural causes of headaches. If the headache is not postural, other causes should be sought.

In cases in which a prolonged low-pressure headache exists, the placing of an epidural blood patch by experienced anesthesiologists is highly successful. An epidural tap is

performed at the level of the prior lumbar puncture. Ten to 20 mL of autologous blood is drawn aseptically into a syringe and slowly injected (1 to 2 mL every 10 seconds) into the epidural space at the site of the dural puncture. The injection is slowed or discontinued if back pain or paresthesias develop. The patient is kept supine for 1 hour while receiving intravenous hydration. Relief usually occurs within 20 to 30 minutes of the procedure. However, epidural patches are less likely to be effective if symptoms have been present for more that 2 weeks. Pain relief is due to the blood patch forming a gelatinous tamponade, hence stopping the CSF leak and providing an immediate elevation of CSF pressure. Patch failures (15 to 20%) are believed to be due to improper needle placement, injection of an inadequate quantity of blood, or an incorrect diagnosis. A second patch is often successful.

Complications reported after an epidural patch include back stiffness (15%), paresthesias, radicular pain, subdural hematoma, adhesive arachnoiditis, and bacterial meningitis. The procedure should be used in patients with refractory headaches who fail to respond to conservative therapy and should be performed by physicians trained in the procedure.

**Infection**

Spinal puncture is absolutely contraindicated in the presence of local infection at the puncture site (cellulitis, epidural abscess, or furunculosis) because of the danger of inducing meningitis.

The postulation that an association exists between performance of a lumbar puncture during bacteremia and later development of meningitis has been examined by several laboratory and clinical investigators. [55] [56] A large concentration of bacteria in the bloodstream at the time of CSF examination is associated with meningitis. The meningitis could be coincidental ("spontaneous meningitis") or could result from leakage of blood containing bacteria into the subarachnoid space after lumbar puncture ("lumbar puncture-induced meningitis"). Eng and Seligman reported that 14% of 165 cases of bacteremia caused by *Streptococcus pneumoniae, Haemophilus influenzae,* and *Neisseria meningitidis* had evidence of meningitis at the time of initial lumbar puncture. [57] They argue that one cannot easily differentiate spontaneous meningitis from lumbar puncture-induced meningitis with these organisms because of their ability to invade the meninges spontaneously. It is likely that many of these rare cases of "lumbar puncture-induced meningitis" represent cases in which the cautious physician has performed a lumbar puncture early in the course of meningitis, that is, before the infection has had time to be reflected in the CSF.

Teele and coworkers, however, reported that 7 of 46 children developed meningitis after an initial normal lumbar puncture in the presence of bacteremia. [56] *S. pneumoniae, H. influenzae,* and *N. meningitidis* were recovered in all cases. All cases of "lumbar puncture-induced meningitis" occurred in children younger than 1 year of age who received no antimicrobial therapy at the time of initial cultures. Empirical treatment for bacteremia despite a clear CSF is recommended by Teele and associates in the child younger than 1 year if a high fever and leukocytosis are present. [56]

Other studies suggest that the development of meningitis in children with occult bacteremia is more strongly associated with *S. pneumoniae, H. influenzae* type B, or *N. meningitidis* species of bacteria and *not* with the performance of lumbar puncture. [58] Suspected bacteremia is not a contraindication for performing a lumbar puncture; delay in diagnosis because of concern regarding the risks of a lumbar puncture is more serious than the risk of causing meningitis with the procedure. [59] [60]

**Herniation Syndromes After Lumbar Puncture**

Lumbar puncture is of value in confirming a diagnosis of meningitis and subarachnoid hemorrhage. Generally, when the patient has symptoms consistent with bacterial meningitis, lumbar puncture is performed before a head CT scan. However, in patients with a suspected intracranial mass lesion, a CT scan is generally performed before the lumbar puncture and antibiotics administered after blood cultures and before the CT scan when meningitis remains on the differential diagnosis list.

Particularly with supratentorial mass lesions, there may be large pressure gradients between the cranial and lumbar compartments. When brain volume is increased because of a mass lesion or edema, rostrocaudal displacement may occur after lumbar puncture if the skull is intact. Techniques for management of increased ICP are discussed elsewhere (see Chapter 64) .

Lowering the lumbar spinal canal pressure by removing CSF may increase the gradient between cranial and lumbar compartments, promoting both transtentorial and foramen magnum herniation. The frequency with which a lumbar puncture causes or accelerates transtentorial herniation is unknown, because a patient might have developed herniation spontaneously without the procedure. Duffy reported experience with 30 patients referred to a neurosurgical service with post-lumbar puncture herniation syndromes; in this selected population of adverse outcomes, he noted that complications occurred in the first 12 hours after the procedure. [22] Half of these referred patients lost consciousness immediately after the puncture. In half of these patients, the lumbar pressure was normal. Only one third had papilledema.

With the availability of CT scanning, patients at risk of herniation should be less likely to undergo lumbar puncture. However, the literature from both the pre- and post-CT eras suggests a risk of herniation after lumbar puncture to be in the range of 2 to 3%. [61] Baker and colleagues noted that CT scans at their institution were poorly correlated with CSF pressures. [62] Among 13 patients with a CSF pressure 210 mm $H_2O$, 6 had normal CT scans and 3 had generalized atrophy. Only 4 had evidence of an intracranial mass, midline shift, or hydrocephalus. Of note, no patient demonstrated herniation over the subsequent 48 hours. Similarly, Zisfein and Tuchman observed 38 patients with CT scan-documented intracranial mass lesions who underwent lumbar puncture. [63] They note that only 1 patient who had fixed, dilated pupils and absent caloric reflexes before the lumbar puncture died. All other patients were neurologically stable or had improved within 48 hours. Hence, with the current use of small-caliber spinal needles and aggressive concurrent use of ICP-lowering agents, herniation appears extremely rare

and may not be fully predictable by CT scan or opening CSF pressure readings.

Horowitz and coworkers reported herniation in 18 of 302 infants with bacterial meningitis, all of whom experienced deterioration within 8 hours of lumbar puncture. [64] Patients with meningitis who have localizing neurologic signs may have a coexisting brain abscess or infarction from arterial or venous thrombosis. Obstructive hydrocephalus and generalized cerebral edema may complicate meningitis with a secondary increase in ICP.

A careful neurologic examination should precede all spinal punctures. When there is a history of headache with progressive mental changes and the development of *localizing* neurologic signs, then spinal puncture should *not* be performed as the initial diagnostic procedure. When these findings are present and meningitis is still clinically suspected, an initial dose of antibiotic should be administered empirically while awaiting results of CT or MRI to determine the safety of a subsequent lumbar puncture. Appropriate cultures of blood and other body fluid should be obtained before antibiotic administration. Blood cultures are positive in 80% of infants with meningitis. Measures to lower ICP before spinal puncture can also be instituted.

A CT scan should identify hemorrhagic lesions and most neoplasms; it should aid in the decision regarding the need for and the risk involved with spinal puncture. Head CT may help identify patients with unequal pressures between intracranial compartments who are at greater risk for cerebral herniation. CT findings that suggest unequal pressure between intracranial compartments include lateral shift of midline structures, loss of suprachiasmatic and circum-mesencephalic cisterns, shift or obliteration of the fourth ventricle, and failure to visualize the superior cerebellar and quadrigeminal plate cisterns with sparing of the ambient cisterns. [65] The presence of a posterior fossa mass would be a strong contraindication to a lumbar puncture. Because of bone and motion artifact, the posterior fossa unfortunately may be a difficult area to visualize on CT.

**Recognition of Herniation Syndromes**

Herniation syndromes are the result of downward displacement of the hemispheres and the basal ganglia, which compress and displace the diencephalon and the midbrain rostrocaudally through the tentorial notch. Etiologic features and pathogenesis are detailed in the monograph by Plum and Posner. [66] Herniations have the potential to initiate vascular and obstructive complications that aggravate the original expanding lesion and can create an irreversible pathologic process. The anterior cerebral artery may be compressed against the falx and may increase ischemia and edema of the herniating hemisphere. Midline displacement posteriorly compresses the deep great cerebral vein and raises pressure in its area of drainage. Compression of the posterior cerebral artery at the tentorial notch can produce occipital infarction and swelling. In addition, kinking of the aqueduct may interfere with CSF circulation. This blockage may produce a normal spinal CSF pressure. Transtentorial herniation displaces the brainstem downward, stretching medial perforating branches of the basilar artery, as the artery is tethered to the circle of Willis. This produces brainstem ischemia and hemorrhages.

In general, pathologic changes with supratentorial mass lesions spread through the hemisphere and move rostrad and caudad in a progressive manner, with progressive dysfunction of the hemisphere and, subsequently, succeeding levels of the brainstem. The infrequent exceptions are seen in patients with acute cerebral-intraventricular hemorrhage and in patients with hemispheric mass lesions with incipient herniation who undergo lumbar puncture. Such conditions may rapidly progress from hemispheric dysfunction to sudden medullary failure.

**Central (Transtentorial) Herniation**

This condition occurs in response to lesions of the frontal, parietal, and occipital lobes and the extracerebral lesions lying toward the vertex or the fronto-occipital lobes (Fig. 65-7) (Figure Not Available) . Frequently, patients are subacutely or chronically ill with bilateral disease, and the diagnosis may be uncertain.  Initially, subjects exhibit a change in alertness or behavior. If the supratentorial lesion enlarges, compressing the diencephalon, stupor and then coma develop. At this point, monitoring of respiratory, ocular, and motor signs helps in diagnosing a supratentorial lesion and in determining the rostrocaudal direction of the disease process. Respirations at this time may be interrupted by deep sighs or yawns and periodic breathing of the Cheyne-Stokes type (periods of hyperpnea regularly alternating with apnea). Pupils are small but react briskly. Eye movements may be conjugate or slightly divergent with roving eye movements. Caloric testing with cold water produces a conjugate slow tonic movement to the side of irrigation. Many individuals have a hemiparesis before herniation. As the diencephalic stage of the central syndrome evolves, the contralateral hemiplegia may worsen, with the homolateral limbs developing a paratonic resistance to movement, but the individual continues to respond to noxious stimuli appropriately. At this stage both plantar responses are extensor. Decorticate responses appear and consist of flexor muscle hypertonus in the upper extremity with predominantly extensor hypertonus in the leg. Recognition of a diencephalic stage of herniation is important in that it gives warning that a potentially reversible lesion may become irreversible.

Once midbrain signs develop, they probably reflect infarction rather than reversible ischemia and compression. The chances of successfully removing or alleviating a supratentorial mass are small once the midbrain stage is reached.

Patients who develop midbrain and upper pons failure exhibit a sustained tachypnea; pupils dilate to a fixed midposition (3 to 5 mm), and oculovestibular reflexes become difficult to obtain, requiring side-to-side head movements and cold caloric irrigation. Disconjugate eye movements appear with failure to adduct (internuclear ophthalmoplegia). Motor responses give way to extensor hypertonus in all limbs (decerebrate rigidity). Midbrain damage results from ischemia and infarction, and few patients recover.

As the brainstem becomes more ischemic, the pupils maintain a fixed position, eye movements are lost, and decerebration gives way to flaccidity. The medullary stage consists of irregular respirations with long periods of apnea. The pupils dilate and the

blood pressure falls, with death being inevitable.

**Uncal Herniation**

Uncal herniation occurs when expanding lesions in the temporal fossa shift the medial temporal lobe (uncus) and the hippocampal gyrus medially over the incisural edge of the tentorium. This flattens the midbrain, pushing it against the contralateral incisura. The third nerve and the posterior cerebral artery on the side of the lesion are caught between the swollen uncus and the free edge of the tentorium (Figs. 65-8 (Figure Not Available) and 65-9) (Figure Not Available) . The earliest sign is a unilaterally sluggish or slightly dilated pupil. Because the diencephalon may not be the first structure encroached on, impaired consciousness is not consistently present as an early sign of uncal herniation. Other respiratory, ocular, and motor findings may not be appreciably changed from earlier examinations. Pupillary dilation may persist for several hours, but once the patient progresses beyond this stage there is a tendency for midbrain dysfunction to occur rapidly. Ipsilateral external ophthalmoplegia soon follows pupillary dilation along with stupor and coma. Oculovestibular reflexes disappear as ischemia spreads to the midbrain. As the opposite cerebral peduncle is compressed against the tentorial edge, hemiplegia may appear ipsilaterally to the expanding supratentorial lesion (Kernohan's notch). Decerebrate posturing develops, with the opposite pupil becoming dilated and fixed. Progression then proceeds as described for the central syndrome. As with transtentorial herniation, once midbrain failure occurs, survival is much less likely.

## Backache and Radicular Symptoms

Minor backache occurs with a frequency of 90% from the trauma of the spinal needle. Frank disk herniation has been reported from the passing of the needle beyond the subarachnoid space into the annulus fibrosis. Transient sensory symptoms from irritation of the cauda equina are also common.

Other reported complications include transient unilateral or bilateral sixth nerve palsies caused by stretching or displacement of the abducens nerve as it crosses the petrous ridge of the temporal bone, subarachnoid hemorrhage, subdural and epidural hematoma, anaphylactoid reactions to local anesthetics, settling of cord tumors, and retroperitoneal abscess produced by dural laceration in patients with meningitis. [67] Most of these are rare and seldom encountered.

Most of the complications of lateral cervical and cisternal puncture are similar to those encountered with a lumbar puncture. In addition, perforation of a large vessel with resultant cisterna magna hematoma or obstruction of vertebral artery flow has been described. Puncture of the medulla oblongata may cause vomiting or apnea, and puncture of the cord may be associated with pain. Long-lasting side effects of cord puncture are probably minor. [34] In addition, traumatic tap and post-spinal puncture headache may occur with lateral cervical and cisternal puncture.

# INTERPRETATION

## Pressure

The pressure of the CSF is of great clinical importance. It should be accurately measured whenever possible. Accurate measurement is dependent on patient cooperation. Elevated pressures are abnormal. Opening pressure is taken promptly, avoiding falsely low values due to leakage through and around the needle. Normal pressure is between 70 and 180 mm $H_2O$. Herniating cerebellar tonsils may occlude the foramen magnum and prevent increased ICP from being reflected in the lumbar pressure reading. Increased ICP can result from expansion of the brain (edema, hemorrhage, or neoplasm), overproduction of CSF (choroid plexus papilloma), a defect in absorption, or obstruction of flow of CSF through the ventricles. Cerebral edema may be associated with meningitis, $CO_2$ retention, subarachnoid hemorrhage, anoxia, congestive heart failure, or superior vena cava obstruction. Pressure may be falsely elevated in a tense patient, when the head is elevated above the plane of the needle, and, possibly, with marked obesity or muscle contraction. [5] Pressure is not usually measured in the neonate, because a struggling or crying child will have a falsely elevated pressure. The upper limits of normal are 50 mm $H_2O$ in neonates and 85 mm $H_2O$ in infants and young children. [68] Although the manometer reading is falsely elevated in the sitting position, the level should not rise above the foramen magnum.

Low pressure should suggest obstruction of the needle by meninges. Low pressure can also be seen with spinal block. Rarely, a primary low-pressure syndrome occurs in a setting of trauma, following neurosurgical procedures, secondary to subdural hematomas in elderly patients, with barbiturate intoxication, and in cases of CSF leakage through holes in the arachnoid.

The Queckenstedt test is useful for demonstrating the presence of obstruction in the spinal subarachnoid space. [4] [5] The test is seldom performed today, because myelographic techniques have been refined and the availability of MRI has reduced the number of myelograms and associated lumbar puncture. With the patient in the lateral recumbent position, jugular vein compression causes decreased venous return to the heart. This distends cerebral veins and causes a rise of ICP, which is transmitted throughout the system and is measured in the manometer. After 10 seconds of bilateral compression, CSF pressure usually rises to 150 mm $H_2O$ over the initial reading and returns to the baseline in 10 to 20 seconds after release. If there is no change in the lumbar pressure or if the rise and fall are delayed, it should be concluded that the spinal subarachnoid space does not communicate with the cranial subarachnoid space. In this situation, Pantopaque should be injected before removal to facilitate subsequent performance of a myelogram. This is necessary because the lumbar dural sac may collapse, making it impossible to reenter the canal. If cervical cord disease is suspected, the test should be repeated with the neck in the neutral position, hyperextended, and flexed. When lateral sinus obstruction is suspected, unilateral jugular venous compression may be used (Tobey-Ayer test).

**Appearance**

If the CSF is not crystal clear, a pathologic condition of the CNS should be suspected. The examiner should compare the fluid with water, viewing down the long axis of the tube or holding both tubes against a white background. A glass tube is preferred, because plastic tubes are frequently not clear. The fluid may be clear with as many as 400 RBCs/mm3 and 200 WBCs/mm3 . [5]

Xanthochromia is a yellow-orange discoloration of the supernate of centrifuged CSF. Xanthochromia is produced by red cell lysis and is caused by one or more of the following pigments: oxyhemoglobin, bilirubin, and methemoglobin. Oxyhemoglobin causes red coloration; bilirubin, yellow; and methemoglobin, brown. Oxyhemoglobin is seen within 2 hours of subarachnoid bleeding and red cell lysis. Formation reaches a maximum in 24 to 48 hours after hemorrhage and disappears in 3 to 30 days. [4] The appearance of bilirubin in the CSF involves the conversion of oxyhemoglobin by the enzyme heme oxygenase. The enzyme is found in the choroid plexus, the arachnoid, and the meninges. Enzyme activity appears approximately 12 hours after the hemorrhage. [4] Bilirubin may persist for 2 to 4 weeks. Bilirubin in CSF caused by hepatic or hemolytic disease does not appear until a serum level of 10 to 15 mg total bilirubin per 100 mL is reached, unless underlying disease associated with a high CSF protein is present. Xanthochromia may be seen with CSF protein values above 150 mg/dL. CSF may clot with complete spinal block and very high CSF protein.

Oxyhemoglobin and bilirubin may be measured chemically or by spectrophotometric analysis. Demonstration of these compounds in CSF may help in the distinction between recent intracranial hemorrhage and a traumatic tap. Oxyhemoglobin may form as a result of red cell lysis if the tube has been allowed to stand for more than 1 hour before testing, however.

Methemoglobin is a reduction product of oxyhemoglobin characteristically found in encapsulated subdural hematomas or in old intracerebral hematomas.

**Cells**

The technique involved in cell counts is reviewed in Fishman's text. [5] WBC counts over 5 cells/mm3 should be taken to indicate the presence of a pathologic condition. In a study of 135 normal university students, Tourtellotte and Shorr reported almost exclusively lymphocytes and monocytes, and the presence of 1 to 5 lymphocytes in the CSF may be normal. [4] Neonatal CSF may show up to 32 WBCs/mm3 with prominent neutrophils; infants 4 to 8 weeks old may have 22 WBCs/mm3 . [71] It has been stated that polymorphonuclear leukocytes are never seen in normal adults. However, with the use of the cytocentrifuge, an occasional specimen may show a neutrophil in an otherwise normal individual. [72] Such a finding should routinely prompt culture of the CSF, because the presence of a neutrophilic pleocytosis is commonly associated with bacterial infections or the early stages of viral infections, tuberculosis, meningitis,

hematogenous meningitis, and chemical meningitis due to foreign bodies.

As many as 30% of patients may exhibit CSF pleocytosis after a generalized or focal seizure. In a review of 102 patients without CNS infection who had lumbar puncture within 48 hours of a seizure, Prokesch reported an average of 72 cells/mm3 , noting the presence of both polymorphonuclear and mononuclear cells. [73] Although these patients did not have CNS infection, many did have serious intracranial pathologic processes (subdural hematoma, subarachnoid hemorrhage, or stroke). This finding should prompt a search for infection and assessment of the seizure as being possibly secondary to an underlying neurologic disorder.

Small lymphocytes may be seen in normal individuals. Small and large immunocompetent cells are found with a variety of bacterial, fungal, viral, granulomatous, and spirochetal diseases as well as the presence of foreign substances.

Eosinophils are always abnormal and most commonly represent a parasitic infestation of the CNS. They may also be seen after myelography and pneumoencephalography and, to a minor degree, in other inflammatory diseases, including tuberculous meningitis and neurosyphilis. CSF eosinophilia has also been reported in cases of subarachnoid hemorrhage, lymphoma, Hodgkin's disease, brucellosis, fungal meningitis, *Mycoplasma pneumoniae* infection, measles, lymphocytic choriomeningitis, rickettsial infections, leukemia, demyelinating diseases, sarcoidosis, acute inflammatory demyelinating polyneuropathy, allergic reactions, and idiopathic eosinophilic meningitis. [74]

Normal CSF RBCs are less than 10/mm3 . Counts up to 100/mm3 that are otherwise unexplained may be due to a traumatic tap. Herpes simplex virus encephalitis may elevate the CSF RBC count in many patients. Myeloid and RBC precursors may contaminate CSF with bone marrow cells from an adjacent vertebral body. [75]

**Glucose**

Glucose enters the CSF by way of the choroid plexus as well as by transcapillary movement into the extracellular space of the brain and the cord by carrier-mediated transport. It then equilibrates freely with the CSF subarachnoid space. Fishman concludes that a low CSF glucose concentration indicates increased glucose use in the brain and the spinal cord and, to a lesser degree, by polymorphonuclear leukocytes, bacteria, and inhibition of membrane carrier systems. [5] Once in the CSF, glucose undergoes glycolysis and there is an invariable rise in CSF lactate levels. Glucose levels remain subnormal for 1 to 2 weeks after the effective treatment of meningitis.

The normal range of CSF glucose is between 50 and 80 mg/dL, which is 60 to 70% of the glucose concentration in the blood. Ventricular fluid glucose levels are 6 to 8 mg/dL higher than in lumbar fluid. A ratio of CSF:blood of <0.5 or CSF levels <40 mg/dL are invariably abnormal. The ratio is higher in infants for whom a ratio of <0.6 is considered abnormal. Hyperglycemia may mask a depressed CSF glucose level, and the CSF to blood glucose ratio should be measured routinely. With extreme hyperglycemia a ratio of 0.3 has been suggested as being abnormal. [76] Between 90 and 120 minutes is required before the CSF glucose reaches a steady state with blood glucose changes

(e.g., after the intravenous injection of glucose). When CSF glucose is of diagnostic importance, CSF and blood samples ideally should be obtained after a 4-hour fast.

Low CSF glucose levels may be found in several diseases of the nervous system (see Table 65-1) . Only low concentrations

| TABLE 65-1 -- Low CSF Glucose Syndromes | |
|---|---|
| Bacterial meningitis | Syphilis |
| Tuberculous meningitis | Chemical meningitis |
| Fungal meningitis | Subarachnoid hemorrhage |
| Sarcoidosis | Mumps meningitis |
| Meningeal carcinomatosis | Herpes simplex encephalitis |
| Amebic meningitis | Hypoglycemia |
| Cysticercosis | Trichinosis |

of glucose are of diagnostic value, and elevated CSF glucose levels generally have no significance; elevation usually reflects hyperglycemia. A rapid estimate of the CSF glucose level can be obtained by using bedside reagent strip testing with a commercial autoanalyzer. However, formal laboratory testing is recommended for confirmation of bedside levels.

**Protein**

The normal range of the lumbar CSF protein level is 15 to 45 mg/dL. Infants normally have a lower level than adults, and protein levels may drop after a lumbar puncture. The

concentration is lower in the ventricles (5 to 15 mg/dL) and the basilar cisterns (10 to 25 mg/dL), reflecting a gradient in the permeability of capillary endothelial cells to proteins in the blood. Levels of CSF protein in premature infants and full-term neonates is higher than in adults with a mean of 90 mg/dL; protein levels decline by 8 weeks of age, reflecting maturation of the blood-brain barrier. Most of the proteins in CSF normally come from the blood, which normally has a protein concentration of up to 8000 mg/dL. Protein entry is determined by molecular size and relative impermeability of the blood-CSF barrier. A full range of serum proteins are found in CSF at several hundredfold dilution. Faulty reabsorption of protein by arachnoid villi may also elevate protein levels. Increases in CSF total protein levels are a nonspecific abnormality associated with many disease states. Levels >500 mg/dL are uncommon and are seen mainly in meningitis, in subarachnoid bleeding, and with spinal tumors. The high levels seen with cord tumors result from an increase in local capillary permeability. With high levels (generally 1000 mg/dL), CSF may clot (Froin's syndrome).

Hemorrhage into the CSF or the introduction of blood by a traumatic tap increases CSF protein levels. If the serum protein is normal, the CSF protein should theoretically rise by 1 mg for every 1000 red cells, but this is variable. The inflammatory effect of hemolyzed RBCs may also significantly increase CSF protein.

Selective measurement of immunoglobulin fractions in CSF has proved to be of diagnostic value in suspected cases of multiple sclerosis. Elevated CSF immunoglobulin levels may reflect blood-brain barrier disruption or local antibody response to a CNS immune response. [77] Stimuli may be infectious or antigenic, producing an inflammatory response. Immunoglobulin elevation has been found in many chronic inflammatory conditions, including syphilis, viral encephalitis including HIV infection, subacute sclerosing panencephalitis, progressive rubella encephalitis, tuberculous meningitis, sarcoidosis, cysticercosis, and acute inflammatory demyelinating polyneuropathy (Guillain-Barre syndrome).

**The Traumatic Tap**

It should not be difficult to distinguish between subarachnoid bleeding and bloodshed by the spinal needle if certain steps are taken *at the time of the initial puncture.* In traumatic punctures the fluid generally clears between the first and third tubes as the needle is washed by CSF. Decreasing cell counts on the first and third tubes help confirm this. In a recent hemorrhage, however, a declining cell count may represent layering of cells in a recumbent patient. The fluid should then be centrifuged. With moderately blood-stained fluid, the supernatant should be clear if the RBCs have been present for less than 2 hours (traumatic tap). Red cells undergo hemolysis in the CSF after a few hours to produce xanthochromia. Xanthochromia persists for up to 4 weeks, depending on the number of RBCs that were originally present. An early CSF examination may show clear fluid before the development of hemolysis, even after spontaneous subarachnoid bleeding. However, xanthochromia may be seen after a traumatic tap if the RBC count exceeds 150,000 to 200,000/mm3 . The yellow color may appear if sufficient serum is present. [78] The presence of a clot in one of the tubes strongly favors a traumatic tap.

In subarachnoid hemorrhage, clotting does not occur because blood is defibrinated at the site of the hemorrhage. Any lumbar puncture performed several days after a traumatic tap may yield stained fluid. An immediate repeat puncture at a higher interspace yielding clear CSF may also help distinguish a traumatic tap. The fluid from a traumatic tap should contain about 1 WBC per 700 RBCs if the complete blood cell count is normal, but this ratio is highly variable. Formulas to assess the contribution of total CSF cell count and protein values from traumatic taps have been proposed but do not have uniform support. [79] [80] Indeed, Bonadio and colleagues suggest that children with meningitis and traumatic taps (i.e., RBC count 1000/mm3 ) generally have other features of meningitis besides an observed-to-predicted WBC ratio 10 (e.g., predominance of neutrophils, low CSF-to-serum-glucose ratio, and positive Gram stain). [81] All blood-contaminated CSF should be cultured, especially from uncooperative infants and children being evaluated for sepsis.

Lang and colleagues suggest the use of a D-dimer test on CSF to identify subarachnoid hemorrhage. [82] Although identifying local fibrinolysis, other conditions such as disseminated intravascular coagulation, a previous traumatic tap, or prior thrombolytic therapy may produce false-positive test results.

## CSF Analysis with Infections

### Bacterial Infections

The CSF findings are essential in establishing a provisional diagnosis of acute bacterial meningitis. CSF analysis establishes the diagnosis, the causative organism, and the choice of antibiotics. CSF must be transported to the laboratory immediately and examined at once. CSF cells begin to lyse within 1 hour of collection, but this may be slowed by refrigeration. In cases of meningococcal infection, a delay in processing may cause the diagnosis to be missed, because the organism tends to autolyze rapidly. Speed is only slightly less important with other organisms, because early initiation of antibiotic therapy is crucial.

The Gram stain is of great importance, because this often dictates the initial choice of antibiotic therapy. The physician should become expert at examining Gram stains of CSF, and it is suggested that one should spend 10 minutes personally examining each CSF Gram stain specimen when the CSF WBC count is elevated. Gram-negative intracellular or extracellular diplococci are indicative of *Neisseria meningitidis*. Small gram-negative bacilli may indicate *Haemophilus influenzae*, especially in children. The presence of gram-positive cocci indicates *Streptococcus pneumoniae,* other *Streptococcus*

species, or *Staphylococcus.* Twenty percent of Gram stains may be falsely negative

because too few organisms are present. The Gram stain smear is more likely to be positive in patients who have not received prior antibiotic therapy. Acridine orange stain may improve the yield in bacterial infections with negative Gram stains.

For culture, blood and chocolate agar are required. *N. meningitidis* and *H. influenzae* grow best on chocolate agar. The plates are incubated under 10% $CO_2$ . Thioglycolate medium is used for possible anaerobic organisms. Cultures are examined at 24 and 48 hours, but plates should be kept for at least 7 days. Large volumes of CSF may improve yields. [84]

While the culture is pending, one may suspect a bacterial infection in the presence of an elevated opening pressure and a marked pleocytosis ranging between 500 and 20,000 WBCs/mm3 . The differential count is usually chiefly neutrophils. A count above 1000 cells/mm3 seldom occurs in viral infections. Occasionally, acellular fluid may be found in the severely immunosuppressed patient or others with appropriate presentations. Repeat lumbar puncture may be required in febrile patients in whom the clinical features remain compatible with meningitis.

CSF glucose levels less than 40 mg/dL or less than 50% of a simultaneous blood glucose level should raise the question of bacterial meningitis, even in the presence of a negative Gram stain and a low cell count. Glucose levels with bacterial meningitis are occasionally below 10 mg/dL; levels are normal in 9% of bacterial meningitis. [76] The CSF protein content in bacterial meningitis ranges from 500 to 1500 mg/dL and usually returns to normal by the end of therapy. CSF protein values above 220 mg/dL virtually ensure an acute meningitis of being bacterial. Of note, prior antibiotic therapy may adversely affect the sensitivity of cultures and Gram stains for bacterial meningitis but does not significantly affect WBC counts, CSF to blood glucose ratios, or CSF protein values. [87] Spanos and colleagues [88] have developed a useful nomogram to help distinguish bacterial from viral infections (Fig. 65-10) (Figure Not Available) .

A useful test that can be performed in nearly all laboratories is the measurement of CSF lactate dehydrogenase (LDH) levels. In bacterial and fungal meningitis, LDH levels are increased. [89] The LDH level may be elevated even in patients who have received antibiotics for 1 or 2 days. The LDH levels in viral infections tend to be normal, whereas values in bacterial meningitis are usually two to four times greater than the normal concentration of approximately 1.6 mEq/L.

A study by Durack and Spanos questions the use of repeat spinal taps as a test of meningitis cure. [90] Their review of 165 meningitis cases revealed 13 instances in which the repeat tap led to unnecessary intervention and 2 others in which treatment failure was *not* detected by the repeat spinal tap.

**Microbial Antigens and Polymerase Chain Reaction**

Several tests other than CSF culture and Gram stain are available to establish a bacterial etiology of meningitis. These include blood cultures, CSF counterimmunoelectrophoresis (CIE), CSF latex agglutination (LA), and coagglutination counterimmunoelectrophoresis. [7] All of the ancillary tests have a low sensitivity for

bacterial meningitis, thus limiting their use. In 50 to 80% of bacterial meningitis cases, blood cultures are positive for the etiologic agent. [91]

CIE uses wells in two rows of agarose gel. A different antiserum is placed in each well. A current is passed through the gel with the reactants then moving toward each other by electrophoretic mobilization of the antigen. A line of precipitation visualized in 1 to 4 hours represents positive reaction between antiserum and antigen. [92] Commercial kits are available to detect *S. pneumoniae*; *Listeria monocytogenes*; *H. influenzae*; *N. meningitidis* A, B, and C and W135; group B *Streptococcus*; K1 strains of *Escherichia coli*; *Klebsiella*; and *Pseudomonas* species. [93]

Particle agglutination involves staphylococcal coagglutination and latex agglutination. Antibody on the surface of a colloid combines with antigen binding sites to cross-link the colloid-forming antigen bridges. A matrix forms and appears as a macroscopic agglutination. Agglutination tests can detect approximately 10 times less antigen than CIE. False-positive tests can occur in the presence of rheumatoid factor, serum complement components, and possibly other serum proteins. The technique may be used in infections due to *H. influenzae*, *S. pneumoniae*, *N. meningitidis*, and group B *Streptococcus.*

Another technique having some potential use is the enzyme-linked immunosorbent assay. This technique may detect 100 to 1000 times less antigen than agglutination tests but is technically more difficult and requires 4 hours to perform.

A positive CSF antigen test may be expected in 70 to 90% of patients with *Neisseria* meningitis. This compares with a positive Gram stain in approximately 70% of patients. Positive latex antigen tests have been reported in approximately 60% of *S. pneumoniae* meningitis cases, with a positive Gram stain in 80%. A positive latex test and Gram stain are reported in approximately 85% of *H. influenzae* meningitis cases.Group B *Streptococcus* can be detected with a 60 to 90% sensitivity. The Gram stain may be difficult to assess after antibiotic therapy has been initiated. Bacterial antigens may persist in the CSF for several days after antibiotic therapy. Twenty-five to 33% of positive tests are lost per day in the setting of appropriate antimicrobial therapy. A negative test, however, does not rule out bacterial meningitis. [93] In addition, blood and urine should be examined for antigen. Often antigen may be found only in the urine. Urine needs to be concentrated and may have the disadvantage of reflecting urinary tract infections. The particle agglutination test for *H. influenzae* type B may be positive for up to 10 days after children have received *H. influenzae* polysaccharide vaccine. Antigen tests are not useful in diagnosing gram-negative bacillary, staphylococcal, and *Listeria* meningitis. In addition, although antigen tests may identify the bacterial pathogen, they do not provide information about the antibiotic susceptibility of the organism.

Future use of polymerase chain reaction (PCR) will aid the rapid diagnosis of CNS infection when results of current techniques are suboptimal. PCR is a method for amplifying target nucleic acid in CSF by use of repeated cycles of DNA synthesis. PCR requires use of flanking DNA sequences at the opposite ends of the target DNA. Synthetic primers anneal to their respective recognition sequences at the opposite end

of the target sequence; they serve as primers for new DNA synthesis. PCR allows detection of and quantification of organisms whose genetic material is DNA or messenger RNA. PCR permits the diagnosis of infectious disease with a high degree of sensitivity and specificity and allows rapid reliable detection of microbes present in small numbers. Laboratory false-negative and false-positive results may occur. PCR is only available at limited centers, although this seems likely to change in the near future. [94]

**Empirical Antibiotic Use Before**

Lumbar Puncture

Many patients are transported to a referral center or within a facility for a CT scan to rule out an intracranial mass after a clinical concern for meningitis is raised. In such instances, CSF examination may not be performed before transport. This may be due to technical problems (uncooperative or large patient) or concerns regarding safety of lumbar puncture in an obtunded patient with possible increased ICP.  The initial physician may have to decide whether to initiate empirical antibiotic therapy. Prior antibiotic administration could obscure the bacterial etiology, whereas a delay in initiating therapy may increase the morbidity and mortality of the illness. It may be difficult to identify individuals at risk for a fulminant course, and the diagnosis of bacterial meningitis cannot always be made with confidence; some cases may be misdiagnosed as subarachnoid hemorrhage or metabolic encephalopathy.

Talan and associates note that parenteral antibiotic treatment decreases the percentage of positive CSF cultures by 4 to 33% and of positive CSF Gram stains by 7 to 41%. [91] A minimum window of 2 to 3 hours exists after giving parenteral antibiotics when CSF cultures are not adversely affected. After 24 hours post treatment, as many as 38% of meningitis patients may still have positive CSF cultures. When CSF is cultured more than several hours after parenteral antibiotics are administered, antigen tests may be of help. Of course, blood cultures should be obtained immediately before antibiotic administrations whenever possible. Occasional patients may develop a lymphocytic pleocytosis with antibiotic therapy; but in most cases, cell count, differential, glucose and protein concentrations are not changed in the first 2 to 3 days of antibiotic therapy. [76] Although there are no data to confidently address the potential advantages or disadvantages of antibiotic therapy before lumbar puncture, it is reasonable to initiate therapy on the premise that a delay may be deleterious. If a lumbar puncture cannot be done, consultation with physicians at the referral center would seem appropriate. If a lumbar puncture is performed before a transfer, a portion of the CSF (chilled on ice) should be sent with the patient.

Bacterial meningitis occurring in children younger than 10 years of age historically has been often due to *H. influenzae*. *H. influenzae* appears to be easier to grow from early postantibiotic cultures and is more likely to be associated with positive blood cultures and antigen tests. In the pediatric population a single dose of antibiotic before transport is unlikely to prevent bacterial identification. In neonates, adults, and immunosuppressed patients, the sensitivity of blood cultures and immunologic tests is less reliable. CSF examination before antibiotic administration or *early* in the course of

treatment is preferred.

For suspected or confirmed cases of acute bacterial meningitis, antimicrobial therapy can be started based on the most likely causative organism based on age of the subject, associated diseases, and renal function. For immunocompromised and postneurosurgical patients, a third-generation cephalosporin (cefotaxime, ceftizoxime, ceftazidime, or ceftriaxone) and vancomycin should be used for coverage against staphylococci, *L. monocytogenes,* and gram-negative organisms. [7] Table 65-2 (Table Not Available) offers guidelines for emergency antibiotic therapy. The third-generation cephalosporins are efficacious in many empirical regimens or situations where the organism is known. To rely on third-generation cephalosporins for all cases of bacterial meningitis would result in treatment failures of all *Listeria* species and increasing numbers of *Enterobacter, Serratia,* and *Pseudomonas* groups. Treatment with older agents may be as or more effective in bacteria demonstrating appropriate sensitivity.

**Dexamethasone Therapy in Bacterial Meningitis**

Studies have suggested benefit from adjunctive dexamethasone therapy in reducing neurologic sequelae, especially hearing loss, in children with *H. influenzae* meningitis. The adjunctive benefit of corticosteroids during treatment of meningitis caused by other organisms is unknown.

In acute bacterial meningitis, bacterial cell wall components including lipopolysaccharides and teichoic acid initiate and exacerbate the host response. These stimulate the production of cytokines, including interleukin-1 and tumor necrosis factor, from macrophages and monocytes. Cytokines may injure vessels, diminish cerebral perfusion, and stimulate cerebral swelling. [68] The dosage of dexamethasone is 0.15 mg/kg every 6 hours for 4 days. When used, it is recommended that the corticosteroid be given before antibiotic use. Benefit in adults is less certain but experimental data in children would seem to support corticosteroid use, with caution being exercised in immunocompromised or leukopenic patients. A moderate inflammatory response in the meninges is required for penetration of the CNS by many antibiotics. Reducing meningeal inflammation will reduce the concentration of antibiotics in the CSF. Corticosteroids should be discontinued after approximately 4 days of treatment, at which time meningeal inflammation has been reduced by antibiotics. [95] [96]

Although an intriguing concept, the actual benefit from adjunctive corticosteroids is controversial. Current data do not allow for definitive recommendations regarding the use of corticosteroids in bacterial meningitis. With the increasing use of *H. influenzae* vaccines, the point may become moot.

**Neurosyphilis**

The true incidence of this disease is unknown. Approximately 5000 new cases of neurosyphilis are estimated to occur in the United States each year. [97] The natural history and clinical manifestations have been modified in the antibiotic era. The widespread use of oral antibiotics has changed neurosyphilis into a chronic partially treated meningitis. Partial therapy may clear peripheral infection and attenuate the

immune response. Therapy may be insufficient to eradicate organisms in the CNS and eye, which may then multiply. Seizures were considered in the preantibiotic era to complicate general paresis only late in the course of the illness, and then only in untreated patients. Previously, seizures were reported as an early manifestation in less than 5% of symptomatic neurosyphilis cases. Seizures now occur in 25% of symptomatic cases and may on occasion be the sole manifestation of neurosyphilis. [97] Seizures are usually partial (focal), with one third of patients having no interictal clinical findings. A treponemal serologic test should be obtained in every adult with acquired partial seizures.

Ophthalmologic findings are frequently present in syphilis. These include a slowly progressive optic atrophy, an acute optic neuritis, cranial oculomotor neuropathy, and a chorioretinitis. A more specific sign is a dissociated pupillary response to light and convergence with loss of the light reflex (Argyll Robertson pupil). Meningovascular neurosyphilis involves infection of both the meninges and the cerebral vasculature. The clinical picture is that of a cerebral infarction or an acute meningoencephalitis. Meningovascular syphilis also may present as headache, nausea, vomiting, confusion, stiff neck, and cranial nerve palsies. Arteritis may affect small, medium, or large vessels, producing infarction or ischemia of brain or spinal cord. The peak incidence is 5 to 7 years after initial infection. Tabes dorsalis, general paresis, and gummas occur 10 to 20 years after initial infection.

CSF findings suggestive of neurosyphilis include more than 5 leukocytes/mm3 , elevated protein concentration, elevated gamma-globulin concentration, and a positive serologic test for syphilis. The glucose concentration is usually normal. Higher cell and protein values are seen in early as opposed to late neurosyphilis.

Diagnostic certainty remains difficult. The diagnostic criterion standard is darkfield microscopy to identify morphology and flexing "corkscrew" motility of spirochetes. Serologic tests for syphilis are either treponemal or nontreponemal. Nontreponemal tests detect a nonspecific globulin complex called reagin. Reagin tests, such as the Venereal Disease Research Laboratory (VDRL) flocculation test, lack sensitivity and should not be used to exclude the diagnosis of neurosyphilis. One third to one half of patients with neurosyphilis have a negative VDRL test in the serum, and more than one third have a negative VDRL test in the CSF. [97] CSF VDRL is quite specific with false-positive results seen primarily with traumatic taps.

Treponemal tests provide evidence of a specific immune response to *Treponema pallidum*. These include the serum fluorescent treponemal antibody adsorption (FTA-ABS), microhemagglutination tests for *T. pallidum* (MHA-TP), and the *T. pallidum* hemagglutination assay (TPHA). These assays are believed to remain positive for life. The FTA-ABS and MHA-TP tests may revert to negative in 13 to 24% of patients after therapy for early (primary) syphilis. There is no evidence that these tests revert to negative in untreated disease. [98] The serum FTA-ABS test is the test of choice to confirm the diagnosis of neurosyphilis. The serum FTA-ABS test is reactive in 95 to 100% of cases of neurosyphilis. A negative serum FTA-ABS test makes CSF examination unnecessary. Its false-positive rate is less than 1%, but the incidence of

biologic false-positive tests may increase in the presence of collagen vascular disorders.

A positive serum treponemal test indicates past infection with syphilis and may be reactive indefinitely, even after treatment. Therefore, CSF is used as a guide to the presence and the activity of neurosyphilis. The VDRL test is the test of choice in CSF and, when positive, is strong evidence for neurosyphilis. False-positive CSF VDRL tests are rare. The FTA-ABS test is not used in CSF; the false-positive rate is between 4 and 6% and is believed possibly to represent antibodies that have passively entered from serum. [99] The FTA-ABS test measures IgG antibody and cannot differentiate active from past infection. The CSF VDRL either may be reactive by contamination with seropositive blood (traumatic tap, subarachnoid hemorrhage) or may occur with entry of serum reagin into CSF during meningitis.

There is some concern that today many patients with parenchymal neurosyphilis have normal CSF. This finding leads to the recommendation that a patient with signs of progressive neurosyphilis and a positive treponemal serologic test be treated with antibiotics regardless of the CSF findings. A CSF pleocytosis may be provoked after 1 week of therapy and may supply supportive evidence for a diagnosis of neurosyphilis. PCR may have future applications for diagnosis of neurosyphilis (see the section on neurosyphilis and HIV infection later in this chapter).

**Viral Studies**

The organisms most commonly isolated in viral meningitis are the enteroviruses (coxsackieviruses, echoviruses) and mumps virus. Enteroviruses are most commonly seen in the summer and fall, and mumps appears most frequently in the winter and spring. Viral cultures in most hospitals are not available and play little role in acute decisions regarding diagnosis and treatment. A serial rise in CSF antibody titers may be helpful but may be difficult to obtain in patients who have clinically recovered. Intrathecal production of organ-specific antibodies (IgM, IgG, and IgA isotopes) may be diagnostic of neurologic infection if there is no prior history of infections. This measurement of both serum and CSF antibody titers must be done in a specialized laboratory. Viral meningitis is diagnosed when bacterial culture and Gram stain are negative. A tentative diagnosis may be based on analysis of the CSF.

The WBC count in viral meningitis and encephalitis characteristically shows 10 to 1000 cells/mm3 . The differential cell count is predominantly lymphocytic and mononuclear in type. In the early stages of meningoencephalitis, however, polymorphonuclear cells may predominate, making the distinction between viral and bacterial infections difficult. In such cases, a repeat tap in 12 to 24 hours will assist in clarifying the diagnosis. Protein levels are usually mildly elevated, but normal levels may be seen. Antibiotic coverage pending culture results may be reasonably initiated if the diagnosis of viral meningitis is in doubt. [76] The CSF glucose is characteristically normal; however, notable exceptions include some cases of mumps meningoencephalitis and herpes simplex encephalitis. CSF pleocytosis and elevated protein levels have also been found in asymptomatic HIV-seropositive individuals. [100]

If the CSF cannot be delivered to the viral laboratory in 24 to 48 hours, it should be

refrigerated at 4 °C. Members of the enterovirus group are occasionally isolated from CSF. Herpesviruses and arboviruses are rarely found in CSF. In known viral CNS disease, the stool is more rewarding (85% positive) than CSF (10% positive). [101] Because CSF is normally sterile, any isolate is significant, whereas a stool isolate does not necessarily indicate that the agent is responsible for CNS disease. [84] The PCR is the diagnostic test of choice for herpes simplex meningoencephalitis and PCR will be increasingly applied to the diagnosis of other CNS viral infections.

## CSF Analysis in Immunocompromised Patients

The number of immunocompromised individuals is increasing because of the HIV epidemic and the increased survival of patients with cancer and autoimmune disorders. The nervous system is a major target of the HIV virus, with 40 to 60% of infected individuals developing neurologic disease during their lifetime; one third will present with neurologic complaints as the initial manifestations of the acquired immune deficiency syndrome (AIDS), and an even higher incidence of nervous system involvement is found at autopsy. [102] Risk of CNS infection depends on the underlying disease, treatment, duration, and type of immune abnormality. Abnormalities include defects in T-lymphocyte and macrophage cellular immune function, defects in humoral immunity, defects in number and function of neutrophils, and loss of splenic function with inability to remove encapsulated bacteria. [103] A summary of the major neurologic manifestations of HIV infection including their clinical characteristics is presented in Table 65-3 (Table Not Available) .

Patients with defects of their cell-mediated immunity include those with lymphoma, organ transplant recipients, daily corticosteroid therapy, and patients with AIDS. These individuals are vulnerable to infections with microorganisms that are intracellular parasites. The most common source of acute bacterial meningitis in such patients is *L. monocytogenes*. The clinical presentation includes fever, headache, seizures, focal neurologic deficits and a brainstem encephalitis.

Patients with defective humoral immunity include those with chronic lymphocytic leukemia, multiple myeloma, and Hodgkin's disease after radiotherapy or chemotherapy. These patients have difficulty controlling infection by encapsulated bacteria. They may develop a fulminant meningitis due to *S. pneumoniae*, *H. influenzae* type b, and *N. meningitidis*. Patients after splenectomy are at risk for the development of meningitis for the same reason. Neutropenic patients are at risk for meningitis due to *P. aeruginosa* and the Enterobacteriaceae.

Establishing a specific diagnosis in HIV and organ transplant patients may be difficult to impossible because of overlapping clinical and radiographic presentations, the presence of simultaneous infections with more than one organism, and CSF changes that may be nonspecific. The immune response may be altered with the absence of signs of meningeal irritation; patients may present with a diffuse encephalopathy or with focal neurologic deficits. CSF is abnormal in 60% of asymptomatic HIV-infected individuals, complicating CSF/clinical correlation. [102]

**Neurosyphilis in Patients with HIV Infection**

Both syphilis and HIV infection are sexually transmitted diseases, and patients with syphilis are probably at increased risk of HIV infection. CNS invasion is probably no more common in HIV-infected and HIV-noninfected patients. [104] Both diseases may have elevations in CSF WBC counts, protein levels, and gamma-globulin levels. Early CNS infection may be more common in patients with HIV infection. Reports also have noted an increased incidence of syphilitic meningitis, meningovascular syphilis, and ocular syphilis, which has been uncommon in the past. Studies suggest HIV patients treated for syphilis may have viable organisms in CSF after therapy or have persistent CSF VDRL titers. Treatment failures are more likely to occur with single-dose benzathine penicillin therapy.

Diagnosis of neurosyphilis may also be more difficult in HIV-infected patients. A small number of patients with secondary or ocular syphilis have been described with negative serum reagin tests. Positive treponemal tests may revert to nonreactivity after treatment, particularly in individuals with advanced symptomatic HIV disease and a low VDRL titer at the time of diagnosis. CSF pleocytosis and increased gamma-globulin levels may not help distinguish between HIV infection and CNS syphilis.

HIV-infected patients should have serum treponemal and nontreponemal tests early in their illness to minimize a false-negative result. [104] Infected patients should undergo a CSF examination. Previously treated patients without a CSF examination should have a lumbar puncture because of a probable increased risk of neurosyphilis even with a decline in serum nontreponemal titers. Asymptomatic patients with neurosyphilis should be treated to prevent CNS relapse.

**Cryptococcal Meningitis**

The most common CNS fungal infection is due to *Cryptococcus neoformans*. Approximately 5% of AIDS patients will develop infection with this common fungus. Clinical presentation in AIDS and non-AIDS patients include nonspecific symptoms of headache and altered mental status with or without meningeal signs. Most patients have increased ICP. Immunocompetent patients show a lymphocytic pleocytosis with CSF WBC counts under 500/mm3 . Glucose levels are depressed with elevation of CSF protein. India ink preparations are positive in 50% of cases. The CSF is less likely to be abnormal in HIV infection with normal cell counts and chemistries. However, CSF cultures and cryptococcal polysaccharide capsular antigens are almost always positive. False-positive antigen tests are rare but may be seen in the presence of rheumatoid factor. Blood cultures are frequently positive in AIDS patients. Cisternal puncture for fluid analysis may be helpful in undiagnosed cases of lymphocytic meningitis in which multiple lumbar punctures have not established a diagnosis. [102]

**Toxoplasmosis**

*Toxoplasma gondii*, an intracellular protozoan, is associated with CNS infection in up to

30% of AIDS patients who have antibodies to *T. gondii*. Most adults have antibodies; infection is believed to represent reactivation of latent primary infection. *Toxoplasma* encephalitis will develop within the first 2 years after the diagnosis of AIDS. Cerebral toxoplasmosis usually presents with the acute/subacute appearance of focal disease including seizures. MRI or CT shows multiple abscesses that may represent multiple pathogens. The distinction between toxoplasmosis and lymphoma may be difficult clinically. Less commonly, the presentation is of a chronic meningitis with confusion, memory loss, and lethargy similar to the AIDS-dementia complex. CSF in these patients is nonspecific with increased protein, mononuclear pleocytosis (<100 cells/mm3 ) and, rarely, reduced glucose concentration. Serum and CSF serologies may be either positive or negative and do not help make a diagnosis, although most patients with encephalitis have detectable IgG antibodies. Diagnosis is usually made based on clinical and imaging responses to antibiotics (pyrimethamine or sulfadiazine) or brain biopsy. Treatment failures with relapse occur in 50% of AIDS patients and 15 to 25% of non-AIDS patients, necessitating lifelong treatment.

**Mycobacterial Tuberculosis**

CNS mycobacteria infection is almost always the result of infection with *Mycobacterium tuberculosis*. Infection occurs in the setting of disseminated tuberculosis. Atypical *Mycobacterium* infection occurring in HIV-infected individuals uncommonly affects the CNS. Clinical presentation is that of meningitis (particularly involving the basal cistern), encephalitis, or abscess formation. If tuberculosis is suspected, a large volume of CSF (10 mL) is required for adequate culture. The cell count varies from 100 to 400 cells/mm3 , with a lymphocytic predominance; 30% may show predominately neutrophils early in the course of infection. Protein levels are elevated (100-500 mg/dL); CSF glucose level may be depressed. Acid-fast stains should be examined by experienced technicians. Fluid is inoculated onto Lowenstein-Jensen medium, and the absence of visible growth on the medium should not be considered negative for 8 weeks. CSF cultures are more sensitive than stains. Many of the current tests for mycobacteria are likely to be replaced by PCR tests. [103]

**Primary CNS Lymphoma**

The risk of developing CNS lymphoma in an AIDS patient is 2%. Presentation is that of a diffuse encephalopathy, although occasionally focal neurologic deficits occur. Leptomeningeal spread of malignancy is reflected in a modest lymphocytic pleocytosis with slightly elevated protein and decreased glucose. Cytologic yield is improved by repeat lumbar punctures and submitting large quantities of CSF or sampling fluid by cisternal puncture. [102]

**Progressive Multifocal Leukoencephalopathy**

Progressive multifocal leukoencephalopathy is an uncommon disorder in individuals with impaired cell-mediated immunity and is caused by reactivation of the JC papovavirus in the kidney. Progressive demyelination presents as combinations of dementia, blindness, aphasia, hemiparesis, and seizures that progress until death. MRI and CT demonstrate nonenhancing white matter lesions without mass effect. Definitive diagnosis is made by

brain biopsy, but CSF may show the presence of myelin basic protein, increased IgG, with acellular or a mild CSF pleocytosis (<50 WBCs/mm3 ). Average survival is 4 months. [103]

**Brain Abscess**

Brain abscesses also occur in the immune-deficient host. Diverse causes have been described as well as multiple pathogens. Lesions may be difficult to detect by CT with contrast enhancement, decreased by corticosteroid therapy and a diminished host inflammatory response. Organisms reported include *T. gondii*, *Nocardia asteroides*, *Cryptococcus neoformans*, *Mycobacterium* species, aerobic gram-negative bacteria, *Aspergillus* species, *Candida* species, and Zygomycetes.

**Cytomegalovirus Infection**

Cytomegalovirus may be detected in 30% of brains of HIV-infected persons who come to autopsy. A distinct CNS disorder has not been defined. CSF pleocytosis may be minimal. Retinitis and painful polyradiculopathies are recognized with a prominent CSF pleocytosis in the later condition.

# CONCLUSION

A spinal tap should only be performed when the treating physician believes the CSF specimen or specimens will be of diagnostic or therapeutic value, as in the case of patients with symptomatic pseudotumor cerebri. The procedure is often indicated in the diagnosis of meningitis or subarachnoid hemorrhage. Complications are uncommon, and risks are usually outweighed by the benefit of the procedure. Most contraindications are relative and not absolute, particularly if infection is an overriding consideration.

# Chapter 66 - Special Neurologic Tests

**J. Stephen Huff, Paul B. Baker**

## CALORIC TESTING

An accurate assessment of the comatose patient requires a thorough neurologic examination, including careful evaluation of the patient's responses to a variety of external stimuli. In a comatose individual with normal brainstem and cranial nerve function, stimulation of the vestibular labyrinth results in a well-described and reproducible compensatory deviation of the eyes. This response is known as *the vestibulo-ocular reflex* and forms the physiologic basis for the caloric test of the vestibular system. During caloric testing, a thermal stimulus, usually water at a specific temperature, is delivered to the external auditory canal to activate the labyrinth and produce the characteristic ocular movements. Pathologic conditions involving either the vestibular or oculomotor reflex pathways will alter or abolish the response to caloric stimulation.

Caloric tests are performed in both conscious and unconscious patients, depending on the diagnostic circumstances. Quantitative caloric examination is conducted in the ambulatory patient for evaluation of possible vestibular dysfunction. This type of testing requires precisely controlled irrigation temperatures and specialized recording devices and is best undertaken in a properly equipped laboratory under the supervision of an experienced neuro-otologist. However, the neurologist, neurosurgeon, or emergency physician may perform *qualitative* caloric testing in the comatose patient for detection of gross disruption of vestibulo-ocular reflex pathways indicative of structural lesions or metabolic abnormalities involving the brainstem. In this setting, large quantities of ice water provide maximal stimulation of the vestibular apparatus. Such testing needs no special expertise and can be done at the bedside using equipment readily available in the emergency department (ED). This simple procedure can provide valuable diagnostic and prognostic information necessary for management of the comatose patient.

### Background

In the middle of the 19th century, Brown-Sequard first described the effects of introducing cold water into the ear canal. [1] The clinical importance of the phenomenon was first realized in 1906 by Barany, who developed a caloric procedure using an ice water stimulus. [2] He postulated, correctly, that caloric stimulation of the auditory canal induced formation of convection currents within the semicircular canals of the vestibular labyrinth.

Different methods of caloric testing were later proposed by Kobrak and others, but standardization of the procedure awaited the introduction of the Fitzgerald-Hallpike technique in 1942. This technique, which uses both warm and cool water stimuli under rigidly specified conditions, permits quantification of normal and abnormal caloric responses. Today, most formal caloric testing of conscious patients is based on

variations of the original Fitzgerald-Hallpike procedure. [3]

The value of caloric testing in the assessment of the comatose patient was emphasized by the work of Klingon and Bender and associates in the 1950s. Vaernet and Ethelberg studied the changes in caloric reactions during transtentorial herniation of the brainstem. Blegvad reported the effects of barbiturate intoxication on the vestibulo-ocular reflex. [8]

More recent advances include the development of electronystagmography (ENG), which provides a graphic record of reflex eye movements and permits precise determination of the intensity of the caloric response. [9] Some authorities now advocate performing caloric testing at a single temperature (monothermal calorics) as an equally sensitive and less time-consuming alternative to standard bithermal calorics. [10] Others have recently investigated the use of heated air as an alternative to traditional water caloric tests. [11]

**Physiology and Functional Anatomy**

Proper performance and interpretation of the caloric test require a basic understanding of the structure and function of both the vestibular and oculomotor systems. The anatomic pathways underlying the vestibulo-ocular reflex begin in the posterior portion of the labyrinth of the inner ear. The peripheral vestibular apparatus is located within the temporal bone and consists of the utricle, the saccule, and the lateral, anterior, and posterior semicircular canals (Fig. 66-1) (Figure Not Available) . Because of its proximity to the external ear canal, the lateral or horizontal canal is of principal interest in caloric testing. Note that the lateral canal is oriented at a 30° angle to the horizontal (Fig. 66-2) (Figure Not Available) . Deflections of the cupula due to movement of endolymphatic fluid within the canal result in polarization changes in the underlying hair cell, which in turn are relayed to the afferent limb of the primary vestibular neuron.

Impulses of the primary neuron travel via Scarpa's ganglion and cranial nerve (CN) VIII to the brainstem to synapse with secondary vestibular neurons in the superior and medial vestibular nuclei of the upper medulla and lower pons (Fig. 66-3) (Figure Not Available) . Although the connections between the vestibular and oculomotor nuclei in the brainstem are quite complex, two main pathways exist. The direct projection runs from the vestibular complex to the nuclei of CN III and VI via the medial longitudinal fasciculus (MLF) and involves only three neurons: (1) primary vestibular, (2) secondary vestibular, and (3) oculomotor. [12] The indirect projection between these nuclei occurs over multisynaptic circuits in the tegmental reticular formation. [13] Another brainstem structure that contributes to the vestibulo-ocular interaction is the parapontine reticular formation (PPRF), a poorly characterized group of pontine neurons that coordinates both voluntary and involuntary lateral gaze. The PPRF receives multiple inputs, including projections from the vestibular system and the contralateral frontal cortex, and sends output to oculomotor neurons through both the direct and indirect pathways. Excitatory impulses originating in the lateral canal finally travel via the oculomotor and abducens nerves to the ipsilateral medial rectus and contralateral lateral rectus muscles.

Rotation of the head generates flow of endolymphatic fluid within the semicircular canals. The firing rate of the primary vestibular neuron is dependent on the direction of flow. For example, in the lateral canal, flow toward the ampulla (ampullopetal) increases the firing rate, whereas flow away from the ampulla (ampullofugal) decreases the firing rate. [14] Increased firing on one side results in conjugate deviation of the eyes toward the opposite side, whereas decreased firing causes deviation to the same side. This principle forms the physiologic basis of caloric testing. When the lateral canal is placed in the vertical position and ice water is infused into the ear, the endolymph nearest the canal cools and sinks, resulting in ampullofugal flow (Fig. 66-4) (Figure Not Available) . As the firing rate decreases, the eyes deviate conjugally toward the side of irrigation. Likewise, if warm water were used in the same position or if the canal were inverted 180°, the opposite would occur.

Eye movements induced by caloric stimulation in conscious, neurologically normal individuals are more complex. Ice water infusions induce a rhythmic jerking of the eyes that includes a slow deviation toward the irrigated side followed by a quick compensatory saccade toward the midline. This is known as *caloric nystagmus.* By convention, *caloric nystagmus is named for the fast component*, thus the popular mnemonic "fast COWS" ( *C*old irrigation-- *O*pposite beating nystagmus; *W*arm irrigation-- *S*ame-sided beating nystagmus). Most sources attribute the slow phase of nystagmus to vestibular activity transmitted over the direct pathway, whereas the fast phase is believed to be generated by the PPRF in conjunction with cortical activity and carried over indirect pathways within the reticular formation. Numerous factors, including physiologic, pharmacologic, and pathologic factors, can alter caloric-induced eye movements.

**Indications and Contraindications**

Caloric testing of the comatose patient is indicated when the physician needs information regarding the functional integrity of the brainstem. When the cause of the coma is initially unknown, caloric testing may assist in differentiation among structural, metabolic, and psychogenic causes for unresponsiveness. Even when the cause is clear, caloric testing may provide an indication of the depth of coma and the prognosis for eventual recovery.

In conscious patients who complain of vertigo, caloric testing may be indicated for the nonemergency evaluation of possible vestibular disorders. Ice water produces maximal stimulation of the labyrinth. This can be quite painful and may induce nausea and vomiting in awake, susceptible individuals. These patients are best referred to a qualified neuro-otologist, who can conduct more accurate testing in the ENG laboratory with much less discomfort to the patient.

There are few contraindications to caloric testing. An absolute contraindication is the presence of a basilar skull fracture, either documented radiologically or suspected by clinical signs, because of the risk of introducing infection into the central nervous system (CNS) through an associated dural tear. If bilateral fracture can be readily excluded, testing of the intact ear with both warm and cold water will yield results similar to those

of the standard bilateral examination.

Relative contraindications to water caloric testing include perforations of the tympanic membrane (those not due to temporal fractures), otitis media and externa, and the presence of previous otologic surgery (e.g., mastoidectomy). Although the risk of otitis media is probably small, carrying out the caloric test in the comatose patient under these conditions remains a matter of clinical judgment. When available, auditory evoked potentials provide an alternative source of information when caloric testing is contraindicated.

## Equipment

The equipment needed for performance of the caloric test is minimal and is readily available in the ED or hospital ward. Although almost any size syringe will suffice, a 12- or 35-mL plastic syringe is ideal for irrigation. The syringe may be used as is, or a short length of soft plastic tubing may be attached. A good source of tubing is a butterfly catheter with the needle cut or pulled off. At least a hundred milliliters of ice water should be available, although larger quantities of cool tap water (<25° C) can be used with similar results if ice is unavailable. Sterile or bacteriostatic saline may be used, although its advantage over tap water has not been shown. A small plastic emesis basin is useful to collect water as it drains from the ear canal.

Additional required equipment includes an otoscope, several sizes of ear speculums, and equipment for removal of cerumen. Towels and a thermometer that reads from 0° to 50° C are also helpful.

## Procedure

Caloric testing should be deferred until the patient's condition has been stabilized, including protection of the airway and evaluation of the cervical spine in trauma patients. A thorough neurologic assessment should be performed prior to caloric testing, with special attention given to the ocular examination. Pupillary responses, spontaneous ocular movements, and resting eye position should be accurately recorded. The ears should be inspected prior to insertion of the otoscope. If active bleeding or CSF otorrhea or rhinorrhea is noted in the trauma victim, caloric testing and further otoscopic examination should be curtailed and the patient should be treated for a probable basilar skull fracture. If the external ear canal appears normal, the otoscopic examination should be completed. Signs of active ear infection or perforation of the tympanic membrane are contraindications to caloric testing. Tympanic rupture, hemotympanum, and step deformities of the canal may indicate fracture of the temporal bone; caloric testing in this situation is contraindicated (Fig. 66-5) (Figure Not Available) . Excess cerumen and foreign material must be removed, and the tympanic membrane must be clearly visualized.  The ear speculum may be left in the canal as a guide for irrigation.

The patient should be placed in a supine position. Ideally, the head or upper body should be raised 30° (2 pillows will provide the appropriate angle). This angle places the lateral canal in the vertical position and ensures a maximal response. The patient should be draped with a towel, and a small basin should be positioned below the ear to

collect the water outflow. A container should be filled with ice water and placed near the bedside.

The syringe and catheter system *(minus the needle)* should be filled with 10 mL of ice water, and the irrigation stream should be directed at the upper posterior portion of the tympanic membrane. Because the goal of the qualitative caloric test is to induce a maximum response, the amount and rate of infusion are not critical. As a general guide, 5 to 10 mL of ice water should be initially infused over a period of 5 to 10 seconds; amounts less than 5 mL may be advisable in suspected cases of light coma or psychogenic unresponsiveness. If no response is noted within 1 or 2 minutes, at least 100 mL should be infused before declaring that there is no response. Testing of the contralateral ear may begin 5 or 10 minutes after the eyes have returned to their original position. At the conclusion of the testing, the otoscopic examination may be repeated to check for blanching of the tympanic membrane, a sign that the irrigation stream was properly directed.

Observation of eye deviation is easier when an assistant holds the patient's eyelids open. Movement usually occurs after a latency of 10 to 40 seconds, with persistence of the response for as long as 4 or 5 minutes. Small deviations may be detected by focusing on a small scleral vessel. Alternatively, a dermographic pencil may be used to mark the initial position of the pupil with respect to the eyelid. Variations of the caloric technique may be useful in certain situations. Warm water caloric testing may be performed if no response to bilateral ice water caloric testing is obtained or in cases in which only one ear can be tested. Water temperature should be kept below 50° C. The response elicited will be the opposite of that obtained with ice water. In patients who fail to respond to ice water caloric testing alone, additional stimulation may be obtained by combining irrigation with repeated head turning away from the irrigated side ( *doll's-eye maneuver*). *Obviously, cervical injury must be excluded prior to using this technique*. This combination of techniques may produce eye movements in patients who do not respond to caloric testing alone. [15] Eviatar and Goodhill have described a technique for caloric testing in tympanic perforations using a small latex finger cot placed in the ear canal to prevent water from entering the middle ear. [16]

The technique of bilateral caloric testing is used to evaluate vertical gaze disorders and involves the simultaneous delivery of equal amounts of ice water to both ear canals. A large syringe can be attached to a Y-connector, or two separate syringes can be used. Two persons are needed to administer the caloric challenge properly. In normal individuals, upward-beating nystagmus is seen after a latency of 1 to 3 minutes (as expected, the opposite is seen with warm water). The mechanism of this phenomenon is not clear, but it may involve stimulation of the remaining 2 semicircular canals.

**Complications**

The few complications that are possible with caloric testing can be avoided by carefully selecting both the patients to be tested and the equipment and technique to be used. Using needles or other sharp objects to irrigate the ear may result in laceration or perforation of the tympanic membrane or canal wall if the patient moves unexpectedly.

The use of plastic syringes and soft catheter tubing aid in reducing such occurrences.

Other potential complications of caloric testing include otitis media, meningitis, and the induction of vomiting and subsequent aspiration. Ice water irrigation in the presence of tympanic membrane perforation increases the chance of middle ear infection; however, the incidence of this complication following caloric testing has not been reported. Meningitis may follow basilar skull fractures with meningeal tears; the additional risk of calorics in such situations is not known. Therefore, caloric testing should be omitted in the head-injured patient if there is any suspicion of temporal fracture. Although ice water irrigation may produce nausea and even emesis in a few awake patients, vomiting or aspiration has not been reported as a complication of caloric testing in the comatose patient. Nevertheless, it is advisable to delay testing until the patient's airway is protected.

## Interpretation

### The first phase of interpretation.

Analysis of initial eye position and spontaneous movements should be made prior to irrigation. The eyes of comatose patients with intact oculomotor pathways are usually directed straight ahead or are slightly divergent. Unilateral destructive lesions of the cerebral hemisphere can cause conjugate deviation of the eyes *toward* the side of the lesion, whereas irritative foci, as might be seen in status epilepticus, can cause conjugate deviation *away* from the affected side. Deviations of this type can usually be overcome by caloric stimulation, although combined irrigation and head turning may be required in the first hours following the insult. Lesions in or near the PPRF in the brainstem cause conjugate deviation *away* from the side of the lesion that usually cannot be overcome by calorics. Conjugate downward deviation can be seen with structural lesions of the brainstem or in the deeper phases of metabolic coma. Dysconjugate gaze either indicates damage at the level of the oculomotor nuclei or below or reflects disruption of the ocular muscles themselves. [17] Dysconjugate gaze may also be seen in drug-induced coma in the presence of a structurally intact brainstem pathway. In the very late stages of brainstem dysfunction, the eyes usually return to the central position. Spontaneous roving movements of the eyes, either conjugate or dysconjugate, may be seen in supratentorial insults, but these, too, disappear with brainstem involvement. [15] Ocular "bobbing" is an intermittent, spontaneous downward jerking of the eyes that may occur with massive pontine lesions. Paralysis occurs of both voluntary and reflex lateral gaze, and caloric stimulation may increase the rate of bobbing without causing lateral deviation of the eyes. [18] Ocular "dipping" is a more prolonged, downward conjugate deviation of the eyes and has been reported in cases of severe anoxic encephalopathy (e.g., carbon monoxide poisoning). [19] The pathophysiologic basis of these eye movements is poorly understood. [20]

### The second phase of interpretation.

Analysis of ocular movements after caloric irrigation. Reactions to ice water stimuli may be divided into four categories: (1) caloric nystagmus, (2) conjugate deviation, (3) dysconjugate deviation, and (4) absent responses (Fig. 66-6 (Figure Not Available) *A*

and *B*). The first reaction, caloric nystagmus with the fast component beating away from the side of ice water irrigation, is seen in normal, alert individuals; in cases of psychogenic unresponsiveness; and in those who have very mild organic disturbances of consciousness. The intensity of nystagmus is highly variable in conscious subjects and depends on the degree of visual fixation and the level of mental alertness. The response is present in more than 90% of children by the age of 6 months and declines in magnitude only after the seventh decade of life.  Corneal reflexes and responses to facial pinprick may be abolished by hypnotic suggestion in susceptible individuals; however, caloric nystagmus appears to be immune to similar manipulation. [22]

Caloric nystagmus in the apparently comatose individual is the usual result of caloric testing in cases of psychogenic unresponsiveness due to catatonia, hysterical conversion, schizophrenia, and malingering. Hyperactive caloric responses result from testing in the presence of tympanic perforation and mastoid disease. Hypoactive caloric responses are recorded in a wide variety of vestibular and neurologic disorders.

Hypoactive or abnormal caloric responses may be further evaluated with quantitative caloric testing and ENG. Caloric nystagmus may be *inverted* (beating to the wrong side) or *perverted* (beating in the wrong plane); both responses are seen in brainstem lesions. *Pseudocaloric nystagmus* is a preexisting latent nystagmus that is brought out by the general arousal of ice water irrigation; it can be distinguished from true nystagmus by its failure to reverse direction with warm water irrigation.

As the level of coma deepens, the fast phase of nystagmus becomes intermittent and finally disappears, probably as a result of decreased activity in the cerebral cortex.

In the second type of caloric response, the eyes deviate conjugately toward the side of ice water stimulation (they "look" toward the source of irritation). When present, this reaction indicates intact brainstem function. This is seen during general anesthesia, in supratentorial lesions *without brainstem compression*, and in many metabolic and drug-induced comas. In such situations, bilateral simultaneous irrigation with ice water may result in conjugate downward deviation, implying that brainstem centers for vertical gaze are functional.

Dysconjugate reactions constitute the third type of caloric response to ice water stimuli. The most common dysconjugate reaction is internuclear ophthalmoplegia, in which a lesion of the MLF causes weakness or paralysis of the *adducting* eye following caloric irrigation. Internuclear ophthalmoplegia may be due to acute damage to the rostral pons or may be seen as a manifestation of multiple sclerosis or previous vascular insult.

In acute supratentorial lesions, the development of dysconjugate caloric responses is a significant sign that may indicate compression of the brainstem and impending herniation. Caloric responses of this type are less common with metabolic and drug-induced coma, and when present in metabolic coma, their significance is less ominous. Reversible internuclear ophthalmoplegia has been reported in hepatic coma and may occur during toxic response to phenytoin, barbiturate, or amitriptyline. Forced downward deviation of the eyes, either conjugate or dysconjugate, may be seen in

sedative-hypnotic drug-induced coma when unilateral caloric testing is performed. [23]

Palsies of the oculomotor nerves are another cause of dysconjugate reactions, although most should be apparent before irrigation. Causes include diabetic neuropathy (especially CN VI), increased intracranial pressure, and Wernicke's encephalopathy. Finally, Plum and Posner report that unusual and poorly characterized caloric responses may be obtained from the testing of comatose patients with long-standing severe brain injury. [17]

Absent caloric responses are the fourth category of reactions to ice water stimuli. As a general rule, the oculovestibular response is preserved longer than other brainstem reflexes; however, the oculocephalic or doll's eye response may persist in the absence of caloric responses due to bilateral labyrinthine disease because of additional input from proprioceptive receptors in the neck. Loss of caloric responses in comatose patients with structural lesions is usually a sign of brainstem damage. In supratentorial lesions, progressive loss of caloric responses may be seen in the final stages of transtentorial herniation. The oculovestibular reflex may also be transiently absent or decreased on the side opposite massive supratentorial damage during the first hours following injury. [24] Absent caloric responses may occur in any subtentorial lesion that affects vestibular reflex pathways, including pontine hemorrhage, basilar artery occlusion, cerebellar hemorrhage, or infarction with encroachment on the brainstem, and in any expanding mass lesion within the posterior fossa. Calorics may disappear in deep coma resulting from subarachnoid hemorrhage, perhaps owing to pressure on the brainstem.

The vestibulo-ocular reflex is usually retained until the late stages of metabolic coma. Disappearance of the reflex, as in the case of hepatic coma, is frequently a preterminal event. [25] Nevertheless, caloric responses may be transiently absent in certain types of drug-induced coma, with the *eventual complete recovery of the patient.* The vestibulo-ocular reflex seems particularly sensitive to the effects of sedative-hypnotic drugs (e.g., barbiturates, glutethimide), antidepressants (e.g., amitriptyline, doxepin), and anticonvulsants (e.g., phenytoin, carbamazepine). [8] [26] [27] Obviously, neuromuscular blocking agents (e.g., succinylcholine) will abolish caloric-induced ocular movements.

Finally, the caloric response may be absent for reasons other than the neurologic causes responsible for the coma. Inadequate irrigation due to excess cerumen or poor technique and unilateral or bilateral dysfunction of the peripheral vestibular apparatus must be considered. Bilateral loss of caloric response (arreflexia vestibularis) is uncommon in conscious patients, constituting 1.7% and 0.2%, respectively, of the ENG clinical population in two large series of patients. [28] [29] Some of the causes of unilateral and bilateral loss of oculovestibular reflexes in conscious patients are listed in Table 66-1 .

* Reported rarely in conscious patients who have taken more than normal therapeutic dosage.

The vestibulo-ocular reflex has *prognostic* as well as diagnostic significance in the comatose patient. In a study of 100 patients who were comatose from head trauma, absence of calorics at 1 to 3 days following injury was associated with extremely high mortality. [30] Testing in the immediate post-traumatic period may yield inconsistent responses and is of considerably less prognostic value. Levy and coworkers studied 500 cases of nontraumatic, non-drug-induced coma in a large multicenter effort. Absence of the vestibulo-ocular reflex correlated with less than a 5% chance of achieving functional recovery within 1 year when tested within 6 to 24 hours of coma onset. [31] In one study of comatose patients, the combination of absent vestibulo-ocular reflex and absent pupillary light reflex at 24 hours was associated with a 100% mortality. [32] Complete loss of caloric responses is part of the criteria for the legal diagnosis of brain death in many localities and correlates with the irreversible cessation of cerebral function at least as well as an isoelectric electroencephalogram (EEG). [33] Excessive reliance on a single clinical sign must be avoided, and decisions regarding neurologic prognosis and future therapy should be based on complete consideration of all evidence available to the physician.

**Summary**

The caloric test is a simple, easily performed procedure that may enhance the neurologic assessment of the comatose patient, unless otherwise contraindicated. In the

emergency patient, this test should be reserved for the stable patient undergoing secondary assessment. Even when the cause of the coma is known, the test can provide a baseline for the evaluation of future changes in the patient's status. The examination requires minimal equipment and can be conducted in a few minutes while awaiting laboratory results or during preparation for computed tomographic scanning. Complications are few if patients are properly selected and correct technique is used. When reliably interpreted, caloric testing furnishes valuable diagnostic and prognostic information necessary for proper care of the comatose individual.

## MYASTHENIA GRAVIS TESTING

Myasthenia gravis is the most common disease of neuromuscular transmission, yet its incidence is only 1 in 20,000 in the general population. Patients with myasthenia may be grouped into two major categories. The first group shows weakness in proximal muscles, which increases with activity and later improves with rest. The other group presents with ocular complaints of diplopia or ptosis. Patients in this group may or may not have generalized symptoms as well. Fatigue is the hallmark of the disease; symptoms seem to wax and wane. Patients frequently see a number of physicians before a correct diagnosis is made.

Myasthenia gravis results from an immune-mediated decrease of postsynaptic acetylcholine (ACh) receptors, with variable failure of neuromuscular transmission.  ACh is the transmitter at the neuromuscular junction. When the nerve terminal is stimulated, ACh is released in a quantity far in excess of that needed for effective activation of the ACh receptor. The ACh diffuses across the synaptic cleft to transiently interact with the ACh receptor, and an electrical potential is generated at the myoneural end plate. If it is of sufficient magnitude, the end plate potential initiates an action potential that is propagated along the muscle membrane and leads to muscle fiber contraction. The ACh is rapidly hydrolized by acetylcholinesterase in the synaptic cleft. Figure 66-7 (Figure Not Available) summarizes neurotransmitter action at the neuromuscular junction. Of the millions of receptors at each myoneural junction, only a fraction must depolarize to stimulate muscle fiber contraction. Any factor that decreases the chance of interaction of ACh with ACh receptor decreases the probability of an action potential being generated. Acetylcholinesterase inhibitors (anticholinesterases) have been the mainstay of therapy for myasthenia gravis for years, but they have been supplemented by aggressive immunosuppressive regimens and thymectomy. Failure of neuromuscular transmission may also occur with *excessive* acetylcholinesterase inhibition; the persistence of ACh in the synaptic cleft leads to continuous depolarization of the receptor.

A patient with myasthenia gravis may present to the ED in one of two ways that might necessitate bedside diagnostic testing. The first presentation involves a known myasthenic patient on cholinesterase inhibitor therapy with increased weakness; pharmacologic testing in this setting is controversial and is discussed in the following section. The second presentation involves a previously undiagnosed patient in whom the diagnosis of myasthenia gravis is suspected with ptosis, diplopia, or fluctuating muscular weakness.

Various tests are available to help with the assessment of this second presentation.

ACh receptor antibody assay is now readily available and positive in more than 80% of patients. Repetitive nerve stimulation and single-fiber electromyography tests are available in the electrophysiology laboratory. [40] Several pharmacologic tests have been used, including parenteral administration of edrophonium chloride (Tensilon), neostigmine, and curare. Curare has been used systemically but can also be administered into an ischemic arm; this modification is known as the *regional curare test.* [40] Many of these tests are seldom used, or their performance falls in the realm of the neurologist's expertise. Edrophonium administration for diagnosis of myasthenia gravis (Tensilon test) is described in detail because of the drug's rapid onset, short duration of action, and widespread acceptance for this diagnostic challenge. The "ice pack" test also is included because of favorable reports of its utility and the noninvasive nature of the test.

## Edrophonium (Tensilon) Test

### Background

Edrophonium chloride (Tensilon) is an acetylcholinesterase inhibitor that has been used in the diagnosis of myasthenia gravis for more than 30 years. The short duration of action of edrophonium that made it unsatisfactory as a therapeutic agent makes it useful as a diagnostic agent. The drug's onset of action is rapid, and the duration of maximal effect is short, usually less than 2 minutes. Any effect resolves within 5 to 10 minutes. [43]

Edrophonium administration has been recommended in the past to monitor acetylcholinesterase inhibitor therapy. However, edrophonium is not sufficiently reliable for titrating the effect of anticholinesterase medication. [46]

Myasthenic crisis may be loosely defined as respiratory distress in a patient with myasthenia gravis. Earlier concepts included "myasthenic" crisis from insufficient drug administration, "cholinergic" crisis from cholinesterase inhibitor overdosage, and the "brittle" patient with rapidly changing drug requirements, but terminology in this setting remains controversial. [49] Even the clinical existence of the different types of crisis has been debated. [46] Certainly, in the myasthenic patient with respiratory distress, airway management and assisted ventilation are top priorities. Edrophonium administration should not be viewed as a possible alternative to intubation and ventilation. Several authorities advocate withdrawing all cholinesterase inhibitors in this setting because most patients show increased responsiveness to cholinesterase inhibitors after several days without taking the drug.Others advocate a trial of edrophonium chloride at reduced dosage (1 to 2 mg) only after respiratory support is achieved.

### Indications and Contraindications

The bedside Tensilon test is indicated for diagnosis in patients suspected of having myasthenia gravis. A muscle that is clearly weak must be identified. Ptosis is a commonly monitored sign. A clinically evident extraocular muscle weakness is another clinical example that might allow direct observation of a single weak muscle becoming stronger in response to the drug. Simple grip dynamometry does not aid in evaluation; a

repetitive measure of grip strength (ergogram) is necessary. If a specific muscle cannot be isolated for objective testing, edrophonium administration should be deferred and other approaches to diagnosis pursued, as discussed previously.

A history of asthma or cardiac dysrhythmias is a relative contraindication to administration of cholinesterase inhibitors. Administration of edrophonium to a patient with myasthenia gravis being treated with cholinesterase inhibitors is controversial, and many investigators consider myasthenic crisis to be a contraindication to edrophonium administration, though series of patients with myasthenic crisis continue to report its use.

### Equipment

The following materials are needed for testing an adult. Intravenous access should be secured with $D_5 W$ at a keep-open rate or with a saline lock. Ten milligrams of edrophonium chloride (Tensilon) should be drawn up in a tuberculin syringe. Edrophonium chloride is supplied in 1- and 10-mL vials at a concentration of 10 mg/mL. A second syringe of normal saline should be available to administer as a placebo, although some clinicians have recommended nicotine, calcium chloride, or atropine for this purpose. [45] Atropine and other cardiovascular drugs and resuscitative equipment should be readily available. Cardiac monitoring is generally recommended. Photographic recording equipment is desirable to objectively document improvement in motor function.

### Procedure

Ideally, one person is available to administer the edrophonium or placebo and a second person is free to observe the effect of medication on the patient. It is best if both the person evaluating the response and the patient do not know which syringe contains edrophonium and which contains saline, thus creating a double-blind testing situation.

The paretic muscle to be tested is identified. Ptosis is an easily testable sign and is generally used when present. The principles involved with assessing the effect of edrophonium on ptosis may be extended to testing other muscles. The patient is instructed to look upward for several moments in an attempt to fatigue the levator muscles. The degree of ptosis is noted and documented by measurements or photographs. After a moment's rest, with the patient looking straight ahead, 0.2 mL of the test substance in one syringe is injected (2 mg of edrophonium if active substance). If there is no response within 1 minute, another 0.3 mL is injected (3 mg of edrophonium if active substance). If there is still no response, the remainder of the syringe is injected 3 minutes later. Any increase in strength reflected by an increase in palpebral fissure size is noted. The procedure may then be repeated with the other test substance.

### Complications

A small percentage of individuals are hypersensitive to even the initial small dose of edrophonium and show cholinergic side effects of salivation, lacrimation, and miosis.

These effects are transient. Atropine, 0.5 mg, may be given IV if necessary to counteract these symptoms. A smaller number of patients may experience symptomatic bradycardia that responds to atropine.

**Interpretation**

The key to the procedure is in its interpretation. If a clearly paretic muscle has been identified, objective signs of improvement in the strength of that muscle within a moment of administration of edrophonium and the fading of that improvement over the next 5 minutes are criteria for a positive test result. Up to 90% of patients with myasthenia have a positive test result under ideal circumstances. False-negative results do occur consistently.

For evaluating the effect of edrophonium on ptosis, a positive test consists of the patient having increased ability to elevate the eyelids after administration of 5 to 10 mg of edrophonium. The ptosis returns within 5 minutes. Subjective increases in general strength or relief of fatigue do *not* constitute a positive test. Fasciculations, brief twitches of muscles, are not usually observed in the patient with myasthenia who has received edrophonium, in contrast to normal subjects. The test may be repeated in 30 minutes if necessary.

Normal subjects have no change in muscle strength. They may transiently experience the side effects of salivation, lacrimation, and diaphoresis. Perioral, periocular, or lingual fasciculations are almost always noted in the normal patient following edrophonium administration.

The reproducible and unequivocal reversal of weakness in a specific muscle is extremely specific for myasthenia. False-positive test results have been reported in patients with Eaton-Lambert syndrome and rarely in patients with intracranial lesions. Other rare reports of positive test results involve patients with amyotrophic lateral sclerosis. A "perverse" reaction has been noted rarely, in which a paretic extraocular muscle weak from other causes becomes even weaker with edrophonium administration. [56]

## Ice Pack Test

**Background**

It has been observed clinically that myasthenic patients have exacerbations of weakness with environmental heat and improvement in strength with cold temperatures. A simple bedside test uses these observations to evaluate ptosis. [41] [42] Ice placed in a surgical glove or wrapped in a towel is placed lightly over the eyelid of a patient. Cooling of the eyelid below 29° C is accomplished within 2 minutes. The ptosis has been noted to improve in 80% or more of patients tested and may be more sensitive than the edrophonium test in detecting ocular myasthenia gravis. Although the reported number of patients evaluated by this method continues to be small, the test is included here because of its potential application in the ED, its lack of side effects, and its noninvasive

nature.

**Indications**

Unilateral or bilateral ptosis of uncertain etiology in which myasthenia is a diagnostic possibility is the sole indication for this test.

**Procedure**

Ice and a surgical glove or towel are the only materials required. A camera to record any response is optional.

The degree of ptosis of the patient is noted and, ideally, photographed. Momentary upward gaze may be used to provoke the ptosis. If bilateral ptosis is present, the more affected eye should be tested. Eyelid cooling is accomplished by lightly holding the wrapped ice to the patient's eyelid for 2 minutes or until patient discomfort limits the application. The width of the palpebral fissure is immediately compared with the pretest width (Fig. 66-8) (Figure Not Available) .

**Complications**

Patient discomfort from the ice pack application may limit the cold exposure time to less than 2 minutes but still may allow a successful test.

**Interpretation**

A clear improvement of ptosis in the cooled eye is the criterion for a positive test. The effect should be reproducible. In small clinical studies, the ice pack test is at least as sensitive as edrophonium administration in improving ptosis in patients with ocular myasthenia. False-negative results do occur, probably at about the same frequency as those in Tensilon testing. One individual has been reported to have had a negative ice pack test result with a positive Tensilon test result. Negative or equivocal Tensilon tests have been reported in other individuals who had clearly positive ice pack test results. Normal individuals showed no change in palpebral fissure width after the cold exposure. There are no reports of false-positive results.

## Summary

The bedside Tensilon test has a long history of utility in diagnosing myasthenia gravis, but it has been largely replaced by acetylcholinesterase receptor assay and electrodiagnostic studies in the ambulatory setting. On occasion when rapid diagnosis is desired or myasthenia is suspected in the presence of a normal ACh receptor titer, a carefully performed Tensilon test is still clinically valuable. The use of the Tensilon test in the setting of myasthenic crisis is controversial and is discouraged.

The ice pack test is so simple and noninvasive that it should become the initial

procedure of choice in the ED for evaluating the possibility of ocular myasthenia. A positive ice pack test result strongly suggests ocular myasthenia gravis and alleviates any need for the Tensilon test. False-negative results do occur, and additional testing should be performed if the clinical suspicion of myasthenia gravis is strong.

It is often the case with neuromuscular diseases, given the broad diagnostic possibilities, that the emergency physician is unlikely to establish a confident diagnosis at a single patient encounter. [58] Appropriate consultation and referral are necessary.

# Chapter 67 - Ophthalmologic Procedures

**John R. Samples, Jerris R. Hedges**

The following discussion focuses on procedures commonly performed by emergency physicians during the evaluation and treatment of many eye injuries and diseases. The emphasis is on the practical application of the techniques, and cautions to be heeded by the emergency physician are included.

## DILATING THE EYE

Dilating the eye is an essential step in the management of common eye emergencies. It is useful for both diagnostic and therapeutic purposes. Angle-closure glaucoma may be precipitated by dilating the pupil of the patient with a narrow angle. This is not a concern in patients with open-angle glaucoma, the most common form of glaucoma. However, some patients may have a "mixed-mechanism" glaucoma with both open-angle and narrow-angle components. Systemic reactions can be produced by mucosal absorption of dilating medications. To minimize complications, the correct agent must be chosen and the proper technique used.

There are 2 types of dilators: sympathomimetic agents, which stimulate the dilator muscle of the iris, and cycloplegic agents, which block the parasympathetic stimulus that constricts the iris sphincter. Cycloplegic agents also block the contraction of the ciliary muscles, which control the focusing of the lens of the eye. This second effect of cycloplegic agents is of great importance in the therapeutic use of dilators for iritis.

Cycloplegic agents were used cosmetically as early as Galen's time. Beginning in the early 1800s, extracts from the plants *Hyoscyamus* and belladonna were used in ophthalmology. Atropine was first isolated in 1833. Epinephrine was used on eyes in 1900 as the first sympathomimetic agent. [1]

**Indications and Contraindications**

There are diagnostic and therapeutic indications for dilating the pupil. Dilation is indicated for *diagnosis* when the fundus cannot be examined adequately through an undilated pupil. Such a situation is presented by the elderly patient with miotic pupils and cataracts. Dilation is *therapeutically* useful for many ophthalmic conditions, including inflammation in the eye. In the emergency setting, corneal injury with a secondary traumatic iritis is a common example. Dilation helps the inflamed eye in 2 ways. First, it keeps adhesions (synechiae) from forming between the iris and other ocular structures. Such adhesions eventually limit the movement of the pupil and may precipitate glaucoma. Second, cycloplegic dilating agents relax the ciliary muscle spasm that often accompanies an inflamed eye and thus reduce the pain associated with inflammation.

Whenever dilation is performed, it is important to note on the patient's chart the dose

and time that agents have been given to avoid confusion during subsequent neurologic evaluation. Dilation is contraindicated in the presence of narrow anterior chamber angles. Patients who are predisposed to having narrow angles are usually unaware of this condition. Patients who are using drops such as a beta-blocker, a miotic, or an epinephrine compound are often those who have open-angle glaucoma and are not likely to have an intraocular pressure rise with dilation.

The depth of the anterior chamber can be estimated with a penlight by shining a light in from the side and seeing if the nasal side of the iris lights up. Normally, a uniform illumination of the iris is seen. However, when there is a forward convexity of the iris, only a sector of iris is illuminated with a penlight held tangential to the eye (Fig. 67-1) (Figure Not Available) . With a slit lamp, the depth of the anterior chamber angle can be assessed directly. The definitive test for assessing the anterior chamber angle is gonioscopy, in which the anterior chamber angle structures are viewed directly by means of a special mirrored contact lens and the slit lamp.

Systemic effects can develop after the application of eyedrops.  The reader should review the following sections on agents and complications before using these drugs in patients with compromised cardiovascular function.

## Agents

Only 2 dilators are really needed in the emergency department (ED). Phenylephrine (Neo-Synephrine) 2.5% is used for diagnostic dilation of the pupil for visualization of the fundus. The drug is short acting, and because accommodation is not affected, the patient's vision is not altered. Phenylephrine 10% should not be used routinely because it can seriously elevate the blood pressure in susceptible adults.   For therapeutic cycloplegia in iritis, homatropine 5% works well. Although Table 67-1 indicates a maximum duration of 3 days, 24 hours is a more common duration. Therefore, homatropine 5% is a useful agent for traumatic iritis.

Individuals with lightly pigmented irides tend to have a greater sensitivity to the cycloplegic agents than do individuals with greater pigmentation; the cycloplegic effect may therefore be more prolonged in people with light eyes. Atropine should not be used for traumatic iritis because the undesirable effects of pupillary dilation and blurred vision persist for a week or longer after healing of associated corneal abrasions. Atropine drops may be prescribed as part of the therapy for nontraumatic iritis after appropriate ophthalmologic consultation.

The physician should be aware that malingerers may use mydriatic agents to dilate a pupil unilaterally for the purpose of feigning neurologic disease. Normally, a pupillary dilation caused by intracranial third cranial nerve compression will constrict with 2% pilocarpine eyedrops. The mydriatic-treated eye can be identified by full motor function of the third cranial nerve and the absence of miosis after pilocarpine instillation. It should be noted that legitimate patients may not recall the name of an eye medicine that they used but will usually recall whether the bottle had a red cap, as is found on all cycloplegic solutions. An unexpected mydriasis in a trusted patient may be the result of such an agent. Medications that constrict the pupil, such as pilocarpine, have a green

cap. Pressure-lowering drops for glaucoma may be yellow- or blue-topped (beta-blockers), purple-topped (adrenegic agents) or orange-topped (topical carbonic anhydrase inhibitors).

**Procedure**

The instillation of mydriatic agents is similar to the administration of other eye solutions. For medicolegal purposes, visual acuity should be noted before the instillation of the medicine. This documents that any decreased vision is not the result of the mydriatic agent.

The patient is placed in a supine or a comfortable semirecumbent position. The patient is then instructed to gaze at an object (such as a fixture on the ceiling) in the upper visual field. The physician gently depresses the lower lid using a finger on the epidermis (Fig. 67-2) (Figure Not Available) . A *single* drop of the solution is instilled into the lower lid fornix, and the patient is permitted to blink and to spread the medication. More than a single drop is not recommended, because it produces reflex tearing and reduces the concentration in

| TABLE 67-1 -- Mydriatic Agents | | | |
| --- | --- | --- | --- |

§ The duration of effect shows considerable individual variation. These are general estimates.
* Preferred for funduscopic examination.
A 10% solution may produce cardiovascular reaction and hence should not be used.
Preferred for iritis or corneal abrasion therapy.

contact with the conjunctiva. The patient should be forewarned that the medication is uncomfortable and that the closed eye can be blotted but *not* rubbed with a tissue after the medicine is used. If the desired effect is not noted in 15 to 20 minutes, a repeat dose may be used, but this is seldom required.

**Complications**

As mentioned in the section on contraindications, any dilator can precipitate an attack of angle-closure glaucoma in susceptible patients. [6] In a case of angle-closure glaucoma, it may take several hours before symptoms become evident. The patient often complains of smoky vision with "halos" around lights as well as an aching pain that is sometimes severe. There may be nausea and vomiting. The affected eye becomes injected in association with a hazy cornea, elevated pressure on tonometry, and an oval, fixed pupil. Immediate consultation with an ophthalmologist should be obtained. The treatment usually includes osmotic agents, carbonic anhydrase inhibitors, pilocarpine, and, later, definitive laser or surgical procedures (Table 67-2) (Table Not Available) .

The practitioner should be aware that the use of eye medications may introduce infections. Most solutions contain bactericidal ingredients, although contamination of the tips of the droppers can still occur. [7] Only newly opened bottles of eye medication should be used if the practitioner suspects a deep corneal injury or if the patient has recently had eye surgery. Out-of-date drops and drops in which crust or other material is found around the nozzle should be discarded promptly.

Any cycloplegic (in contrast to a sympathomimetic) blurs a patient's near vision. Patients should be forewarned of this effect. Vision will be less blurred in adults older than 45 years of age, who generally have a reduced ability to focus for near vision. Although

most adults will be able to drive safely, even with both eyes affected, it is advisable to have someone else drive whenever feasible. Light sensitivity caused by pupillary dilation may also be bothersome; sunglasses are sufficient for this problem.

Systemic reactions can be produced by sympathomimetic and cycloplegic eyedrops. In one report of 33 cases of adverse reactions associated with 10% phenylephrine, there were 15 myocardial infarctions (11 deaths), 7 cases of precipitation of angle-closure glaucoma, and a variety of systemic cardiovascular or neurologic reactions. [5]

After instillation of eyedrops into the conjunctival sac, systemic absorption can occur through the conjunctival capillaries as well as by way of the nasal mucosa, the oral pharynx, and the gastrointestinal tract after passage through the lacrimal drainage system. Mucosal hyperemia enhances absorption. Symptoms can often be avoided by maintaining digital pressure on the nasal canthus, thus occluding the puncta, for several minutes after administration.

## THE FLUORESCEIN EXAMINATION

Fluorescein staining of the eye should be part of the evaluation of all cases of eye trauma and infection. It is a quick and easy technique that is crucial for the proper diagnosis and management of common eye emergencies. The fluorescein-stained cornea and conjunctiva should be viewed under a "blue" light and ideally in conjunction with slit lamp magnification (see Slit Lamp Examination).

Sodium fluorescein is a water-soluble chemical that fluoresces--it absorbs light in the blue wavelengths and emits the energy in the longer green wavelengths. It fluoresces in an alkaline environment (such as in the Bowman membrane, which is located below the corneal epithelium) but not in an acidic environment (such as in the tear film over an intact corneal epithelium). [19] Thus, it is useful in revealing even minute abrasions on the cornea.

Fluorescein was first used in ophthalmology in the 1880s. [20] It was first used as a drop, but when the danger of contamination by bacteria (especially *Pseudomonas*) was recognized in the 1950s, [21] paper strips were impregnated with fluorescein. These now are supplied in individual sterile wrappers and should be used instead of the premixed solution.

### Indications and Contraindications

Fluorescein staining is indicated for evaluation of all suspected abrasions, foreign bodies, and infections of the eye. [22] This includes "simple" cases of conjunctivitis, which may actually be herpetic keratitis. In actuality, any red eye should be stained.

Fluorescein permanently stains soft contact lenses. Therefore, when fluorescein is used, soft contact lenses should first be removed and the patient cautioned not to put the lenses back into the eye for several hours. Topically administered fluorescein is considered nontoxic, [23] although reactions to a fluorescein-containing solution have

been described. These reports of vagal reactions [24] and generalized convulsions [25] are rare and are believed to be caused by agents other than fluorescein in the solution. The practitioner who chooses to use one of the fluorescein-containing solutions rather than the fluorescein-impregnated strips should be aware of these potential idiosyncratic reactions.

The physician should also be aware that fluorescein dye may enter the anterior chamber of the eye in the presence of deep corneal defects. This form of intraocular fluorescein accumulation is also nontoxic. When the anterior chamber is viewed under the blue filter of the slit lamp, a fluorescein "flare" is visible. This flare reaction should not be confused with the flare reaction noted with iritis.

## Procedure

Ideally one should not use topical anesthetics before fluorescein staining, because some patients will develop a superficial punctate keratitis from the anesthetic, [26] which can confuse the diagnosis. However, with patients who are tearing profusely and who are squeezing their eyes shut from an abrasion or a foreign body, the examination often is impossible if a topical anesthetic is not first used.

The fluorescein strip is grasped by the non-orange end, and the orange end is wetted with 1 drop of saline (most conveniently available as a small bottle of artificial tears) or dextrose solution. The wetted strip is then placed gently onto the inside of the patient's lower lid. The strip is withdrawn, and the patient is instructed to blink. The patient's blinking spreads the fluorescein over the eye. The key to a good examination is a *thin* layer of fluorescein over the corneal and conjunctival surfaces. If the strip is heavily wetted before application in the lower fornix, the eye may become flooded with the solution, thus making evaluation difficult. On the other hand, use of a dry strip in the unanesthetized eye may be irritating. If too much dye accumulates, the patient can remove the excess by blotting the closed eye with a tissue. The physician uses a Wood lamp, the blue filter of a slit lamp, or simply a penlight with a blue filter to examine the eye in a darkened room, checking for areas of bright green fluorescence on the corneal and conjunctival surfaces. Small defects may not be seen with the naked eye; ideally, a slit lamp should be used to examine the stained cornea before ruling out a pathologic process. After completion of the fluorescein examination, excess dye should be irrigated from the eye to minimize damage to the patient's clothing from dye-stained tears.

A special use for fluorescein is in the *Seidel* test [27] for detection of perforation of the eye. To perform this test, the physician instills a large amount of fluorescein onto the eye by profusely wetting the strip. The eye is then examined for a small stream of fluid leaking from the globe. This stream will fluoresce blue or green in contrast to the orange appearance of the rest of the globe flooded with fluorescein.

## Interpretation

Fluorescein is mainly used for evaluation of corneal injuries. Although conjunctival abrasions pick up the stain, most of the staining on the conjunctiva represents patches of mucus rather than a real pathologic condition. Corneal staining is more specific for

injury, and the pattern of injury often reflects the original insult.

The corneal staining shows patterns as illustrated in [Figure 67-3](). Abrasions usually occur in the central cornea because of the limited protection of the patient's closing eyelids. The margins of the abrasions are usually sharp and linear if seen in the first 24 hours. Circular defects are seen about embedded foreign bodies and may persist for up to 48 hours after removal of a superficial foreign object. Deeply embedded objects may be associated with defects persisting for longer than 48 hours. Objects under the upper lid (including some chalazions) often produce *vertical linear lesions* on the upper surface of the cornea. When vertical lesions are noted, a *diligent search for a retained foreign body under the upper lid should be made*. Hard contact lens overuse diminishes the nutrient supply to the cornea. The central cornea receives the most injury and thus fluoresces brightly when stained. Ultraviolet light exposure from sunlamp abuse, snow blindness, or welding flash produces a superficial punctate keratitis, which in its mildest form may not be visible without a slit lamp. The central cornea is the least protected by the lids, and a central horizontal band-like keratitis can result. Herpetic lesions may develop anywhere on the cornea. Classically, these lesions are dendritic, although ulcers may also be punctate or stellate.

Any area of corneal staining with an infiltrate or opacification beneath or around the lesion should alert the practitioner to the possibility of a viral, [29] bacterial, [31] or fungal [32] *keratitis*. Urgent ophthalmologic consultation should be obtained so that cultures of the possible etiologic agents can be procured and treatment initiated.

Frequently, practitioners are unaware that many *Pseudomonas* organisms fluoresce when exposed to ultraviolet light. [33] The presence of fluorescence before the instillation of fluorescein in the red eye should suggest the possibility of a pseudomonal infection.

**Summary**

Fluorescein staining is a quick, easy diagnostic procedure that should be part of every eye evaluation. The extra minute that the examination takes provides a wealth of diagnostic information for patients with eye trauma or infection. With the exception of the reactions noted with fluorescein solution, the potential discoloration of soft contact lenses, and the potential for infection when the solutions rather than fluorescein-impregnated paper strips are used, no complications are associated with the procedure.

# EYE IRRIGATION

Eye irrigation is the crucial first step in the treatment of chemical injuries to the eye. Irrigation should be clinically appropriate to the exposure and severity of the injury. Serious chemical injury to the eye requires irrigation at the site of injury, *before* the patient is brought to the ED. [34] Corneal injury can occur within seconds of contact with an alkaline substance. Eye irrigation must often be continued in the ED.

This section discusses methods of irrigation. Although it is best to irrigate liberally,

copious irrigation is not needed when the patient has gotten a small amount of a noncaustic, nonalkaline compound in the eye.

## Indications and Contraindications

Irrigation is indicated for all acute chemical injuries to the eyes. Irrigation may also be therapeutic for patients having a foreign body sensation with no visible foreign body. Small, unseen foreign material in the conjunctival tissues may be flushed out with irrigation. There is no contraindication to eye irrigation, but if there is also a possible perforating injury to the eye, the irrigation must be performed especially gently and carefully.

## Equipment

The following equipment is necessary for eye irrigation:

Topical anesthetic, such as proparacaine 0.5%

Sterile irrigating solution (usually, intravenous saline in a bag with tubing is the easiest to obtain)

A basin to catch the fluid

Cotton-tipped applicators

Gauze pads to help hold the patient's lids open

Lid retractors

Irrigating device (e.g., Morgan Therapeutic Lens or modified central venous catheter) for prolonged irrigation

## Procedure

### Basic Technique

Topical anesthetic is instilled. Any particulate matter should be swept out of the conjunctival fornices with moistened cotton-tipped applicators. [34] This requires eversion of the upper lid (see the section on foreign body removal and Fig. 67-4) (Figure Not Available) . During actual irrigation, the lids must be held open. It is easiest to use the gauze pads to get a grip on the wet, slippery lids. At times the patient has blepharospasm to such a degree that lid retractors (Desmarres or paper clip retractors; Fig. 67-5) (Figure Not Available) may be necessary (Fig. 67-6) (Figure Not Available) . When lid retractors are used, the practitioner must be certain that the eye is well anesthetized, that the retractors do not injure the globe or the lids, and that chemicals are not harbored under the retractors. Retractors fashioned from metal paper clips (especially those that are nickel-plated and shiny) may have surface chipping which can create an ocular foreign body. [34A] Caution is needed to avert ocular injury when using

such a makeshift retractor.

Deutsch and Feller recommend an ipsilateral facial nerve block for severe blepharospasm (Fig. 67-7) (Figure Not Available) . [34] To avoid swelling of the periorbital tissue, the facial nerve is blocked just anterior to the condyloid process of the ipsilateral mandible. A line of anesthesia (2% lidocaine) is placed subcutaneously to temporarily paralyze the orbicularis muscle.

The saline exiting from the intravenous tubing is directed over the globe and into the upper and lower fornices. The choice of fluid is less important than the rapidity of irrigation initiation. Tap water should be readily available at the scene of the injury, and copious immediate irrigation should be encouraged before patient transport to the hospital. Out-of-hospital care providers should be taught to irrigate all acid injuries of the eye for at least 5 minutes at the scene and to irrigate all alkali injuries for at least 15 minutes. [35] [36] Normal saline solution is preferred for eye irrigation, because it is isotonic without dextrose. Dextrose can be quite sticky if spilled and may serve as a nutrient for an opportunistic bacterial infection. Balanced saline solution is tolerated better than normal saline, lactated Ringer's solution, or normal saline buffered with sodium bicarbonate. [37] It should be considered when normal saline is poorly tolerated during eye irrigation.

Care should be taken to direct the irrigating stream onto the conjunctiva and then across the cornea without letting the stream splash directly onto the cornea, because the mechanical injury of the solution striking the eye can of itself be harmful. Direct irrigation of the cornea can result in the development of a superficial punctate epithelial keratopathy.

**Duration of Irrigation**

Although Deutsch and Feller recommend that a full liter of irrigating solution be used in every case of caustic injury, [34] the duration of the irrigation is best determined by the extent of exposure and the causative agent. Acids are quickly neutralized by the proteins of the eye surface tissues and, once irrigated out, cause no further damage. The only exceptions are hydrofluoric and heavy metal acids, which can penetrate through the cornea. Alkalis can penetrate rapidly and if not removed (because of the slow dissociation of the cation from combination with proteins) will continue to produce damage for days. [34] Therefore, prolonged irrigation is indicated; at least 2 L of solution should be used over 20 minutes for any significant alkaline injury. [38] If the nature of the offending agent is in doubt, prolonged irrigation should be used.

Ophthalmologic consultation should be obtained for all alkaline, hydrofluoric acid, and heavy metal acid injuries. Irrigation on an inpatient basis may be required for a period of 24 hours or more. This is especially likely when the cornea is hazy or obviously thickened. It should be noted that the magnesium contained in sparklers combines with water from tears to produce magnesium hydroxide. [39] Such fireworks accidents should be treated as alkaline injuries rather than thermal injuries. Eye damage from hair straighteners, [40] phosphate-free detergents, [41] and automobile airbags [42] must also be

treated as alkaline injuries.

A good method of checking the effectiveness of irrigation is to measure the pH of the conjunctival fornices with a pH paper strip. The pH indicator on urine multi-indicator sticks can also be used. The pH indicator on urine dipsticks is conveniently closest to the handle; all the distal indicator squares can be cut off with scissors. The normal tear film pH is 7.4. If the pH measured in the conjunctival fornices after the initial irrigation is still abnormal, irrigation is to be continued. If the pH is normal after irrigation, one should check it again in 20 minutes to make sure that it remains normal.

Delayed pH changes are usually the result of incomplete irrigation and inadequate swabbing of the fornices. In anticipation of this deficiency, one should measure the pH deep in the fornices. Often, double-lid eversion with a lid elevator is required to expose the upper fornix for swabbing, irrigation, and pH testing (see Fig. 67-4) (Figure Not Available) .

**Prolonged Irrigation**

Prolonged irrigation may be required with alkali burns. Ophthalmologic consultation is essential in such situations. One technique for prolonged irrigation uses a contact lens-type irrigation device (e.g., Morgan therapeutic lens), which allows for continuous irrigation once the more vigorous irrigation described earlier has been used. During use, the device is set on the anesthetized eye, and the lids are allowed to close around the intravenous tubing adaptor (Fig. 67-8) (Figure Not Available) . Continuous flow through the device onto the cornea and into the fornices occurs. This contact lens device can become uncomfortable, because local anesthetic agents are washed out during the irrigation process; the anesthetic agent must be reapplied frequently during irrigation for patient comfort. The repeated use of the anesthetic agent may itself inhibit corneal healing.

Another irrigation device can be made for the prolonged irrigation of the fornices by modification of a small-caliber central venous catheter. Multiple perforations are made with a scissors or a scalpel in the distal portion of the catheter. This perforated section is placed in the inferior fornix of the anesthetized eye beginning at the lateral canthus and is then looped back in the upper lid fornix (Fig. 67-9) . The patient is instructed to tilt the head toward the side of the tubing to permit drainage into a laterally placed basin. After loosely applying an eye patch, one attaches the catheter to an intravenous setup for continuous irrigation. An anesthetic agent is also needed with this technique, albeit less frequently than with the contact lens-type device.

Lippas described the successful treatment of 2 alkaline burns using a similar but more invasive continuous irrigation technique for prolonged irrigation after immediate copious irrigation. [43] Continuous irrigation of an alkaline injury with a 10 or 20% acetylcysteine (Mucomyst) solution to inhibit collagenase [44] and topical (1%) calcium gluconate eyedrops [45] have been recommended, although one should await ophthalmologic consultation before using these methods.

**Complications**

The only complication from irrigation is abrasion of the cornea or the conjunctiva. This can be a mechanical injury from trying to keep the lids open in an uncooperative patient, a small corneal defect from a Morgan irrigating lens, or a fine punctate keratitis from the irrigation itself. [46] It is for this reason that the stream should not be directed onto the cornea. If a superficial corneal defect occurs, it is treated in the usual manner by topical antibiotics and consideration of patching. Deep or penetrating corneal injuries are likely to be the result of the caustic chemical and require emergency ophthalmologic consultation. In general, the emergency physician should not patch these deeper injuries. They should receive continuous irrigation pending ophthalmologic consultation. There is some experimental evidence that massive parenteral or oral ascorbic acid supplementation may prevent the development of deep corneal injury, [47] although this treatment has not gained universal acceptance.

**Summary**

Eye irrigation is easy, and complications associated with the technique are minimal. At times, the physician may be unsure whether a chemical injury is toxic enough to warrant irrigation. One should irrigate the eye if any doubt exists rather than omit this vital procedure and permit the progression of eye injury.

# OCULAR FOREIGN BODY REMOVAL

Patients with an external foreign body in the eye are frequently seen in EDs. They are often in pain and desperate for help. A high degree of suspicion for foreign body injuries and perforations of the eye is necessary, because such injuries may be occult and not readily detected. Not all foreign body injuries are associated with pain; glass embedded in the cornea may be particularly difficult to detect. This section is a review of the procedures for locating and removing extraocular foreign bodies. A brief discussion covering evaluation for perforation of the globe and for an intraocular foreign body is provided. Care of the patient after removal of an extraocular foreign body is presented.

**Indications and Contraindications**

Removal of extraocular foreign bodies is always indicated. The timing of removal and the technique that is required vary according to the patient's clinical status and the type of injury. For the most part, the emergency physician can proceed directly to removal of the object using the techniques described in this section. When the patient is extremely uncooperative (e.g., a mentally deficient individual or a young child) or when the injury is complicated (e.g., deeply embedded object, multiple foreign objects from a blast injury, or possible globe penetration), immediate ophthalmologic consultation is indicated. A penetrating injury to the cornea is particularly troublesome in that iris tissue may prolapse and may appear to represent a corneal foreign body (Fig. 67-10) (Figure Not Available) . Hence, an irregular pupil, especially a pear-shaped pupil, should alert the

clinician that a penetrating injury may have occurred.

**Equipment**

The following equipment is necessary for extraocular foreign body removal:

> Topical anesthetic, such as proparacaine 0.5%
>
> Sterile cotton-tipped applicators
>
> Fluorescein strips
>
> Magnification: loupes plus a Wood lamp or a slit lamp
>
> Eye spud or 25-ga needle attached to a 1- or 3-mL syringe or to the tip of a cotton-tipped applicator
>
> Dilator drops, such as homatropine 5% or cyclopentolate 1%
>
> Antibiotic ointment, such as erythromycin
>
> Eye patches
>
> Tape (nonallergenic paper tape is preferable)

**Consideration of Intraocular Foreign Body**

The emergency physician should always remain cognizant of the potential for an *intraorbital* or *intraocular* foreign body when examining the patient with a "foreign body" sensation. Penetrating injuries represent a greater threat of visual loss than extraocular foreign bodies and can be disastrous if overlooked.

The clinical presentation is helpful in the determination of which patients are at risk for a penetrating injury to the globe. An individual who complains of a foreign body sensation in the *absence* of trauma or one whose history is simply that something "fell" or "blew" into the eye is at *low* risk for a globe perforation. On the other hand, there is a greater probability of globe penetration in the individual who has sustained a high-velocity wound to the eye (e.g., drilling or grinding metal, blasting rock). The presence of any of the following physical findings should alert the physician to a probable *intra*ocular foreign body: irregular pupil, shallow anterior chamber on slit lamp examination, prolapsed iris, positive Seidel test (see Fluorescein Examination), focal conjunctival swelling and hemorrhage, hyphema, lens opacification, and reduced intraocular pressure. (Tonometry should not be performed in the presence of other physical findings suggesting penetration of the globe.) One should be aware that a penetrating injury may *not* be associated with eye pain. Strong historical evidence and physical findings supporting a diagnosis of penetration of the globe should prompt emergent ophthalmologic consultation.

Often, *intra*ocular foreign bodies are not visible on direct ophthalmoscopy. Although orbital radiography for radiopaque objects and ultrasonography of the globe have been used for indirect foreign body localization, [48] computed tomography of the orbit is now considered the most useful technique. [49] [50] Patients with a suspected metallic foreign body should *not* undergo magnetic resonance imaging if the foreign body may be *intra*ocular. Therapy for intraocular and intraorbital foreign bodies must be individualized. Often, an ophthalmologist can localize an intraocular foreign body (if the vitreous is clear) using indirect ophthalmoscopy. The role of the emergency physician is to suspect the diagnosis, to protect the eye from further harm, and to obtain ophthalmologic consultation. The remainder of this section addresses the problem of extraocular foreign bodies.

## Procedure

### Foreign Body Location

The first step is to locate the foreign body. A drop of both topical anesthetic and fluorescein is applied to the inside of the lower lid (see Fluorescein Examination). Vertical corneal abrasions from foreign bodies under the lids are helpful for localizing these hidden foreign objects (see Fig. 67-3 *C*). One should use a penlight and loupes or a slit lamp to examine the bulbar conjunctiva by having the patient look in all directions. The physician examines the inside of the lower lid by pulling it down with the thumb while the patient looks up. One everts the upper lid by having the patient look down as the end of an applicator stick is pressed against the superior edge of the tarsal plate of the upper lid. Meanwhile, the physician grasps the lashes and pulls down and then up to flip the lid over (Fig. 67-11) (Figure Not Available) .

Minute foreign bodies under the lid will be missed with simple visual inspection. Ideally, the everted lid should be examined under magnification with loupes or a slit lamp. With simple lid eversion it is still not possible to see the far recesses of the upper conjunctival fornix. Although double eversion of the upper lid (see Fig. 67-4) (Figure Not Available) is helpful, the best way to rule out a foreign body in the upper fornix is to sweep the anesthetized fornix with a wetted applicator as the upper lid is held everted. The applicator tip should be examined for removed foreign material. Small conjunctival foreign bodies not hidden by the lids are often best removed with a wetted nasopharyngeal swab (e.g., nasopharyngeal Calgiswab).

The cornea is then reexamined. Most corneal foreign bodies have an area of fluorescein staining around them. A slit lamp makes the examination easy. If the physician is limited to loupes and a penlight, the light is shined diagonally on the cornea. One then finds a foreign body directly or indirectly by noting a shadow on the cornea or the iris (Fig. 67-12) (Figure Not Available) .

With a history of a high-speed projectile hitting the eye, one must rule out an intraocular foreign body. Except in the case of a blast injury, if one foreign body is found on the surface of the globe, it is highly unlikely that there is a second foreign body inside the eye. If a foreign body cannot be found on the surface despite a suggestive history, the

eye should be examined for physical evidence of penetration as discussed earlier. The pupil is dilated, and the fundus is examined. If in doubt regarding an intraocular foreign body, one should consider computed tomography and ophthalmologic consultation.

**Foreign Body Removal**

Once an extraocular foreign body is located, the technique of removal depends on whether it is embedded. If the foreign body is lying on the surface, a stream of water ejected from a syringe through a plastic catheter usually washes the object onto the bulbar conjunctiva. Once the foreign body is on the inner lid or bulbar conjunctiva, a wetted cotton-tipped applicator can be gently touched to the conjunctiva and the object will adhere to the applicator tip. Overzealous use of an applicator for corneal foreign body removal can lead to extensive corneal epithelial injury. A spud device is required for removal of objects that cannot be irrigated off the cornea.

Embedded corneal foreign bodies are best removed with a commercial spud device or a short 25- or 27-ga needle on a small-diameter syringe (e.g., insulin or "TB" syringe) or a cotton-tipped applicator (Fig. 67-13 (Figure Not Available) *A* and *B*). The applicator or the syringe serves as a handle for the attached needle. Contrary to what one might expect, it is difficult to penetrate the sclera or the cornea with a needle. [51] As with removal of conjunctival foreign bodies, the eye must be well anesthetized. The patient should be positioned such that the head is well secured (preferably in a slit lamp frame). When removing a foreign body, it is useful to have an assistant present to help the patient keep the head properly positioned and the eye opened. The patient must be instructed to gaze at an object in the distance (e.g., the practitioner's ear when a slit lamp is used) to stabilize the eye further. The needle or spud device is brought close to the eye *under direct vision*, then while it is in focus, the device is manipulated under the slit lamp to remove the foreign body. The device is held *tangentially* to the globe, and the foreign object is picked or scooped out (Fig. 67-13 (Figure Not Available) *C*).

During removal, the physician should brace his or her hand against the patient's face. It also may be helpful to brace the elbow with a pad or half-full tissue box to provide further support to the arm as the foreign body is removed. The right-handed physician should place the lower hand against the left maxillary bone when removing a foreign object from the patient's left eye and against the bridge of the patient's nose or infranasal area when removing an object from the right eye. These positions should be reversed by the left-handed physician. The use of loupes or a slit lamp for magnification is highly recommended to minimize further injury during removal. In particular, corneal contact with the spud device is more readily discerned when magnification is used. Only topical anesthesia is required to remove foreign bodies from the cornea. Although the patient may feel pressure during foreign body removal, pain should not be felt after the eye is anesthetized.

**Rust Rings**

A common problem with metallic foreign bodies is rust rings. These can develop within hours because of oxidation of the iron in the foreign body. There are 2 preferred techniques for removal of a rust ring. The most direct method is to remove it at the

same time as the foreign body, either with repeated picking away with a spud device or with a rotating burr. The second approach is to let the iron of the rust ring poison and kill the surrounding epithelial cells during a 24- to 48-hour patching period. At that time, the rust ring will be soft and often comes out in one solid plug. [52] After rust ring removal, the eye must be patched again for another 24 hours to allow the residual corneal defect time to heal. Generally, a small rust ring produces little visual difficulty unless it is directly in the line of sight. The rust ring, if large, may delay corneal healing.

### Multiple Foreign Bodies

The patient with multiple foreign bodies in the eye, such as from an explosion, should be referred to an ophthalmologist. A technique that may be chosen by the ophthalmologist is to denude the entire epithelium with alcohol and remove the superficial foreign bodies. The deeper ones gradually work their way to the surface, sometimes years later.

## Aftercare

After removing the foreign body, one should patch the eye if there is any large corneal abrasion (see the section on patching). An antibiotic ointment is frequently instilled before patching, but the value of the ointment for very *superficial* corneal defects after foreign body removal is unknown. *Conjunctival* abrasions do not need patching. If the eye is patched, the patient should be reexamined in 24 hours. An antibiotic ointment is applied before placement of the patch. If the patient sustains a *superficial* injury from the foreign body and an eye patch is applied primarily for comfort, the physician may wish to instruct the patient to return only if the eye does *not* feel completely normal *or* if there is any blurred vision. The majority of superficial injuries heal without difficulty. The patient should be warned that the foreign body sensation may return temporarily before patch removal when the anesthetic agent has worn off. One animal study with direct ocular exposure to *Clostridium tetani* organisms suggests that nonpenetrating ocular injuries are unlikely to lead to tetanus. [53] However, tetanus prophylaxis appears essential for injuries that penetrate through the cornea or sclera.

## Use of Ophthalmic Anesthetic Agents

Application of topical anesthetic agents can be both diagnostic and therapeutic. Relief of discomfort with topical anesthetic use suggests, but does not ensure, a conjunctival or corneal injury. An ocular irritant may also be masked by the use of these agents. Classic teaching is that the anesthetic preparations should not be self-administered by patients. The absence of protective reflexes while the patient is under the effect of the medicine may encourage the patient to use the eye while a foreign body or a corneal infection inflicts further corneal injury.

Bartfield and coworkers found that the pain of instillation of 0.5% proparacaine was significantly less than that of 0.5% tetracaine. [54] As evident from Table 67-3 , the anesthetic solutions that are commonly used have a duration of action <20 minutes. The patient requiring patching may need a more extended period of pain relief. The discomfort associated with a large healing corneal lesion is usually made tolerable by a pressure patch, bedrest, opioid analgesics, and sedatives (e.g., secobarbital or

triazolam). Even in the absence of infection or a retained foreign body, the *repeated* use of ophthalmic anesthetic ointments may be detrimental to corneal healing. [55] Also, frequent removal of a pressure patch to anesthetize the cornea may lead to disruption of migrating corneal epithelial cells and may thus prolong corneal repair.

A final word of caution should be added regarding the use of ophthalmic solutions. Guaiac solutions are commonly supplied in dropper bottles similar in size and appearance to those containing ophthalmic solutions. Well-intentioned ED personnel may store the guaiac reagent bottles with the ophthalmic bottles. One should encourage both color coding of the bottles and examination of the bottle and its label before each use to avoid corneal injury from the guaiac reagent.

### Complications

Complications associated with ocular foreign body removal are rare. The most frequent problem is incomplete removal of the foreign body. In such cases the epithelium has difficulty healing over the affected area, and thus the eye stays inflamed. Eventually, the diseased epithelium either sloughs off and heals or heals over the foreign body remnants, which are gradually absorbed. In either case, the adverse effects on the eye are minimal; a minute scar on the cornea, even directly in the center, will rarely affect the vision. Nonetheless, incomplete removal of a corneal foreign object warrants ophthalmologic follow-up.

Conjunctivitis may develop after removal of an extraocular foreign body. In most cases, the bacteria producing the infection are introduced by the patient through rubbing of the irritated eye.

Although perforation of the globe by the physician's spud device is theoretically possible, this complication is exceedingly rare. Treatment of such a minor corneal puncture wound consists of antibiotics, eye shield placement, and ophthalmologic consultation. In the absence of resultant endophthalmitis, permanent sequelae are unlikely to develop.

Much epithelial injury can occur when cotton-tipped applicators are vigorously used to remove corneal foreign bodies. Indeed, the use of cotton-tipped applicators for *corneal* foreign body removal is condemned.

### Summary

Ocular foreign bodies are one of the most common eye emergencies. Searching for and removing the foreign body is usually straightforward. The only real trap is missing an intraocular foreign body. This must be ruled out if there is a history of a high-speed projectile hitting the eye or if physical findings suggestive of globe penetration are present.

## EYE PATCHING

Patching the lids shut has traditionally been the last step in treatment of a number of common eye emergencies. Many physicians, however, have only a vague idea of what the purpose of patching is, how to do it, and how to follow-up. Even this simple procedure can be performed incorrectly.

Patching may be used for several goals. A simple patch may be used to protect the dilated eye from bright light. Pressure patching as discussed in this section is the use of a patch to hold the eyelid closed to facilitate healing of a corneal defect, by limiting eyelid movement over an injured area.

It has been suggested in some studies that small, simple corneal abrasions do not require patching to aid healing or for reduction of pain. Unfortunately, these small studies have a number of limitations, including minimal description of the patching technique and patient compliance. In one study, 29% of eye pads "fell off during sleep." [57] However, collectively these studies support the treatment of small corneal defects (i.e., <2 mm width) without a pressure patch.

### Indications and Contraindications

Patching is indicated whenever the surface of the cornea has been injured. This can occur after a mechanical abrasion,

| **TABLE 67-3** -- Ophthalmic Anesthetic Agents | | | |
|---|---|---|---|
| Generic name | Tetracaine | Proparacaine | Benoxinate |
| Trade name | Pontocaine | Ophthaine, Ophthetic | Dorsacaine |
| Concentration | 0.5 to 1.0% | 0.5% | 0.4% |
| Onset of anesthesia | Less than 1 min | Less than 20 sec | 1-2 min |
| Duration of anesthesia | 15-20 min | 10-15 min | 10-15 min |

| | | | |
|---|---|---|---|
| Comments | Marked stinging; also available in ointment | Least irritating; no cross-sensitization with other agents | Only anesthetic compatible with fluorescein in solution |

such as a fingernail scratch, or after the removal of a foreign body. Chemical damage, damage from prolonged *hard* contact lens use, and ultraviolet light injuries, which are commonly seen in the ED, also may benefit from patching. With each of these forms of injury, the purpose of the patch is to keep the lids from moving over the cornea and to keep light out. After patching, the patient should immediately experience less pain and tearing.

Patching is contraindicated when the corneal epithelial loss results from an active infection--such as a corneal ulcer--rather than from an abrasion. The first consideration in the differentiation between ulcer and abrasion is the history of the injury (how recently it occurred and how clean the offending object was). The second determining factor is the appearance of the cornea (i.e., an ulcer will have an infiltrate of white cells beneath the area of epithelial loss and will be accompanied by a purulent discharge). Generally, abrasions associated with *soft* contact lens use should be considered infected and patching avoided until ophthalmologic evaluation. [59] Of particular concern is the rapid development of *Pseudomonas* keratitis, an unusual, but serious infection associated with corneal abrasions from soft contact lenses. A pressure patch should never be applied to an eye with a penetrating injury. A protective cup is the preferred covering in such cases pending ophthalmologic consultation.

**Equipment**

The following equipment is necessary for patching the eye:

> Gauze eye patches (2)
>
> Tape (e.g., 1-in. paper tape, preferably nonallergenic)
>
> Antibiotic ointment (e.g., sulfacetamide 10%)
>
> Dilator eyedrops (cyclopentolate [Cyclogyl] 1% or homatropine 5%)

The tape should be precut into 4-in. strips and should be kept within reach. Commercial patching products are also available and are discussed later.

**Procedure**

Before patching a corneal abrasion, one should apply both a dilator drop and an antibiotic ointment. The dilator must be a cycloplegic to relax the ciliary muscle spasm that accompanies corneal abrasions. Both cyclopentolate 1% and homatropine 5% last approximately 24 hours. The patient should be checked for a narrow anterior chamber

before the drop is instilled (see Fig. 67-1) (Figure Not Available) . Antibiotic ointment is used prophylactically, although it is rare for abrasions to become infected. [60] In the past it was thought that the ointment vehicle would slow epithelial healing, but the vehicles that are currently used do not have this effect.

An effective patch must be put on tightly enough to keep the lids shut. The physician should have the patient shut both eyes and should remind him or her to keep them shut throughout the entire procedure. Two patches are used. The vertically positioned first patch is doubly folded and placed over the closed lids. The unfolded second patch is then put horizontally over the first (Fig. 67-14) . The tape strips are stretched diagonally from the center of the forehead to the cheekbone. The physician can pull up the skin of the cheek; when he or she lets go, the tape will be even tighter. If the tape completely covers the patch, slippage of the patch and resultant eye movement are avoided (Fig. 67-15) (Figure Not Available) . The tape should not extend onto the angle of the mandible, because mastication loosens the tape in such a situation. Some physicians paint the skin about the eye with tincture of benzoin to help secure the tape. Care must be taken not to introduce the benzoin into the eye. The presence of extensive facial hairs may prevent tight taping of the patch. An adjustable elastic strap pressure patch (e.g., Presspatch II, Precision Therapeutics, Inc, Las Vegas) may be useful in this setting (Fig. 67-16) (Figure Not Available) . Anecdotally, the patient must be carefully instructed in the use of this commercial patch and avoidance of excessive globe pressure from the elastic straps must be confirmed.

It is imprudent to leave a pressure patch on for >24 hours. When repatching to promote healing is required, a clean patch should be applied within each 24 hours. Repatching prevents a patch from becoming moist and serving as a nidus for the development of infection.

The Donaldson Eyepatch (Keeler Instruments, Inc, Broomall, Pa) is a commercial product used for enforced eyelid closure that avoids the bulkiness of pressure patching (Fig. 67-17) (Figure Not Available) . The device has 2 components: one adheres to the upper lid, and the other is a circle that adheres to the ipsilateral cheek. A tab on the upper component connects by Velcro to the lower component. This patch may be advantageous in some settings, but its design may encourage some individuals to release the lid closure prematurely.

Because of conjugate eye movement, patching only one eye does not totally immobilize the globe. When all movement must be stopped, bilateral eye patches should be applied. The use of bilateral patches may not be accepted by all patients, and one must seek both patient understanding and family support for patient home activities if dual eye patching is to be successful.

## Complications

There are few complications involved in patching. It is possible to patch the patient's lashes in between the lids so that they abrade the cornea. This can occur if the patient partially opens the eye during the procedure. This can be avoided by insisting that both

eyes stay closed during the entire patching.

Most problems develop when the eye is not securely patched and excessive lid motion occurs. In this situation the corneal epithelial cells are not permitted to migrate over and close the epithelial defect. This leads to increased pain and delayed healing. Some corneal defects are extensive and may require 3 to 5 days for healing. Patients with extensive injuries should be observed frequently and treated with cycloplegic agents, pain medication, and (if clinically indicated) sedatives for sleep. The practitioner should document the size of the corneal defect at each visit. If healing does not occur in a progressive fashion, ophthalmologic consultation should be obtained. As mentioned earlier, patching is contraindicated when a corneal ulcer is present. A corneal "abrasion" that does not heal could very well be a herpetic ulcer.

All patients whose eyes have been patched for a corneal abrasion should be warned about possible *recurrent corneal erosions* that might occur in the future as a complication of the original injury. The original abrasion may appear to have healed perfectly, but days, weeks, or even months later a small area of corneal epithelium can come off, re-creating the symptoms of the original abrasion in the absence of new trauma. This usually occurs in the mornings as the patient opens the eyes, presumably due to adherence of the weaker, recently healed corneal epithelium to the upper lid during sleep. These erosions may heal before the patient is reexamined and can be very puzzling. The cause is a failure of bonding of the corneal epithelium to its basement membrane. [63] Patients who develop this syndrome are given 5% sodium chloride ointment to use nightly to prevent the erosions; some require bandage soft contact lenses. [64]

**Summary**

Patching should be an easy, straightforward procedure. A common problem is the lack of follow-up instructions given to the patient after the patching. Too often, the patient is given a bottle of antibiotic drops to be used every 4 hours and only vague recommendations for a follow-up check. When patients remove the patch to put in an antibiotic drop, they are never able to replace the patch properly again. Instead, they should be told to keep the patch on for 24 hours and to return to have their abrasion checked by a physician after that time. This is the only safe way of ensuring that the abrasion has healed properly. As discussed earlier, trustworthy patients with very *superficial* corneal injuries may be given more responsibility (and instruction) for their own subsequent care, and many such cases do not require a patch at all. The physician should, however, make a follow-up telephone call to these individuals if they choose not to return to ascertain their compliance with the instructions.

The patient with an eye patch should be instructed to rest the uninjured eye. Reading should be discouraged, because involuntary movement of the patched eye will result. Watching television from a distance of 10 feet or more promotes eye fixation and is acceptable. Distant vision is unaffected by patching, although a small degree of peripheral vision is lost on the patched side. Although the visual field is minimally affected, driving after a patch is placed is not advisable. Preferably, the patient should be driven home from the hospital to minimize the potential for patient injury. An elderly

patient may require assistance with routine ambulation after eye patching. Use of collagen shields applied directly to the cornea may offer an attractive alternative to eye patches. [65] These devices have yet to be introduced into ED practice.

# CONTACT LENS PROCEDURES

An estimated 24 million Americans wear a form of contact lenses. [66] Removal of these lenses in the ED may be required to permit further evaluation of the eye or to prevent injury from prolonged wear. Emergency physicians also evaluate patients for "lost" contact lenses, which may be trapped under the upper lid. At times, the patient may request that the physician remove a lens that he or she has failed to extract from the cornea. Corneal ulcers may occur in patients who wear contact lenses and may require prompt treatment. This section on contact lens procedures addresses these concerns and discusses injuries associated with removal attempts, the mechanism of injury from prolonged wear, and instructions to be given to patients at discharge.

The first contact lenses were scleral lenses made of glass. These lenses, covering the cornea as well as much of the surrounding sclera, are reported to have been in use from 1888 to 1948. [67] Glass corneal lenses (sitting entirely on the cornea) made by the Carl Zeiss Optical Works of Jena were first described in 1912. A practical synthetic scleral lens using methyl methacrylate rather than glass was discussed by Obrig and Mullen in 1938. [68] [69] In 1947, Tuohy redeveloped the corneal lens using methyl methacrylate. This was the forerunner of the current hard contact lens. [70] The development in Czechoslovakia of lenses made of soft gas-permeable polymers was reported in 1960. [71] These hydrogel (hydrophilic gelatinous-like) lenses have evolved into today's soft contact lenses. Soft contact lenses now come in a variety of types including extended and daily wear. Some extended-wear lenses are disposable. All lenses should be removed at least once a week.

## Mechanism of Corneal Injury from Contact Lens Wear

### Hard Contact Lenses

The oxygenation of the cornea is dependent on movement of oxygen-rich tears under the hard contact lens during blinking. During the "adaptation" phase of early wear, the wearer of hard contact lenses produces hypotonic tears as a result of mechanical irritation from the lens. [72] This results in corneal edema, which reduces subsequent tear flow under the lens during blinking. Overwearing a lens at this time leads to corneal ischemia, with superficial epithelial defects predominantly in the central corneal area (see Fig. 67-3 *D*), where the least tear flow occurs. With adaptation, the tears become isotonic and the blinking rate normalizes, permitting increased wear time. During early adaptation blinking is more rapid than normal and then slows to a subnormal rate during late adaptation. Mucus delivery to the cornea in the tear film may also play an important role in maintaining corneal lubrication. Tight-fitting contact lenses may never permit good tear flow despite an adaptation phase; individuals with tightly fitted lenses may never be able to wear their original contact lenses for longer than 6 to 8 hours. Lenses that are excessively loose can also cause irritation by moving during blinking. Rough or

cracked edges can cause corneal abrasions.

In the ED, the patient who presents with irritation caused by prolonged wear may be either a new or an adapted wearer. The adapted wearer may have been exposed to chemical irritants (e.g., smoke), which reduce the tonicity of tears and lead to corneal edema and decreased tear flow. Alternatively, the adapted wearer with irritation may have ingested sedatives (e.g., alcohol) or may have fallen asleep wearing the contact lenses, thus decreasing blinking and tear flow. Another possibility is that the patient may actually be wearing tight-fitting contact lenses that have never allowed true adaptation despite many months of wear.

The patient with the overwear syndrome usually awakens a few hours after removing the lenses. The patient experiences intense pain and tearing similar to that caused by a foreign body. The delay in the onset of symptoms until after removal of the lenses is caused by a temporary corneal anesthesia produced by the anoxic metabolic by-products that build up during extended lens wear. [73] A second factor is the slow passage of microcysts of edema, which are pushed up to the corneal surface by mitosis of the underlying cells. When the cysts break open on the surface, the corneal nerve endings are exposed. [74]

Most patients with the overwear syndrome can be managed with reassurance, frequent administration of artificial tears, oral analgesics, and advice to "wait it out" in a darkened room. Some patients require patching for comfort. A patient who has experienced no problems with contact lenses before an overwear episode can return to using the lenses after 2 or 3 days of wearing glasses but should be advised to build up wearing time gradually. A patient who was having chronic problems with lens comfort before the episode should check with an ophthalmologist before using the contact lenses again.

**Soft Contact Lenses**

Although there is also oxygenation of the cornea by way of the tear film with soft contact lenses, only approximately one tenth of the flow behind the lens that occurs with a hard lens is present during soft contact wear. [75] The high degree of lens gas permeability permits the majority of oxygenation to occur directly through the lens. The hydrogel lens is more comfortable than the hard contact lens because lid motion over the lens is smooth. The minimization of lid and corneal irritation allows a more rapid adaptation phase because the initial reflex-induced tearing and blinking changes are reduced. Nonetheless, the lenses may still lead to corneal edema and secondary hypoxic epithelial changes if worn for an excessive period when blinking is inhibited. Some individuals can tolerate the lenses for extended periods and may on occasion sleep with the contact lenses in place, although this practice is not encouraged. Newer extended-wear hydrogel lenses (e.g., Permalens) permit wear for several days without injury. These lenses are not discernible from standard soft lenses on examination.

Although the acute overwear syndrome that occurs with hard contact lenses can also occur with soft lenses, it is infrequent. More commonly, ocular damage from soft contact lenses falls into one of the 3 following categories:

1. *Corneal neovascularization.* Often the patient is asymptomatic, but on slit lamp examination fine vessels are seen invading the peripheral cornea. The treatment is to have an ophthalmologist refit the patient with looser or thinner lenses or with contact lenses that are more gas permeable.
2. *Giant papillary conjunctivitis.*[76] The patient notes decreased lens tolerance and increased mucus production. On examination of the tarsal conjunctiva (best seen on eversion of the upper lid), large papillae are seen. These grossly appear as a cobblestoned surface. The treatment is to discontinue wearing the lenses until the process reverses and then have the lenses refitted.
3. *A sensitivity reaction to the contact lens solutions* (usually thimerosol or chlorhexidine). There is diffuse conjunctival injection and sometimes a superficial keratitis. The treatment is to switch to preservative-free saline with the use of heat sterilization. Often, the contact lenses will need to be replaced before lens wear can be resumed.

All of these problems with soft lenses have bilateral, subacute onsets and do not require emergency treatment. The only form of ocular damage associated with soft contact lenses that is a true emergency is a bacterial (often *Pseudomonas* or *Acanthamoeba* with soft contact lenses) or fungal corneal ulcer. Because the nature of soft contact lenses is to absorb water, they also can absorb pathogens, which then can invade the cornea. This is especially true if the soft lens is worn continuously for extended periods of time. The patient presents with a painful, red eye associated with discharge and a white infiltrate on the cornea. Immediate ophthalmologic consultation is required for appropriate culturing and antimicrobial treatment because these infections can permanently affect the patient's visual acuity.

**Indications for Removal**

Removal of a contact lens is recommended in the following situations:

1. *Contact lens wearer with an altered state of consciousness.* The emergency physician should always be aware that the patient with a depressed or acutely agitated sensorium may be unable to express the need to have his or her contact lenses removed. Furthermore, it is likely that patients with a depressed sensorium will have decreased lid motion. During the secondary survey of these patients, the emergency physician should identify the presence of the lenses and should arrange for their removal and storage to prevent harm from excessive wear or possible accidental dislodgment at a later time. Without magnification, soft contact lenses may be difficult to see. Examination with an obliquely directed penlight should reveal the edge of the soft lens 1 to 2 mm from the limbus on the bulbar conjunctiva.
2. *Eye trauma with lens in place.* After measurement ofvisual acuity with the patient's lenses in place, the lenses should be removed to permit more detailed examination of the cornea. Fluorescein may discolor hydrogel lenses; when possible, extended-wear lenses should be removed before the use of this chemical. After the dye is instilled, the eyes should be flushed with normal saline; at least 1 hour should pass before reinsertion. [82] The availability of single-use

droppers of 0.35% fluorexon (Fluresoft) has permitted the safe staining of eyes when soft lenses are to be worn immediately after the examination. A limited eye irrigation after the use of fluorexon drops is still recommended before the reinsertion of soft contact lenses.

3. *Inability of the patient to remove the contact lens.* A patient may present with a hard contact lens that cannot be removed because of corneal edema from prolonged wear. Alternatively, the patient may present with a "lost" contact lens that is believed to be behind the upper lid. There is no urgency for contact removal in the out-of-hospital setting; hence, removal can wait until the patient has been evaluated by a physician.

## Contraindication to Removal

The only major problem with contact lens removal occurs when the cornea may have been perforated. In this case, the suction cup technique of removal described later is preferred.

## Procedure

### Hard Contact Lens Removal

A number of maneuvers have been devised for removal of the corneal lens. One technique is to first lean the patient's face over a table or a collecting cloth. The physician pulls the lids temporally from the lateral palpebral margin to lock the lids against the contact lens edges. The patient should look toward the nose and then downward toward the chin. This movement works the lower eyelid under the lower lens edge and flips the lens off the eye. The technique requires a cooperative patient, because the physician must pull the patient's lids tightly against the edge of the contact lens. The movement of the patient's eye then flips the contact free.

In the unresponsive patient, a modification of the technique can be used while the patient is supine. The physician takes a more active role in lid movement using the following procedure: One thumb is placed on the upper eyelid and the other on the lower eyelid near the margin of each lid. With the lens centered over the cornea, the eyelids are opened until the lid margins are beyond the edges of the lens (Fig. 67-18 (Figure Not Available) *A*). The physician then presses both eyelids gently but firmly on the globe of the eye and moves the lids so that they are barely touching the edges of the lens (Fig. 67-18 (Figure Not Available) *B*). One presses slightly harder on the lower lid to move it under the bottom edge of the lens. As the lower edge of the lens begins to tip away from the eye, the lids are moved together, allowing the lens to slide out to where it can be grasped (Fig. 67-18 (Figure Not Available) *C*). The physician should remember to use clean hands (and preferably wear examination gloves that have been rinsed in tap water or saline) when removing the lens.

Alternatively, one can move the lens gently off the cornea using a cotton-tipped applicator to guide the lens onto the sclera, where the applicator tip can be forced under an edge of the lens to flip the contact loose. Topical anesthesia is indicated when using an applicator and the patient is awake. Care must be taken with this technique to avoid

contact of the applicator with the cornea when the lens is moved off the eye. Perhaps the easiest technique is to use a moistened suction-tipped device and simply lift the lens off the cornea (Fig. 67-19) (Figure Not Available) .

Several lenses (those hard contact lenses that cover both the cornea and an amount of the sclera) can be removed by an exaggeration of the manual technique described earlier (Fig. 67-20) (Figure Not Available) . Elevation of the lens with a cotton-tipped applicator or a suction-tipped device is also an effective technique. Soft contact lenses should not be removed with a suction-tipped device because tearing or splitting of the lens may occur.

### Soft Contact Lens Removal

With clean hands (preferably using gloves rinsed in saline or tap water), the physician pulls down the lower eyelid using the middle finger. The tip of the index finger is placed on the lower edge of the lens. The lens is slid down onto the sclera and is compressed slightly between the thumb and the index finger. This pinching motion folds the lens and allows its removal from the eye (Fig. 67-21) (Figure Not Available) .

## Lens Storage

After a contact lens has been removed, it should be stored in sterile normal saline solution. It is best to use the patient's own storage container and, if available, the patient's lens solution. A variety of alternative sterile containers are available for use in the ED. One should be certain that right and left lenses are kept separate and in appropriately labeled containers. The containers should be kept with the patient until a friend or family member can procure them or should be locked with the patient's valuables.

## Evaluation of the "Lost Contact"

A patient may present with a request to be examined for a "lost" contact lens. The patient may be unsure if the lens is hidden under a lid, remains on the cornea, or is truly outside the eye.

The evaluation of the patient with a "lost" contact should begin, as should all eye examinations, with the measurement of visual acuity. Visual acuity is preferably measured using a 20-foot eye chart. A diminished visual acuity in the eye in which a patient just cannot seem to "take out" a soft contact lens may be the most convincing evidence that the lens is missing. Although transparent, soft contact lenses in proper position are usually seen easily when viewed closely with loupes or on slit lamp examination. The lens forms a fine line where it ends on the sclera several millimeters peripherally to the limbus. Hard contact lenses are even more evident as they change in position on the cornea.

If the contact is not evident on initial inspection, the lids are everted as discussed in the section on foreign body removal (double eversion of the upper lid). If the lens is still not

visible, a drop of topical anesthetic is placed in the eye. The upper fornix is gently swept with a wetted cotton-tipped applicator while the patient looks toward the chin. If the lens is still not evident although the patient remains insistent that it is in the eye, one may perform a fluorescein examination after explaining that the dye will color the lens (permanently). The upper lid should again be doubly everted and visualized using an ultraviolet light source.

If the lens remains elusive, the patient should be reassured that a thorough examination has been performed and that no object has been located under the eyelids or on the cornea. The cornea should then be examined for defects that warrant antibiotic ointment and a pressure patch placed (as discussed in the section on patching). Follow-up with the patient's eye specialist for a replacement lens and further reassurance is encouraged. One also should ask the patient to retrace movements at the time the contact began to give trouble or was missed and to check the clothing being worn for the presence of the lens. A final possibility is that the patient may have accidentally placed the 2 lenses together in the same side of the carrying case, causing them to stick together. In fact, patients have inadvertently placed one contact lens over the other--both in the same eye! One should note that hard contact lenses have been found embedded in conjunctival tissue under the upper lid (Fig. 67-22) (Figure Not Available) , at times for more than a year. [83] [84] Hence, a methodical approach as outlined earlier should be taken to ensure that no lens remains hidden in the eye.

**Complications of Lens Removal**

Unless care is used during lens removal, a corneal abrasion can occur. It may be difficult at times to determine whether the injury was produced by the patient or was a result of the physician's technique. Fortunately, the corneal injury is usually of a superficial nature and responds well to eye patching.

**Summary**

Contact lens removal is seldom a difficult task. More challenging situations are the identification of emergency patients at risk for corneal injury due to overuse, the evaluation of patients who cannot locate a soft lens, and the instruction of patients with contact lens-related problems concerning aftercare.

# INFECTIOUS KERATITIS

Infectious keratitis with corneal ulceration can have a variety of causes, including the overwear of contact lenses. Diagnosis of a corneal ulcer requires the use of a slit lamp and an accurate determination of the patient's history. Infectious keratitis is a frequent problem in ophthalmic practice. Herpes simplex is a common corneal pathogen. *Acanthamoeba* is another pathogen that has been particularly associated with contact lens use and exposure to organism-tainted environments. Patients presenting with a corneal ulcer require prompt referral to an ophthalmologist. When immediate referral to an ophthalmologist is not possible, bacterial and viral cultures need to be obtained and

therapy needs to be initiated.

Patients with herpes simplex keratitis will often give a history of prior episodes of the disease. Patients who undergo almost any form of corneal stress may sustain an activation of preexisting corneal disease. Herpes simplex keratitis is classically recognized by its dendritic pattern on fluorescein staining.

*Acanthamoeba* keratitis is a recently described disease with potentially devastating consequence. Its frequency seems to be increasing particularly in contact lens wearers, and its pathophysiology is not completely understood. Patients will often present with a red eye in which initial bacterial culture results are negative.

Bacterial keratitis can occur in a variety of settings. Organisms range from the relatively common *Staphylococcus* or *Streptococcus* to *Mycobacterium,* which can be difficult to identify. A variety of antibiotics are used against bacterial agents. Ciprofloxacin is a quinolone that has demonstrated efficacy against most of the common causative agents. Bacterial organisms in the cornea can develop resistance to any antibiotic and resistance to fluoroquinolones has been observed. [85] Ideally, treatment should follow culturing of the ulcer.

In instances in which a cellular infiltrate is seen on slit lamp examination and in which there will be a delay of hours before an ophthalmologic consultant can culture the patient, it may be prudent to initiate therapy with topical ciprofloxacin. In such circumstances, the emergency physician may obtain corneal cultures under the telephone guidance of the consultant before administering the antibiotic. One approach is to lightly touch a culture-moistened cotton-tipped swab against the ulcer and then streak standard culture media. If the ulcer has been chronic or the patient is immunocompromised, fungal cultures also should be obtained. Finally, a saline-moistened cotton-tipped swab can be used to obtain a Gram stain of the ulcer. Initiation of therapy before obtaining specimens for culture will make the subsequent identification of an organism difficult, and for this reason the immediate initiation of treatment must depend on the circumstances of the individual case.

## TONOMETRY

Tonometry is the estimation of intraocular pressure obtained by measurement of the resistance of the eyeball to indentation of an applied force. Elevated intraocular pressure is associated with visual field loss and blindness. Sudden elevation of intraocular pressure can follow trauma or occur with primary angle-closure glaucoma. Often, patients with primary angle-closure glaucoma come to the ED with systemic complaints that include nausea, vomiting, and headache; the emergency physician must determine the intraocular pressure and its relationship to the systemic symptoms. Occasionally, such patients are surprisingly free of pain in or about the eye.

Patients with an elevated intraocular pressure are at risk for retinal hypoperfusion when their systemic blood pressure is suddenly lowered. The emergency physician who treats patients in shock or uses potent antihypertensive agents needs to remain vigilant for the development of decreased retinal perfusion. Monitoring such patients for retinal artery

perfusion with the direct ophthalmoscope is helpful.

Ophthalmologists depended on tactile estimation of eye pressure until the 1860s, when von Graefe developed the first mechanical tonometer. [86] Applanation tonometry was introduced in 1885 by Maklakoff [87] but was not popularized until Goldmann improved the instrument in the 1930s. [88] Schiotz developed an impression tonometer in 1905 and modified it in the 1920s; this form is still in use today. [89] Aside from modifications in configuration, current tonometers closely resemble the devices popularized by Schiotz and Goldmann. The most dramatic variations are the Mackay-Marg tonometer, [90] which permits a continuous tonographic recording, and the noncontact tonometer, which is a pneumatic applanation tonometer. [91] Pocket-sized tonometers using the MacKay-Marg tonometer principle are available. One such device is the Tono-Pen XL (Mentor O & O, Inc, Norwell, Mass). [92] These devices are portable, lightweight, and relatively accurate, with built-in provisions for calibration. They have the advantage of using a one-time-use cover that eliminates concern about the possible transmission of an infectious agent.

**Tonometric Techniques**

Three tonometric techniques are reliable and clinically useful for estimating intraocular pressure:

1. The impression method uses a plunger 3 mm in diameter to deform the cornea and then the "indentation" is measured. This technique was popularized by Schiotz and commonly bears his name.
2. The MacKay-Marg method is a refined version of the impression technique in which smaller amounts of cornea are indented.
3. In the applanation method a planar surface is pressed against the cornea.

One can either measure the pressure necessary to flatten a defined area or determine the size of a flattened area produced by the defined pressure. These tonometric techniques are based on the Imbert-Fick law, which states that if a plane surface is applied with force (F) to a thin, spheric membrane within which a pressure ($P_t$) exists, at equilibrium the expression $P_t = F/A$ is valid if A is the area of the applied surface (Fig. 67-23) (Figure Not Available) . The Schiotz tonometer (Fig. 67-24) (Figure Not Available) actually measures the total intraocular pressure (initial pressure plus the pressure added by the weight of the tonometer and the plunger). Friedenwald [93] empirically found that a "rigidity coefficient" could be introduced to allow an estimation of the true intraocular eye pressure. One must be aware, however, that calculated conversion tables for Schiotz tonometers use an average estimate of the rigidity coefficient and hence are not accurate when eye rigidity is altered (e.g., after scleral buckle procedures for retinal detachment or with extreme myopia). Although the applanation tonometer (Fig. 67-25) (Figure Not Available) also increases the intraocular pressure during measurement, the applied pressure is much smaller and is partially countered by the surface tension of the eye tear film. Studies have shown the applanation tonometer measurements to be within 2% of the true intraocular pressure. [94]

The noncontact tonometer is a pneumatic applanation tonometer that permits

intraocular pressure measurement without eye contact. A pulsed air jet is used to deform the cornea. The technique is also dependent on ocular rigidity. Although readings taken by different examiners correlate well, the measurements are altered by the use of local anesthetics and show a wide standard deviation of measurement in patients with pathologic elevation of ocular pressure (when standard applanation tonometry is used as a reference). [95] Furthermore, the technique is not useful with corneal surface irregularities (e.g., corneal edema, keratoconus, corneal perforation) or when medications in viscous preparations have been used. The use of this type of tonometer is not recommended when accurate determination of the intraocular pressure is required. This type of device is primarily useful for glaucoma screening.

**Indications for Tonometry**

Measurement of intraocular pressure in the ED is part of any complete eye examination. Special situations in which tonometry is required are as follows:

1. *Confirmation of a clinical diagnosis of acute angle-closure glaucoma.* The middle-aged or elderly patient who presents with acute aching pain in one eye, blurred vision (including "halos" around lights), and a red eye with a smoky cornea and a fixed midposition pupil obviously needs a pressure reading. Sometimes the findings are less dramatic, and sometimes the patient complains mostly of nausea and vomiting that suggest a "flu" rather than an eye disorder.
2. *Determination of a baseline ocular pressure after blunt ocular injury.* Patients with hyphema often have acute rises in intraocular pressure because of blood obstructing the trabecular meshwork. [96] Later, angle recession can cause a permanent form of open-angle glaucoma. Arts and coworkers suggest that an intraocular pressure >22 mm Hg or a difference of 3 mm Hg or greater between eyes is a good marker for "ocular injury" in the setting of an orbital fracture. [97]

3. *Determination of a baseline ocular pressure in a patient with iritis.* Patients with iritis can develop both open- and closed-angle glaucoma as well as corticosteroid-induced glaucoma.
4. *Documentation of ocular pressure in the patient at risk for open-angle glaucoma.* All patients older than 40 with a familial history of open-angle glaucoma, optic disc changes, visual field defects, and pressures over 21 mm Hg should be referred to an ophthalmologist for further work-up. Referral should also be made for those patients with suspiciously cupped discs who have normal pressures; some of these patients may have "low pressure" glaucoma associated with visual field defects.
5. *Measurement of ocular pressure in patients with glaucoma and hypertension.* There is conflicting evidence  concerning the relationship between acute reductions in systemic blood pressure and further visual field loss in glaucoma patients. Progressive or rapid visual field loss is a rare but reported phenomenon in association with systemic blood pressure reduction. The prudent physician measures the intraocular pressure and consults with the glaucoma patient's ophthalmologist before instigating treatment for systemic hypertension. Consideration should also be given to the use of a beta-blocker to lower

intraocular and systemic pressures simultaneously.

## Contraindications to Tonometry

Tonometry is relatively contraindicated in eyes that are infected unless one is using a device such as the Tono-Pen XL, which uses a sterilized cover. [106] One should sterilize a tonometer before and after applying it to a potentially infected eye. Infected eyes are preferably measured with either a noncontact tonometer or a device with a covered tip (e.g., Tono-Pen). The contact portions of any device should be swabbed with alcohol and allowed to dry before use on another eye. Not all viruses may be destroyed by alcohol cleansing. Hydrogen peroxide is effective for deactivating the human immunodeficiency virus responsible for the acquired immunodeficiency syndrome (AIDS). Ultraviolet sterilization, cold-sterilizer bathing of the footplate and plunger, and ethylene oxide sterilization have been advocated as alternatives to sterilize the Schiotz tonometer tip. The Schiotz tonometer may also be used with sterile disposable coverings (marketed as Tonofilm). Nonetheless, measurement of intraocular pressure in an obviously infected eye can be deferred until a subsequent visit to the ED or private physician unless the red eye demands an immediate determination of intraocular pressure.

Examples of a need for immediate tonometry in the setting of a red eye are suspected angle-closure glaucoma (acute onset of redness and pain in the eye with smoky vision, a cloudy cornea, and a fixed pupil in mid-dilation) and iritis (ciliary injection with photophobia), in which secondary angle-closure or corticosteroid-induced pressure changes may occur. Reported cases of conjunctivitis spread by tonometry predominantly tend to be viral infections. Particular efforts should be made to avoid use of the instrument on patients with active facial or ocular herpetic lesions or on patients who may have AIDS.

The presence of corneal defects also represents a relative contraindication to tonometry. [20] The use of a tonometer on an abraded cornea may lead to further injury and is commonly deferred until a subsequent visit. Patients who cannot maintain a relaxed position (e.g., because of significant apprehension, blepharospasm, uncontrolled coughing, nystagmus, or uncontrolled singultus) are unlikely to permit an adequate examination and can receive corneal injury when sudden movements occur during an examination. Furthermore, tonometric examination, with the exception of the palpation technique (through the lids) and the noncontact method, should not be performed on a cornea without complete anesthesia.

Tonometry should *not* be performed with a suspected penetrating ocular injury. [106] Globe perforation may be exacerbated by pressure on the globe with resultant extrusion of intraocular contents. Slit lamp examination can be used for detection of a possible perforation.

## Procedure

**Palpation Technique**

All forms of tonometry are essentially ways of determining the ease of deforming the eye; an eye that can easily be deformed has a low pressure. The most direct way to do this is simply to press on the sclera through the lids and grossly compare one eye with the other. One can easily distinguish the rock-hard eye of acute glaucoma from the normal opposite eye by this method. Another method is to anesthetize the eyes topically and press a wetted applicator on the sclera of each eye. Again, eye deformation is inversely related to ocular pressure. Rigidity of the globe also is a factor in this crude method of tonometry.

**Impression (Schiotz) Technique**

Use of the Schiotz tonometer requires relaxation on the part of the patient and steadiness on the part of the physician. The patient is placed in either a supine or a semirecumbent position and is instructed to gaze at a spot directly above the eyes. A spot on the ceiling should suffice; alternatively, the patient can stretch the arm up over the head and gaze at the thumb. A drop of topical anesthetic is placed in each eye. After the irritation of the drop passes, the patient is allowed to blink while the physician blots the tears away with a tissue. Rubbing the eyes lowers intraocular pressure. The patient is reassured that further discomfort during the procedure will not occur.

The patient *keeps both eyes wide open and fixed on an object*, and the physician separates the eyelids on the side to which he or she is standing. Care must be taken to direct pressure onto the orbital rims rather than into the orbit, because pressure directed into the orbit falsely raises the reading (Fig. 67-26) (Figure Not Available) . The tonometer is momentarily held over the open eye, and the patient is informed that the instrument will block vision in the one eye. The patient is instructed to continue to gaze at the fixation point as though the instrument were not there. After the patient relaxes the involuntary muscle contraction that occurs when the instrument is first placed in the line of sight, the instrument is gently lowered onto the middle portion of the cornea. The instrument should be vertically aligned with the footplate resting on the cornea; the reading should be in midscale. Should the reading be on the low end of the scale (<5 units), additional weight should be added to the plunger after the instrument has been removed. The process should be repeated as before with the additional weight.

The opposite eye should be measured in the same fashion. A converted scale reading giving an intraocular pressure of >21 mm Hg requires ophthalmologic referral (Table 67-4) . Patients with elevations of intraocular pressure >30 mm Hg require more urgent consultation and initiation of therapy.

| **TABLE 67-4** -- Schiotz Tonometry |
| --- |
|  |

| Tonometer Scale Reading (Units) | Tonometer Weights (g) | | |
|---|---|---|---|
| | 5.5 (mm Hg) | 7.5 (mm Hg) | 10 (mm Hg) |
| 2.50 | 27 | 39 | 55 |
| 3.00 | 24 | 36 | 51 |
| 3.50 | 22 | 33 | 47 |
| 4.00 | 21 | 30 | 43 |
| 4.50 | 19 | 28 | 40 |
| 5.00 | 17 | 26 | 37 |
| 5.50 | 16 | 24 | 34 |
| 6.00 | 15 | 22 | 32 |
| 6.50 | 13 | 20 | 29 |
| 7.00 | 12 | 18 | 27 |

| | | | |
|---|---|---|---|
| 7.50 | 11 | 17 | 25 |
| 8.00 | 10 | 16 | 23 |
| 8.50 | 9 | 14 | 21 |
| 9.00 | 8 | 13 | 20 |
| 9.50 | 8 | 12 | 18 |
| 10.00 | 7 | 11 | 16 |

The table provides estimates of the intraocular pressure to the nearest mm Hg for the different weight of the Schiotz tonometer. Accuracy is most dependable with scale readings larger than 5. If the scale reading is less than 5, use the next highest weight that will give a reading of 5 or more.

Associated symptoms or signs of angle-closure glaucoma (primary or secondary) represent an ophthalmologic emergency. [107]

**Errors with impression tonometry.**

Inaccurate readings can occur with the Schiotz tonometer for a variety of reasons. If the plunger is sticky, falsely low readings may be obtained. Plunger motion and the zero point of the tonometer should be checked on a firm test button before use. A sticky plunger can be cleaned with isopropyl alcohol and dried with a tissue. When the lids are held open, pressure directed into the orbit elevates the intraocular pressure and provides a falsely elevated reading. The following eye movements have been found to elevate the intraocular pressure: closure of the lids (increase by 5 mm Hg), blinking (increase by 5 to 10 mm Hg), accommodation (increase by 2 mm Hg), and looking toward the nose (increase by 5 to 10 mm Hg). [108] Repeated measurements or prolonged measurements have been found to lower the intraocular pressure approximately 2 mm Hg and may also lower the pressure in the opposite eye. [109] As mentioned in the introduction to this section, the calibration of the Schiotz tonometer is

based on a mean rigidity coefficient. Factors that produce a reduction in ocular rigidity falsely lower the measured pressure. These factors include high myopia, anticholinesterase drugs, overhydration (e.g., 4 large cups of coffee or 6 cans of beer), and scleral buckle operations. [108] [110]

Ocular pressure measurements can vary with ocular perfusion. When measured after a premature ventricular contraction, the intraocular pressure may be reduced as much as 8 mm Hg. [111] Similarly, decreased venous return as produced by breath holding, the Valsalva maneuver, or a tight collar can increase the intraocular pressure. [108]

**Impression (Tono-Pen XL) Technique**

When using this device, the preparations for testing are similar to those for the Schiotz device. The patient is encouraged to relax, and a topical anesthetic is used to numb the corneas. The patient should be encouraged to stare with both eyes at a distant object during testing. As noted previously, the operator can help separate the eyelids, but any pressure on the globe itself should be avoided. One major advantage to the use of the Tono-Pen XL is that the patient may be evaluated in any position as long as the device is applied perpendicular to the corneal surface. Another advantage is that the device can be used in cases of irregular or high corneal astigmatism.

Although ideally the complete instructions that are provided with the device kit should be consulted prior to each use, the following synposis is provided to help in circumstances in which instructions are unavailable. It is assumed that the previously mentioned preparations for testing have been made before the device is used.

The probe tip is first sprayed with compressed gas to clean the mechanism and ensure its free movement. An Ocu-Film (latex) cover is placed snugly (but without tension) over the probe tip.

Calibration is performed before use at least once each day. The *activation* switch is momentarily depressed and released. The liquid crystal display (LCD) should show "----". If the device beeps and "====" appears on the LCD, the activation switch should be pushed again so that the "----" reappears. If the prior calibration was "bAd" (on LCD), a long beep sounds, followed by "CAL" (on LCD). A short beep follows and then the desired "----" is displayed.

Once the "----" is displayed, the probe is held vertically with the tip pointing straight down. The activation switch is then pressed and released twice in rapid succession. Two beeps will then sound, and "CAL" will appear (on LCD). The probe is held in this position (up to 20 seconds) until a beep sounds and "-UP-" appears (on LCD). The probe is then immediately turned 180° so that the tip points straight up. In a few seconds, another beep occurs, and the LCD changes. If the LCD reads "Good", the calibration was successful. If the LCD reads "bAd", the calibration was unsuccessful.

With an unsuccessful calibration, repeat the calibration steps above until two consecutive "Good" readings are obtained. If further attempts are unsuccessful, loosen

the Ocu-Film tip cover and repeat the calibration process. If attempts are still unsuccessful, press the RESET button and repeat the process. If still unsuccessful, use compressed air to clean the probe tip and repeat the process. If still unsuccessful, the battery should be replaced and the process repeated. Continued failure warrants a call to the MENTOR Technical Service Group at 800-992-7557 or 617-871-6950.

Measurement occurs once the device is calibrated and the patient is prepared as outlined earlier. The activation switch is again depressed and released to obtain "====" (on LCD). A beep will occur with this change. If the switch is not depressed long enough, the LCD will be blank. If a blank screen is seen, again use the activation switch to obtain "====" (on LCD). The probe is held like a pen and briefly and lightly touched to the cornea. This is done four times. A click will sound and a reading will appear on the LCD each time a valid reading is obtained. After four valid readings, a final beep will sound and the averaged measurement will appear on the LCD. The number represents the intraocular pressure in millimeters of mercury. The associated bar reflects the statistical reliability (a reading of >20% reflects an unreliable measurement, which should be repeated).

If four dashes ("----") appear on the LCD after the final beep, too few valid readings were obtained. In such a case, the probe can be reactivated (without recalibration) and the measurement procedure repeated. If the probe is not reactivated within 20 seconds, the LCD will clear, but the device can be activated as noted previously without recalibration.

The values are interpreted as outlined earlier for the Schiotz device. Readings may be affected by the same features noted as causes of errors with impression tonometry via the Schiotz device. The device should be stored with a unused Ocu-Film cover protecting the probe tip.

**Applanation Technique**

One can perform this technique using a slit lamp attachment for an applanation tonometer with the patient's head stabilized in the headrest of the slit lamp (see the following section on the slit lamp examination) (Fig. 67-27) (Figure Not Available) . [112] [113] A portable device also is available and is similar in principle. The portable device is not discussed specifically.

The patient must be comfortable and relaxed. The physician should anesthetize the eye as discussed previously, avoiding ocular pressure, which can lower the subsequent measurements. Fluorescein should be applied to each eye. Excess fluorescein should be blotted from the eye. The patient's head should be in the slit lamp with the forehead firmly against the headrest, and the physician should direct the patient to gaze straight ahead. One can use a light for fixation or can ask the patient to focus on the physician's ear on the side opposite the eye being examined.

The cobalt blue light filter is placed in the light beam, and the slit diaphragm is opened fully. The light arm is angulated to shine on the applanation prism in the region of the encircling black line near the anterior prism tip at an angle of 45° to 60° to the line of observation. The voltage is turned to the maximum setting, and the low-power

microscopic system is focused through the plastic prism so that the front face is clearly seen through the chosen eyepiece. The pressure knob of the tonometer is turned to 1 g (10 mm Hg), bringing the prism arm to its forward stop. Thus, when corneal contact is made, the prism will be exerting only light pressure. The room lights are dimmed.

The patient's eye that is being examined and the applanation prism are watched from the side (or with the operator's eye not sighting through the microscope) as the instrument is brought forward by the joystick control until gentle contact is made between the prism face and the corneal center. Contact is evidenced by an immediate bluish glow throughout the limbus. The patient's lids must be wide open and unblinking. Contact with the lid margins produces reflex blinking, and the lids may require separation by the physician's fingers. Pressure during lid separation must be exerted only against the orbital rims. Through the microscope, the physician sees 2 blue semicircles (surrounding the flattened area of cornea). Each semicircle is bordered by an arc of green light and pulses synchronously with the cardiac rate (Fig. 67-28) (Figure Not Available) .

The semicircles should be of equal size; their width should be approximately one tenth the diameter of the flattened surface contained within each arc. If the semicircles are grossly widened, either excessive tears are present or the prism was probably wet before contact. A wet prism must be withdrawn, dried, and reapplied. If the semicircles are grossly narrowed, the tear film has dried excessively. In this case, the prism must be withdrawn and the patient instructed to blink several times before contact with the cornea is attempted again. If the semicircles are so broad that they extend beyond the illuminate field, there is excessive flattening and the slit lamp must be drawn back. If the semicircles suddenly shrink, either the patient has moved back or the instrument has been backed away from the eye. The semicircles should be of equal extent above and below a horizontal dividing line. If the dividing line is not horizontal, the applanation prism assembly should be rotated on its holder until the line is horizontal. If the semicircles are not equally divided above and below the line, vertical adjustments of the slit lamp should be made.

Readings should be taken at approximately the midpoint between systole and diastole, when the inner (concave) boundaries of each semicircle rhythmically glide past each other through excursions of equal distance (see Fig. 67-28 (Figure Not Available) C). One finalizes adjustments to the end point of properly located and sized semicircles by rotating the pressure knob back and forth. When applanation pressure exceeds intraocular pressure, the semicircles are too small to intersect.

At the end point is a flattened disc area 3.06 mm in diameter within the 7-mm diameter of the prism face. Here the attractive surface tension of the tears toward the prism is counterbalanced by the elasticity, or springiness, of the cornea; at this point the grams of force applied through the prism (indicated on the pressure knob) are directly convertible (when multiplied by 10 into millimeters of mercury) to express intraocular pressure. With an applanation tonometer, the average intraocular pressure in a seated adult is 14 to 17 mm Hg.

After use, the tonometer should be wiped dry and removed for storage if used

infrequently in the ED. One should verify the pressure adjustment periodically using the test weight or metal balance bar supplied with the instrument.

Potential sources of error with the applanation tonometer are similar to those mentioned for the impression tonometer, with the exception that ocular rigidity is not a factor. Inaccuracies primarily result from ocular motion or tensing of the lids.

### Complications

When tonometric instruments are used properly and reasonable precautions are taken, complications are unusual. The eye with preexisting corneal injury should be spared the additional trauma of tonometer placement. Corneal abrasions can be produced by ocular movement during testing. In particular, patients with uncontrollable nystagmus, singultus, or coughing or those who are extremely apprehensive should not be subjected to tonometry. Infection can be transmitted by the use of the instrument. Careful cleansing of the device and avoidance of tonometry in patients with obvious conjunctivitis, corneal ulcers, or active herpetic lesions should minimize the risk of spreading the infection to the unaffected eye or to subsequent patients. Although protective coverings can be placed over the tonometer contact, tonometry can usually be postponed in the aforementioned individuals until the risk of infection is minimal. Extrusion of ocular contents with penetrating injuries is a potential but rare complication.

### Summary

Tonometry is an easily learned technique that should be used by the emergency physician for the detection of elevated intraocular pressure. An elevated intraocular pressure in conjunction with physical findings suggestive of acute angle-closure glaucoma is an indication for therapy and consultation with an ophthalmologist. The baseline measurement of intraocular pressure will aid the ophthalmologist in subsequent evaluation of a referred patient. In addition, the emergency physician can serve as a referral source for patients with elevated intraocular pressure who are suspected of having open-angle glaucoma. In particular, future drug therapy for systemic hypertension may be altered by the presence of concomitant intraocular hypertension. The emergency physician who aggressively manages patients with hypertensive crises must also be aware of potential visual field defects when systemic blood pressure is vigorously lowered without concurrent lowering of intraocular pressure.

## SLIT LAMP EXAMINATION

The slit lamp is an extremely useful instrument; it makes the examination of the anterior segment of the eye a pleasure. The instrument can reveal pathologic conditions that would otherwise be invisible. The slit lamp permits detailed evaluation of external eye injury and is the definitive tool for diagnosing anterior chamber hemorrhage and inflammation. The emergency physician should not attempt to diagnose any but the simplest of eye problems without the aid of a slit lamp.

Since the 1800s, physicians have searched for a better way both to magnify and to illuminate the anterior segment of the eye. In 1891, Aubert developed the first true binocular stereoscopic microscope. Then, in 1911, Gullstrand introduced a slit illuminator device. The microscope and the illuminator were combined by Henker in 1916; the result was the first true slit lamp. Goldmann improved the mechanical supports for the microscope and the illuminator and in 1937 marketed a slit lamp that resembles closely the device that is used today. [114]

## Indications and Contraindications

The slit lamp can be used in every eye examination. It is especially useful in the ED for the diagnosis of corneal abrasions, foreign bodies, and iritis. [115] The slit lamp facilitates foreign body removal and is also used in conjunction with most applanation tonometers. Although portable slit lamp instruments exist, emergency physicians generally have access only to a stationary, upright device. Therefore, in the absence of a portable device, a slit lamp examination is contraindicated in patients who cannot tolerate an upright sitting position (e.g., those with orthostatic syncope).

## Equipment

The slit lamp has 3 essential components: a binocular microscope mounted horizontally, a light source that can create a beam of variable width, and a mechanical assembly to immobilize the patient's head and to manipulate the microscope and the light source. The location and arrangement of the knobs that control these components vary in devices made by different manufacturers. Usually, by simply turning each knob and watching the results, one can quickly master a new machine. Figure 67-29 (Figure Not Available) illustrates the location of the functional controls on one particular instrument.

The first knob that one should locate is the on/off switch for the entire machine. Often this switch incorporates or is adjacent to a rheostat that provides 2 or 3 different power settings. The lowest setting is adequate for routine examination and will preserve bulb life. One can use a high-intensity setting when examining the anterior chamber with a narrow slit beam. Often, these controls are located on a transformer placed beneath the table to which the slit lamp has been attached. The second knob that one should find is the locking nut for the mechanical assembly. This must be loosened for the assembly to be moved.

The patient should be comfortable while sitting with the head in the device. The patient's forehead should be firmly against the headrest, and the chin should be in the chin rest. By varying the table height and height of the chin rest, one should be able to maximize the comfort of the patient's neck and back. The chin rest should be adjusted to align the patient's eye level with the mark on the headrest support rods.

The binocular microscope has a control for varying the magnification. Usually low powers, such as 10× or 16×, are the most useful. A higher power is helpful when the anterior chamber is examined for cells and flare and when the cornea is examined in

minute detail. The binocular interpupillary distance should be adjusted to match that of the examiner. One can focus the eyepieces by moving the instrument forward and backward until the narrowed vertical beam is sharpest on the patient's cornea when viewed with the unaided eye. Then, while viewing through each eyepiece individually, the physician adjusts the focus of each to produce a sharp image of the anterior cornea.

The light source is mounted on a swinging arm. There are knobs to vary the width and the height of the light beam. There are also filters that can be "clicked" in; only white and blue filters are usually needed. The angle of the slit beam can be varied from vertical to horizontal. The vertical alignment is preferred for routine examinations in the ED.

Both the microscope and the light source are mounted on swivel arms, linked at their base to a movable table. One can change the position of this table by pushing on any part of it. For finer movements, the physician uses a joystick. One can vary the height of the microscope and the light source by twisting either the joystick or a separate knob at the base, depending on the design of the instrument.

**Procedure**

There are 3 setups that every slit lamp operator must know. [116] [117] The first is for an overall screening of the anterior segment of the eye. For examination of the patient's right eye, the light source is swung to the examiner's left at a 45° angle while the microscope is directly in front of the eye. The slit beam is set at the maximum height and the minimum width using the white light. To scan across the patient's cornea, one first focuses the beam on the cornea by moving the entire base of the slit lamp forward and backward. One then moves the whole base left and right to scan across. The 45° angle between the microscope and the light source should not be varied. The most common mistake is to try to scan by swinging the arm of the light source in an arc; this does not work because the light beam will remain centered on the same point of the patient's eye. The examiner scans across at the level of the conjunctiva and the cornea and then pushes slightly forward on the base and scans at the level of the iris. The depth of the anterior chamber is determined by this low magnification setup. When the depth of the anterior chamber is reduced, one should suspect a corneal perforation or a predisposition to angle-closure glaucoma.

This basic setup can also be used to examine the conjunctiva for traumatic lesions, inflammation, and foreign bodies. The lids can be examined for hordeolum, blepharitis, or trichiasis. Complete lid eversion (as described in the section on foreign body removal) can be performed in conjunction with the slit lamp examination to permit evaluation of the undersurface of the upper lid for foreign body retention.

Corneal foreign body removal can be enhanced by use of the slit lamp. In particular, the instrument allows stabilization of the patient's head. Magnification also minimizes corneal injury during foreign body or rust ring removal. The upper eyelid may be immobilized by a cotton-tipped applicator, as discussed previously. The physician's hand can be steadied against the patient's nose, cheek, or forehead or against the support rods of the headrest. The patient should be instructed to stare straight ahead at

a fixed light or at the physician's ear during removal of the foreign body.

The second setup is essentially the same as the first but uses the blue filter. The purpose is to identify any areas of fluorescein staining. After fluorescein is applied, the blue filter is "clicked" into position, and the beam is widened to 3 or 4 mm. A patient can tolerate a wider beam without photophobia if it is blue. Corneal defects (as discussed in the section on the fluorescein examination) are sought with this setup. The blue filter is also used with applanation tonometry, as discussed in the section on tonometry.

The purpose of the third setup is to search for cells in the anterior chamber--either the white cells of iritis or the red cells of a microscopic hyphema. The height of the beam should be shortened to 3 or 4 mm and should be as narrow as possible. The microscope should be switched to high power. The beam is first focused on the center of the cornea and is then pushed forward slightly so that it is focused on the anterior surface of the lens. When the joystick is again pulled back to a focus point midway between the cornea and the lens, it will be focused on the anterior chamber (Fig. 67-30) . One should keep the beam centered over the pupil so that there is a black background. Normally, the aqueous humor of the anterior chamber is totally clear. If small particles are visible floating up or down through the beam, these are usually circulating cells. If the beam lights up the aqueous like a searchlight in the fog, then the examiner has found the protein flare that accompanies iritis. Note should be made of the fact that fluorescein can penetrate an abraded cornea, producing a fluorescein flare on slit-lamp evaluation. To avoid confusion, some physicians prefer to examine for anterior chamber flare before the stain is used.

**Summary**

In practice, the 3 setups described here take only 1 minute per eye. Experience with the instrument enhances the ability of the user. The device is helpful for the evaluation of ocular infections and corneal lesions, the removal of corneal foreign bodies, the measurement of intraocular pressure by applanation tonometry, and the diagnosis of iritis.

# UNILATERAL LOSS OF VISION

There are a variety of reasons that an individual may sustain a complete loss of vision in one eye, but most commonly such loss may be related to occlusion of the central retinal vein or the central retinal artery or to optic nerve damage. Less commonly, pressure in the orbit from a retro-orbital hemorrhage may compromise the ophthalmic artery.

Although discussion of all the potential causes of unilateral loss of vision is beyond the scope of this text, amaurosis fugax desires special mention. Amaurosis fugax is a transient loss of vision that is most commonly due to cholesterol or platelet emboli from atherosclerotic carotid occlusive disease. When plaques are visualized in the retinal vasculature, it is prudent to auscultate for carotid bruits and to refer the patient for ultrasound examination of the carotid artery.

**Central Retinal Artery Occlusion**

The patient with central retinal artery occlusion generally presents with a recent sudden (complete or nearly complete) unilateral vision loss. On examination there is an afferent pupillary defect (i.e., sluggish or nonreactive pupil in the affected eye with direct illumination with a normal consensual response) and reduced visual acuity. Immediately after the event, the fundus may appear nearly normal; however, it soon becomes pale and a classic "cherry-red spot" in the macula may be evident as a result of patent choroidal vessels showing through the transparent fovea.

**Therapy**

If the patient presents within 2 hours after the initial onset of symptoms, immediate attempts at improving retinal flow are indicated. [120] Studies in laboratory animals have demonstrated visual recovery after central retinal artery occlusion for over 1½ hours. [121] Ophthalmologic consultation should be made while initiating therapy.

Although of unknown value, slow *rebreathing* into a paper bag is believed to increase the arterial $CO_2$ level, thus aiding vasodilation and permitting the occlusion to move more peripherally, possibly reducing the ischemic area. The physician should concurrently initiate *digital globe massage*. With the patient lying supine, firm steady pressure is applied to the affected globe through the patient's closed lids using the physician's thumb. The pressure is applied for 5 seconds and then abruptly released. The procedure is immediately repeated several more times. The technique is intended to help break up the occlusion and to encourage its movement more peripherally.

A more aggressive therapy is *anterior chamber paracentesis*. This technique should be considered when central retinal occlusion is recent and unresponsive to the above therapeutic approaches. For this procedure, the patient is kept supine with the head and eyelids secured. The cornea is anesthetized with topical anesthetic drops (e.g., 0.5% proparacaine drops) and the conjunctiva is anesthetized. The conjunctiva is injected adjacent to the limbus using a 27- or 30-ga needle until the entire perilimbal area is infiltrated, giving the appearance of chemosis in all quadrants. During the remainder of the procedure, an assistant must firmly grasp the conjunctiva with toothless forceps at the 3 and 9 o'clock positions to stabilize the eye. A 30-ga needle on a tuberculin syringe is then inserted obliquely just adjacent to the limbus, at either the 4:30 or 7:30 o'clock position and directed toward the 6 o'clock position to avoid the lens (Fig. 67-31) (Figure Not Available) . After 1 to 2 drops of aqueous are expressed with gentle pressure on the globe, the needle is withdrawn.

**Complications**

Overzealous globe massage has the potential to produce intraocular trauma including retinal detachment and intraocular hemorrhage. Anterior chamber paracentesis may produce hemorrhage, infection, or mechanical injury to the cornea, iris, or lens. [124] Although these complications are rare, ophthalmologic consultation for assistance with

the underlying central retinal artery occlusion and surveillance for these potential complications should be initiated on an emergent basis.

**Retrobulbar Hemorrhage**

Acute facial trauma may produce retrobulbar hemorrhage with sufficient pressure to compromise the ophthalmic artery. A form of post-traumatic glaucoma may also occur when the retrobulbar hematoma forces the globe against the eyelids and intraocular pressure rises precipitously, because the globe is in a relatively closed space due to the firm attachment of the eyelids to the orbital rim by the medial and lateral canthal ligaments. In this situation an emergency canthotomy should be considered for relief of the pressure on the eye.

Ophthalmoscopic evaluation should reveal a blanched ophthalmic artery in the presence of obvious retrobulbar pressure and ecchymosis around the eye. The patient exhibits *decreased visual acuity,* and an afferent pupil defect is often seen. The intraocular pressure is markedly elevated but may be relieved by an emergency lateral canthotomy. Such a procedure needs to be performed quickly because the ischemic retina will not retain function if it is deprived of blood for a long period of time.

### Technique

The goals of the procedure are to release pressure on the globe and to decrease intraocular pressure enough to reinstitute retinal artery blood flow. Because retinal recovery will be unlikely to occur if rapid relief of ischemia is not accomplished, taking time to clean the eye beyond simple saline cleansing of the lids and lateral canthus is ill-advised. While the patient's head and lids are stabilized, the lateral canthus is first anesthetized with injectable 2% or 4% lidocaine with epinephrine. A small hemostat is used to crush the lateral canthus for 1 to 2 minutes to minimize bleeding before incising the lateral canthus. The canthus is incised using iris scissors, with precautions taken to avoid injury to the protruding globe (Fig. 67-32) (Figure Not Available) . The incision begins at the lateral canthus and extends toward the orbital rim. The lateral canthal ligaments are found and released from the orbital rim.

### Complications

Although hemorrhage, infection, and mechanical injury may result from the procedure, these complications generally respond to therapy better than retinal injury from prolonged ischemia. Emergent ophthalmologic consultation should be obtained, although when the procedure is indicated, it should not be delayed pending arrival of the consultant. Lateral canthotomy incisions generally heal without suturing or significant scarring.

# REDUCTION OF GLOBE LUXATION

Although luxation of the globe is uncommon, the emergency physician should be aware of the condition and its mechanisms, know how to reduce the globe, and know when to

prioritize ophthalmologic consultation. With luxation of the globe there is extreme proptosis, which permits the lids to slip behind the globe equator (Fig. 67-33) (Figure Not Available) . Subsequent spasm of the orbicularis oculi muscles sustains the luxation and limits extraocular movements. Traction on the optic nerve and retinal vessels may produce direct or indirect injury to the optic nerve and retina.

Luxation may be spontaneous, voluntary, or traumatic. A variety of conditions (e.g., orbital neoplasms, Graves' disease, histiocytosis X, cerebral gumma, and craniofacial dysostoses) may predispose the patient to luxation. Triggering events include maneuvers increasing intraorbital pressure (e.g., the Valsalva maneuver), trauma to the orbit or forehead, or eyelid manipulation.

### Indications and Contraindications

Early globe reduction is indicated to relieve symptoms and to minimize visual impairment. Attempts at reduction in the ED are relatively contraindicated when there is obvious rupture of the globe.

### Technique

Before globe reduction, it is valuable to perform a rapid eye examination to document visual acuity, range of eye motion, pupillary reactivity, and any evidence of globe rupture (see earlier). [125] The patient is made comfortable in a recumbent position, and a topical ocular anesthetic agent (e.g., 0.5% proparacaine) is administered. When the lashes are visible, an assistant should apply steady outward and upward traction while the globe is gently pushed behind the lids. The globe is manipulated back into the orbit using gloved fingers to apply steady scleral pressure. When the lashes cannot be grasped, a lid retractor may be introduced behind the lid to provide countertraction. Others recommend placement of a suture through the anesthetized skin of each lid to provide countertraction.

After the procedure, a repeat eye examination documenting visual acuity and extraocular movement is warranted. It is not uncommon for return of full visual function to be delayed for several days, occasionally longer.

### Complications

It is common with this procedure for lashes to be retained in the conjunctival fornices. It is important to evaluate for and remove any free lashes to prevent corneal injury. Edema, retrobulbar hemorrhage, or orbital deformity may prevent outpatient reduction. When reduction is not possible in the ED, saline drops should be applied to the globe and a noncontact eye shield applied.

### Aftercare

Patients with spontaneous luxation and no visual impairment in whom the globe is easily reduced warrant follow-up within 24 to 48 hours. Instructions to avoid potential triggering

maneuvers should be given. Recurrent luxation may warrant lateral tarsorrhaphy. Further evaluation of potential precipitating illness can be pursued on an outpatient basis.

Patients with traumatic luxation are at greater risk for underlying ophthalmic injury and warrant emergent consultation. A computed tomographic scan of the orbit is helpful for evaluating both the soft tissue and bony structures about the globe.

# Chapter 68 - Otolaryngologic Procedures

**David E. Manthey, Benjamin P. Harrison**

Examination of the oropharynx, larynx, ear canals, and nasal passages and the management of related acute disorders are most effectively performed using special equipment and techniques. This chapter addresses these techniques from the perspective of the emergency physician who often must assess injuries or illnesses of potential compromise to the airway and to auditory function. Decisions related to definitive treatment in the emergency department (ED) vs timely referral are addressed. Related topics, including airway management, esophageal and laryngeal foreign bodies, and assessment of caloric testing, are discussed elsewhere.

## PHARYNX

### Examination of the Larynx

Several techniques to visualize the larynx are discussed and the clinician should become adept with more than one method of examining the hypopharynx and larynx (Fig. 68-1) . Laryngoscopy is indicated for the evaluation of unexplained hoarseness, dysphagia, odynophagia, or foreign body sensation. The majority of patients will require a repeat examination by an otolaryngologist for verification, but laryngoscopy in the ED may identify pathologic conditions requiring more urgent consultation. Latex gloves should be worn at all times while performing any of the following methods of examination to minimize exchange of body fluids.

Traditionally, laryngoscopy has been discouraged in the patient with a high potential for epiglottitis, as oropharyngeal manipulation may rarely precipitate laryngospasm and acute respiratory arrest. However, some authors report that careful laryngoscopy may be performed in stridulous patients with the presumed diagnosis of croup to rule out epiglottitis when the suspicion for the latter condition is low. [1]

When impending airway obstruction from epiglottitis is suspected, the first priority is to quickly assemble a predesignated team (usually consisting of an anesthesiologist and an otolaryngologist in the operating room). Any attempt at laryngoscopy should follow full preparation for rigid bronchoscopy or a surgical airway. Patients with severe laryngeal trauma or partially obstructing hypopharyngeal foreign bodies should be approached in a similar manner.

#### Illumination

The reflected light from a head mirror or direct illumination from a head lamp can be used not only for indirect laryngoscopy, but also for inspection of the oropharynx, nares, and auditory canal. The advantages of a head mirror are the high degree of brightness it provides into deep recesses and its simplicity of design. Generally, the beam of light

from an electric head lamp is easier to focus than is the head mirror.

**Procedure**

**Head mirror/light source.**

The head mirror is convex with a central hole that allows the examiner to see directly along the reflected light beam. Begin by swinging the mirror down over the dominant eye just touching the skin or glasses. Position the light source (a 150-watt bulb works well) over the patient's shoulder on the same side as the head mirror. Keeping your eyes open, adjust the focus of light by adjusting your distance from the patient. Change the direction of the beam by tilting the mirror or turning your head slightly.

**Head lamp.**

The electric head lamp also attaches by a forehead strap, and the light should be placed nearly between the examiner's eyes to be maximally effective. The intensity of light in this position is nearly as bright as the head mirror. After securing the head lamp, hold your hands in front of you at a distance that is comfortable for working. Focus the beam of light at that point by adjusting the head lamp into position without moving your head or eyes. This allows for the beam to shine on and follow the area on which your eyes are focused.

**Indirect Laryngoscopy**

This traditional method is most commonly used by the otolaryngologist, but it has some application in the emergency setting if the necessary equipment is readily available. The clinician who is unfamiliar with this method should practice frequently, as it requires significant eye-to-hand coordination to reflect the light beam off the angulated mirror onto the larynx. When this procedure is properly performed, most patients are able to tolerate it without anesthesia of the oropharynx. In EDs, where fiberoptic nasopharyngeal scopes are available, the latter technique has largely replaced indirect laryngoscopy.

Begin by establishing a rapport with the patient by explaining how the examination will be performed. Have the patient sit erect in the "sniffing position," with the feet flat on the floor and leaning slightly forward. Warm the mirror with warm water or in a flame to prevent fogging, but check the temperature of the mirror with your hand before placing it into the oropharynx. Alternatively, anti-fogging solutions can be applied to the mirrored side. With your nondominant hand, grasp the patient's tongue (after wrapping it with gauze to prevent it from slipping or being injured by the lower incisors) (Fig. 68-2) . Apply gentle traction to the tongue with your thumb and index finger while lifting the patient's upper lip with your middle finger. Slide the mirror into the oropharynx with the glass surface parallel to the tongue but not touching it. Place the back of the mirror against the uvula and soft palate, smoothly lifting until the larynx is visualized. While this should not induce gagging, try to make only slight changes in mirror position to inspect

the appropriate structures.

In patients who cannot tolerate this procedure without gagging, apply topical anesthetic to aid in the examination. Benzocaine (Hurricaine spray or Cetacaine gargle) or aerosolized tetracaine or lidocaine may be used. One or two quick sprays of benzocaine into the posterior oropharynx is sufficient. Prolonged or repeated spray use may result in methemoglobinemia. Reassure the patient beforehand that although this may make the throat feel as if is swelling or paralyzed, in actuality it is just the numbness that accounts for the sensation. The tendency to gag also can be minimized by having the patient concentrate on his or her breathing efforts and keep the eyes open, with vision fixed on an object in the distance.

Once the patient is anesthetized, repeat the above steps and position the mirror against the soft palate. Rotate the angle of the mirror and systematically inspect the base of the tongue, valleculae, epiglottis, pyriform recess, arytenoids, false and true vocal cords, and, if possible, the superior aspect of the trachea (Fig. 68-3) . Observe for masses, evidence of infection, asymmetry, or foreign bodies. Further evaluate the anterior structure of the larynx and function of the vocal cords by having the patient say "eeee" in a high-pitched voice. This should move the epiglottis away from blocking the view of the larynx and bring the true cords together at the midline.

**Laryngoscopy by Angled Telescopes**

A less frequently used method of examining the larynx in the emergency setting is by rigid angled laryngoscopy (e.g., LarynxVue II, Astralite Corp., Anaheim, Calif). This provides a clear and more continuous view of the larynx during respiration, but its use is limited in patients whose epiglottis blocks the view. The light source is powered by batteries or wall outlet. The degree of mirror angulation is fixed, but it may vary between instruments (usually 70° to 90°). At 70° of mirror angulation, the scope does not need to be placed as far posterior into the oropharynx to visualize the structures.

Position the patient as for indirect laryngoscopy and anesthetize the soft palate if necessary, as previously described. Gently grasp the tongue and slide the scope into the oropharynx. Stabilize the scope on the fingers that are holding the tongue, taking care not to touch the sensitive base of the tongue. Once the scope is touching the soft palate and is near proper position, look into the eyepiece and make final adjustments to bring the laryngeal structures into focus. Observe the anatomy and function as previously described in a systematic fashion.

**Flexible Fiberoptic Laryngoscopy**

Fiberoptic examination of the nasopharynx and larynx can be accomplished with either a flexible nasopharyngoscope or a bronchoscope. The nasopharyngoscope is thinner, shorter, and easier to manipulate (Fig. 68-4) . Fiberoptic visualization is especially useful in patients who are difficult to examine because of persistent gagging or unusual anatomy.  Attach the endoscope to its light source, attach the suction to its port (if available), and ensure that both are functioning properly before beginning. Prior to inserting the scope, the eyepiece is adjusted to the operator's visual acuity; it is helpful

to check the scope focus on newsprint or a small object at this time. Review of the scope directional controls is also recommended.

Examine the nares and choose the more patent one to enter. Anesthetize and vasoconstrict the naris with lidocaine and epinephrine (as described in Epistaxis, later in the chapter). Some clinicians also anesthetize the pharynx to minimize gagging. Warm the end of the scope in warm water to help prevent fogging. The patient should be seated, with the head placed against a headrest, in the "sniffing" position. Insert the tip of the lubricated scope just inside the naris. A series of soft nasal trumpets may be used to dilate the nasal cavity, allowing easier passage of the scope. The movement of the scope against the inside of the nasal passage may be irritating; this discomfort can be minimized by resting the fourth and fifth fingers on the bridge of the patient's nose while stabilizing and guiding the passage of the scope between the thumb and index finger (Fig. 68-5) .

While looking through the eyepiece, slowly advance the endoscope past the inferior turbinate into the nasopharynx or through the lumen of the trumpet. To clear fogging or mucus off the lens, have the patient swallow, wipe the lens against the pharyngeal mucosa, or use the suction. Once it is in the nasopharynx, direct the tip inferiorly, using the thumb control near the eyepiece. *Up-and-down movements of the scope may be accomplished with the thumb control, whereas rotating the scope about its axis and then applying the thumb control provides for lateral movement and visualization.* At this point, the base of the tongue and tonsils will come into view. Slide the scope further caudad to bring the larynx into focus. Once again, systematically view the anatomy and function during both respiration and phonation.

If the nasopharyngeal scope will not pass through either naris, pass it through the oropharynx. Properly anesthetize the oropharynx and avoid the posterior tongue to prevent gagging. Cut a 10-mL syringe (without the plunger) in half. Have the patient hold this in the mouth between the incisors. Pass the fragile endoscope through this tube to prevent accidental biting of the scope.

Complications include traumatic abrasions and bleeding anywhere along the path of the laryngoscope. In patients with head injury, there is always the rare risk of passing the scope intracranially if a basilar skull fracture exists, but use of a soft nasal trumpet significantly reduces that risk. The induction of laryngospasm and acute airway compromise is possible in patients with paraglottic infections.

## Peritonsillar Abscess

### Anatomy

Peritonsillar abscess, also known as *quinsy*, is most common during the second and third decades. It remains the most common head and neck abscess in adults. Currently, treatment of peritonsillar abscess includes tonsillectomy (immediate or delayed), intravenous (IV) antibiotics, incision and drainage, needle aspiration, or any combination

of the above.

The relative anatomy must be understood to treat peritonsillar abscesses (Fig. 68-6) . The palatine tonsils are located between the anterior and posterior pillars of the throat, bound in a capsule and covered by mucosa. The lateral wall of the tonsil is defined by the superior pharyngeal constrictor muscle. Of great importance is the *internal carotid artery,* which lies approximately 2.5 cm posterolateral to the tonsil.

**Pathophysiology and Presentation**

Peritonsillar abscess occurs in patients with inadequately treated tonsillitis and in recurrent tonsillitis. The abscess is usually unilateral and spreads to the peritonsillar space between the tonsillar bed, the capsule, and the superior constrictor muscle in the region of the anterior pillar. The abscess is most commonly initiated from the upper pole of the tonsil. However, it can also spread from the middle or the inferior poles. Complications may include pharyngeal obstruction or extension into the closely approximated neurovascular bundles and parapharyngeal space.

Inadequately treated tonsillitis occurs when a patient fails to follow the prescribed regimen or when the regimen is inadequate. The latter may occur as the result of an improperly chosen antibiotic or because of increasing antibiotic resistance. Anecdotal cases of failure after intramuscular long-acting penicillin also have been noted. Although Group A *Streptococcus* remains the leading cause of peritonsillar abscess, *Staphylococcus aureus*, *Haemophilus influenzae*, and mixed anaerobic infections are common. Recent literature reveals cases of tonsillitis due to beta-lactamase-producing organisms, which confers resistance to beta-lactam antibiotics. [2] Fine-needle aspiration of peritonsillar abscesses may allow identification of organisms and appropriate modification in antibiotic therapy, thus avoiding the need for tonsillectomy.

Patients with peritonsillar abscesses present with sore throat, odynophagia, low-grade fever, and a variable degree of trismus. The trismus develops secondary to pterygoid muscle irritation. The patient may also complain of ipsilateral otalgia or have dysarthria ("hot potato" voice). As the abscess expands, swallowing becomes increasingly painful and may lead to dehydration secondary to poor intake. Tender ipsilateral anterior cervical lymphadenopathy is frequently present. Be cautious of a fever >39.4 °C, as this has been associated with parapharyngeal extension and sepsis. [3]

Examination of the oropharynx may be difficult because of associated trismus. Have the patient sit with the head in the sniffing position. Encourage the patient to open the mouth as wide as possible, and depress the tongue to obtain a better view of the oropharynx. Use a head lamp or head mirror/light source to ensure adequate illumination. Digital palpation for a fluctuant site can be useful, but the patient may gag or bite the examiner by reflex. Generally, the same information can be obtained using a cotton-tipped applicator. Medial displacement of the tonsil and uvula are noted with a fluctuant mass involving the tonsillar pillar. The normally sharply delineated pillar-like structure will be obliterated by swelling. The tonsil will look edematous and erythematous, and it may be covered with a whitish exudate.

The differential diagnosis for this acute process includes unilateral tonsillitis, peritonsillar cellulitis, peritonsillar abscess, and, possibly, carotid artery aneurysm. Chronic conditions include leukemia, carcinoma, and parapharyngeal space tumor.

Differentiation of a peritonsillar abscess from peritonsillar cellulitis may be difficult, especially in the early stages of an abscess. The histories and time course for the two disease processes are quite similar. Trismus is uncommon in peritonsillar cellulitis. Needle aspiration will be diagnostic if purulent material is removed. However, a negative test does not rule out an abscess. The abscess may be located posteriorly, which is not accessible to the aspiration needle. Intraoral sonography has a sensitivity and specificity of 91% and 80%, respectively, in detecting peritonsillar abscesses [4] and may therefore augment diagnostic accuracy.

**Indications for Needle Aspiration**

Treatment of peritonsillar abscess has undergone significant change in the past 100 years and continues to do so at this writing. A myriad of opinions exists on the appropriate treatment method, although most agree that some form of drainage procedure should be performed. Treatment of an initial peritonsillar abscess commonly included an incision and drainage followed by an interval tonsillectomy to prevent recurrence. Emergent tonsillectomies had been traditionally avoided because of fear of septicemia and increased intraoperative bleeding. However, this procedure gained favor in the early 1970s, as these concerns were never substantiated. The emergent tonsillectomy removes the source as well as the abscess itself. Recently, treatment with needle aspiration and IV antibiotics in lieu of traditional incision and drainage has been performed with a recurrence rate from 3 to 23%. Some studies report an average cure rate of 80% with needle aspiration.

Points of discussion concerning needle aspiration include the following:

1. Aspiration may miss the peritonsillar abscess and therefore allow misdiagnosis as peritonsillar cellulitis. Up to

   12 to 24% of abscesses have been missed on initial aspiration. [5] [6] Therefore, some authors propose admission of patients with negative aspirations with the presumed diagnosis of peritonsillar cellulitis for IV antibiotics and observation to prevent further morbidity. [7]

2. Recurrence rates of 3 to 23% have been noted after needle aspiration. This recurrence rate matches that noted for young adults with incision and drainage at a rate of 5.9 to 22.7%. [10] Some suggest immediate (quinsy) tonsillectomy to prevent recurrences.
3. Repeat aspirations are often necessary, which causes further morbidity. Repeat aspirations were required in 6 to 10% of patients. [6]

Benefits of needle aspiration over incision and drainage include decreased pain and

trauma. Although most studies were performed with hospitalization and IV antibiotics, outpatient treatment with oral antibiotics has been successful. [7] [8] This approach adds the benefits of no hospital stay and decreased costs.

Treatment guidelines based on a review of the literature [11] suggest that (1) pediatric patients with peritonsillar abscess be admitted for IV antibiotics and observation with possible quinsy tonsillectomy; (2) adult patients with *recurrent* tonsillitis/peritonsillar abscess be treated with either quinsy tonsillectomy or interval tonsillectomy after initial treatment with incision and drainage or aspiration; and (3) adult patients with an initial episode be managed with either incision and drainage or needle aspiration. This applies especially to those with a low risk of recurrence, such as persons older than 40 years. These procedures can be done in combination with hospital admission and administration of IV antibiotics or as an outpatient with oral antibiotics. The approach depends on the patient's clinical status and medical history. Decisions about the treatment of a peritonsillar abscess in the ED should be made in consultation with an otolaryngologist.

**Needle Aspiration/Incision and Drainage**

The two procedures described here include needle aspiration and incision and drainage. They should be performed in consultation with an otolaryngologist. They should only be performed in the cooperative patient without severe trismus. With the carotid artery located 2.5 cm behind and lateral to the tonsil, there is minimal room for error, patient movement, or poor anesthesia.

Have the patient sit upright, with a support behind the head. This is best done as a 2-person procedure. An assistant can retract the cheek laterally to maximize visibility. A head lamp provides optimal lighting; a double tongue-blade setup aids visualization of the operative area (Fig. 68-7) . Topically anesthetize the area with Cetacaine spray, or 4 to 10% lidocaine. *Stay within the maximal allowed dosage* (see below and Chapter 31) . Determine the fluctuant area of the abscess using a cotton swab. Additionally anesthetize this area with local infiltration of 1 to 2 mL of 2% lidocaine with 1:100,000 epinephrine via a 27-ga needle. Infiltrate the lidocaine intramucosally for the best results. During the injection, be careful not to increase the abscess size by direct injection into the abscess cavity. If the trismus is so pronounced as to prevent adequate anesthesia administration, it will probably be too difficult to incise the abscess properly.

For *aspiration*, prepare a 20-ga needle on a 10- to 20-mL syringe. Smaller syringes limit the operator's view of the pharynx. Fashion a needle guard by cutting off the distal 0.5 cm of the plastic needle cover (or impale a stopper from a test tube with the aspirating needle). Securely attach this guard to the needle and syringe with tape to prevent inadvertent displacement (Fig. 68-8) . Ensure that the needle protrudes only 0.5 cm beyond the cover. This procedure will lessen the risk of entering any major vascular structure. Insert the needle into the most fluctuant (or prominent) area as previously determined, which is most commonly the superior pole of the tonsil. Note that the tonsil itself is not aspirated, because the abscess develops in the peritonsillar space surrounding the tonsil. *The needle is advanced only in the sagittal plane and is not directed laterally, where it may injure the carotid artery.* If the aspirate is positive,

remove as much purulent material as possible. If the aspirate is negative, attempt aspiration again in the middle pole of the tonsil approximately 1 cm caudal to the first aspiration. A third and final attempt should be performed at the inferior pole. It must be stressed that a negative aspirate does *NOT* rule out a peritonsillar abscess. Obtain culture and sensitivity on any aspirated fluid. Some clinicians advise a formal incision and drainage (see below) if frank pus is obtained, whereas others accept needle aspiration (with close follow-up) as the definitive *initial* treatment.

To *incise* a peritonsillar abscess, anesthetize the area as described earlier. Prepare a No. 11 or 15 scalpel blade by taping over all but the distal 0.5 cm of the blade to prevent deeper penetration (Fig. 68-9) . Incise the area of maximal fluctuance or where a preceding aspiration, if one was performed, located pus. Incise the mucosa in an area 1 cm long in a posterior to anterior direction. A stab incision with a No. 11 blade usually suffices. Warn the patient that the pus will flow posteriorly and the patient will have to expectorate this fluid. Expect bleeding, as this is a vascular area. Suction the incised area with a No. 9 or 10 Frazier suction tip or a tonsil suction tip to aid in removal of the purulent material. Place a closed Kelly clamp into the opening and gently open it to break up the loculations. Culture the abscess for both aerobic and anaerobic organisms. Allow the patient to rinse and gargle with a half hydrogen peroxide and half normal saline solution. Packing is *not* used in the drainage of this abscess. *Following aspiration or incision, it is prudent to observe the patient for about an hour to watch for complications (e.g., bleeding) and to ensure the ability to sustain oral fluids.*

Antibiotics are recommended to eradicate the offending organisms. Penicillin or cephalosporins are a reasonable first choice. Reasonable cure rates have been obtained with oral penicillin in modest doses (500 mg PO QID). Many clinicians prefer to administer an IV loading dose of penicillin (2 to 4 million units) or cefazolin (1 g) prior to releasing the patient. Any patient who appears to be having a toxic response, whose immune system is compromised, is unable to take oral antibiotics, or is dehydrated should be admitted for IV fluid hydration and antibiotics administration. Reevaluation of all patients treated with needle aspiration drainage should be performed in 12 to 24 hours to assess the need for repeat aspirations or formal incision and drainage. Warm saline gargles and mild opioid analgesics also are recommended with outpatient care. Patients treated with incision and drainage also benefit from a short-term follow-up visit, but are less likely to require intervention than patients treated with aspiration. All patients should immediately return for recurrence of symptoms, fevers, or continued bleeding from the incision.

### Complications

Aspiration or incision of a carotid artery or misdiagnosed carotid artery aneurysm may have devastating results. As discussed before, the misdiagnosis of a peritonsillar abscess as cellulitis will lead to further morbidity. A too-large or too-small incision may lead to poor healing or inability to completely evacuate the abscess, respectively.

# EAR

## Anatomy of the External Auditory Canal

The external auditory canal (EAC) extends from the tympanic membrane to the concha and measures approximately 2.5 cm in the adult. It is relatively short and straight in early infancy but begins to take on its adult S-shape and overall anterocaudal orientation beginning at age 2 years. Initially, the EAC is almost entirely cartilaginous, but by adulthood its medial two-thirds is comprised of bony support with an overlying thin, stratified, squamous epithelium. The lateral third has a less sensitive, thicker, hairy epithelium that produces cerumen and retains its cartilage as support. The arterial supply to the EAC originates from the external carotid artery via the posterior auricular, maxillary, and superficial temporal branches. The mandibular branch of the fifth cranial nerve ($V_3$ ) and the vagus nerve innervate the ear.

Other important anatomic considerations include the following: (1) Two natural narrowings of the EAC exist, which are important when considering foreign bodies. One is located at the junction of bone and cartilage and the other lies just lateral to the tympanic membrane. (2) A blind spot may occur in the tympanic sulcus (inferior and anterior to the tympanic membrane) due to the oblique orientation of the tympanic membrane. An examiner using a simple otoscope may not visualize a foreign body in this sulcus.

## Anesthesia of the Ear

### External Ear/Auricle

Indications for local anesthesia of the auricle include closure of extensive lacerations or other painful procedures, such as hematoma incisure and drainage. Four nerve branches supply the external ear, and knowledge of their anatomy is required to understand the location for anesthesia injection (Fig. 68-10 *A* and *B*). The *greater auricular nerve* (branch of the cervical plexus) innervates most of the posteromedial, posterolateral, and inferior auricle. A few branches of the *lesser occipital nerve* may contribute to this area. The *auricular branch of the vagus* supplies the concha and most of the area around the auditory meatus. The *auriculotemporal nerve* (from the mandibular branch of the trigeminal nerve) supplies the anterosuperior and anteromedial aspect of the auricle.

#### Procedure.

Fill a 10-mL syringe with either 1% lidocaine or 0.25% bupivacaine (both with epinephrine if a regional block is planned in an area *without* evidence of traumatized vascularity) and attach the syringe to a 25- or 27-ga needle (5 to 7 cm in length). One of several methods may be used to accomplish partial or complete anesthesia, depending on the area of concern. The greater auricular and lesser occipital nerve branches may be anesthetized by injecting between 3 and 4 mL of anesthetic in the posterior sulcus (Fig. 68-11 *A*). Insert the needle behind the inferior pole of the auricle and gradually aspirate and inject toward the superior pole, following the crescent-shaped contour of

the posterior auricle. Anteriorly, the auriculotemporal nerve may be anesthetized by placing 3 to 4 mL of anesthetic just superior and anterior to the cartilaginous tragus. Use the technique shown in Figures 68-12 and 68-13 to provide anesthesia of the auricular branch of the vagus to include more central areas of the auricle.

Another and possibly more effective option is the regional block shown in Figure 68-11 B. Insert the needle subcutaneously (SQ) at a point approximately 1 cm above the superior pole of the auricle and direct it to a point just anterior to the tragus. Be sure to inject the skin of the scalp while avoiding the auricular cartilage. Aspirate, then slowly withdraw the needle, injecting anesthetic until the needle is almost to the puncture site. Redirect the needle posterior and repeat the process while aiming at the skin just behind the mid-auricle. Remove the needle and perform the same procedure, but insert the needle just inferior to the insertion of the ear lobule and anesthetize in a superior direction. Again, block the auricular branch of the vagus as described in Figure 68-13 if additional anesthesia of the concha is required.

The addition of epinephrine to the anesthetic solution should be used with caution when placing regional blocks of the ear, especially if the blood supply has already been traumatically reduced. Do not include epinephrine when directly infiltrating wounds of the auricle, as restriction of blood flow through end arteries here may result in tissue necrosis. Other complications related to local anesthetics and regional blocks may be reviewed in Chapters 31 through 33.

**External Auditory Canal and Tympanic Membrane**

The EAC is innervated by the auricular branch of the vagus (inferiorly and posteriorly) and by the auriculotemporal nerve (superiorly, anteriorly, and inferiorly). The primary indication for local anesthesia of the auditory canal is for foreign body removal, including debridement of otitis externa or removal of significant cerumen impaction. Topical anesthetics are inadequate due to their poor absorption through the rather impermeable and keratinized epithelial surface of the EAC. Although effective, instilling local anesthetics in and around the auditory meatus is quite painful and is often difficult to perform in a struggling and uncooperative patient. Certain instances warrant adjunctive use of conscious sedation (see discussion under Foreign Body Removal).

It is quite difficult to obtain anesthesia of the tympanic membrane. The membrane is sensitive and can be stimulated during attempts at removing a foreign body from the ear canal. Topical anesthetics have limited value, but Moller and Grontved demonstrated that 10% aerosolized lidocaine (first sprayed into a syringe and shaken to evaporate the propellant) and 4% lidocaine suspension, when dripped into the ear canal, provided good anesthesia of the membrane. [12] However, it required 30 minutes for this anesthesia to take effect. Both solutions were alkaline and it was noted that the lidocaine hydrochloride, the form usually used for wound infiltration, is acidic and provided no anesthesia when applied topically.

**Procedure.**

Local anesthesia is performed with a 25- or 27-ga needle (3 to 5 cm in length) attached

to a syringe of 1% lidocaine with epinephrine (1:100,000). A 1:10 mixture of 8.4% sodium bicarbonate to lidocaine helps to reduce pain with injection in this sensitive area. Place a speculum just inside the auditory meatus and inject 0.3 to 0.5 mL of the anesthetic into the SQ tissue, stopping after a small bulge in the skin is raised. Inject in this manner in all four quadrants by moving the speculum after each injection (Fig. 68-12) . If additional anesthesia is necessary, 2 more small injections can be made. Inject the same amount slightly further into the canal, once along the anterior wall and again at the posterior wall at the bone-cartilage junction.

Another similar technique involves depositing the anesthetic just lateral or exterior to the external auditory meatus. Using the same size needle and type of anesthetic solution as just described, inject approximately 0.5 to 1.0 mL into each of 5 points around the auditory meatus and tragus (Fig. 68-13) .

## Examination

Several methods are available to examine the EAC and tympanic membrane. In all methods, the superior pinna should be grasped and pulled cephalad and posterior to straighten the slightly tortuous EAC. The most common manner of examination is with a *fiberoptic otoscope* (Fig. 68-14) . The clinician may insufflate the tympanic membrane as well as examine the EAC with the diagnostic head, while the operating head allows for instruments to be passed into the EAC and maneuvered more easily. A plastic or metal speculum may be placed in the auditory meatus for examination, using a head lamp or head mirror/light bulb as a light source.

Although this provides excellent illumination, magnifying loupes are generally needed for adequate visualization during procedures. The ideal setup for cerumen or foreign body removal consists of an operating microscope and a speculum. This provides binocular vision and frees the examiner's hands for instrumentation (unfortunately this equipment is seldom found outside of the otolaryngology clinic setting). The hand holding the otoscope is stabilized against the patient's temporal skull to prevent inadvertent canal injury due to unexpected patient movement.

## Cerumen Impaction

The apocrine and sebaceous glands lining the EAC excrete cerumen, which subsequently migrates out the auditory meatus. Cerumen repels water, has documented antimicrobial activity and forms a protective barrier against infection. Cerumen often becomes impacted, causing complaints of a "blocked" ear, hearing impairment, or dizziness. Symptomatic impaction is an indication for removal, although symptoms are rare until complete obstruction is present. More commonly in the emergency setting, cerumen obstructs visualization of the tympanic membrane and needs to be evacuated as a part of the evaluation of a febrile child or the patient complaining of ear pain.

### Cerumen Removal

Irrigation is an effective approach for cerumen removal and has the advantage of being painless and simple to perform. The patient does not have to remain completely still; thus, it is ideal for the pediatric population. Although usually more time-consuming than manual extraction, irrigation is an appropriate initial method to attempt and can be performed by technicians with guidance from the physician. One contraindication is known or suspected tympanic membrane perforations. Use irrigation judiciously in elderly and immunocompromised patients, as malignant otitis externa is frequently preceded by irrigation of the EAC. [13]

**Ceruminolytics.**

These products may soften obviously hardened or impacted cerumen. Although many products are available to assist in this, a 5 or 10% solution of sodium bicarbonate much more quickly and efficiently disintegrates cerumen compared with commercially prepared ceruminolytics and other products. Cerumenex, Cerumol, Auralgan, Buro-Sol, alcohol, and oils were all tested and took more than 18 hours to disintegrate cerumen vs 90 minutes for the sodium bicarbonate solutions. [14] Place the patient in the supine position with the affected ear up and instill the solution at least 15 minutes prior to attempts at removal. Instillation can be repeated between attempts at manual extraction or irrigation.

**Irrigation.**

This procedure is best achieved by having the patient sit upright and hold an emesis or ear irrigation basin flush against the skin just below the ear lobule (Fig. 68-15) . Insert the irrigation tip into the EAC only as far as the cartilage-bone junction, and direct the stream of water around the cerumen to prevent further impaction. Water should be near body temperature to prevent caloric stimulation. Multiple attempts may be necessary, and intermittent attempts at manual removal of loosened cerumen may help hasten the process. During the irrigation, the operator or an assistant should apply traction to the pinna to straighten the canal for more efficient irrigation.

Irrigation techniques using manual pressure to discharge the water include metal ear syringes and bulb syringes. Improvisational irrigators can be assembled with equipment found in the ED. Attach a 20- or 30-mL syringe to a 19-ga or larger butterfly device, cutting off the needle and wings and leaving the resultant tubing for irrigation. A plastic or Teflon IV catheter (16- or 18-ga with the needle removed) can similarly be affixed to a syringe.

Although most commonly found in an otolaryngologic clinic, automated pressure devices may also be available. The *DeVilbiss irrigator* (Fig. 68-16) uses a pressurized air source to propel the irrigating solution into the ear. *Oral jet irrigators* (Water Pik) are another accepted method. Although the instances have been rare, tympanic membrane rupture has been documented with these apparatuses. [15] Therefore, use the lowest-power setting and guide the stream of the water against the EAC wall, not

directly toward the tympanic membrane.

After irrigation of the EAC, application of several drops of isopropanol in the EAC will facilitate evaporation of residual moisture. The tympanic membrane must be intact if isopropanol is to be used. Further, topical Cortisporin suspension drops may be soothing after prolonged irrigation.

Although more common with jet irrigators, complications may occur with any method of ear irrigation. These include otitis externa, tympanic membrane perforation, or middle ear injury from a preexisting defect in the tympanic membrane. Irrigation should be stopped and the tympanic membrane examined in any patient experiencing sudden pain, tinnitus, hearing loss, nausea, or vertigo. If the membrane is ruptured, prophylactic antibiotics for otitis media should be given along with a referral to an otolaryngologist for an audiogram and possible tympanic membrane grafting.

**Manual instrumentation.**

This procedure is more advantageous as it is usually quicker, and the examiner may more easily remove hardened or larger concretions of cerumen under direct visualization. Either the diagnostic or operating head of the fiberoptic otoscope or a speculum may be placed in the auditory meatus to serve as a protective port through which instruments are passed and manipulated (Fig. 68-17) (Figure Not Available) . An operating microscope works best in this situation but, again, is usually not available. To prevent startling or agitating an already anxious patient, allow the patient to experience the sensation of an instrument in the canal by first placing the instrument softly against the ear canal wall.

Instruments used for cerumen removal include *flexible plastic or wire loops, right-angle hooks, suction-tip catheters, or plastic scoops* (Fig. 68-18) . The spoon-like instruments and irrigation are both more effective in removing softer cerumen. Firm cerumen ordinarily is more easily withdrawn with loops or right-angle hooks. Gently tease the cerumen off of the canal wall using loops and then pass hooks or loops around the cerumen and withdraw the cerumen slowly (Fig. 68-19) . Care should be taken to keep both hands in contact with the patient's head, as any sudden movement may cause trauma to the canal or the tympanic membrane. Complications most commonly occur when inadvertent contact is made with the thin, friable skin of the bony canal. Trauma may cause EAC laceration, hematomas, otitis externa, or tympanic membrane perforations.

## Otitis Externa

Otitis externa, or "swimmer's ear," is an infection of the auditory canal usually due to *Pseudomonas*, *Staphylococcus*, and mixed gram-positive and gram-negative organisms. The disease process involves a continuum of gradually worsening inflammatory changes. The patient may present with symptoms ranging from slight itching and discomfort to severe pain, purulent discharge, or systemic toxicity. Pain with manipulation of the pinna is the hallmark for otitis externa. Otoscopy of the external auditory canal may initially reveal minimal debris and erythema, but as the infection

progresses more edema, exudate, erythema, and possibly even a surrounding cellulitis may become apparent. In severe stages the edema may obstruct the canal, preventing instillation of ear drops.

*Aspergillus* is the most common cause of a fungal otitis externa, which presents as a furry lining of the canal. Herpes zoster affecting the geniculate ganglion may appear as grouped vesicles on an erythematous base within the canal. This condition, known as Ramsay Hunt syndrome, is associated with facial nerve palsies, hearing loss, and other cranial nerve impairment. Diabetics and other immunocompromised patients are susceptible to *malignant otitis externa*, a life-threatening form of otitis externa caused by *Pseudomonas*. Deep tissue necrosis, osteomyelitis, intracranial extension, systemic toxicity, and failure of initial outpatient therapy help differentiate malignant otitis externa from otitis externa.

**Canal Debridement/Wick Placement**

In the early stages of inflammation, remove debris using suctioning, a curette, or a cotton-tipped applicator (Fig. 68-20) . The cotton is soaked with Cortisporin or acetic acid solution. For more advanced cases presenting with significant exudate and edema, this procedure remains necessary but is intensely painful. The authors recommend using a local block of the auditory canal (see Fig. 68-13) as long as the cellulitis has not extended out to the tragus or concha. Administer parenteral analgesics if additional pain control is required.

Ear wicks may be used when edema, debris, and exudate are marked enough to impede antibiotic drops from contacting the canal skin. After debridement, use one of several methods to accomplish this. A 0.25-in. strip of Nu-Gauze dressing is covered with an antibiotic and steroid cream (Cortisporin otic cream) and may be packed into the external acoustic canal in a fashion similar to the technique used for anterior nasal packing. Using an otoscope and alligator forceps, place the leading edge of the gauze deeply in the canal until it is fully packed. Withdraw the otoscope and finish by packing the lateral aspect of the canal as well.

Another choice is to place commercially available ear wicks, such as the Pope Merocel ear wick. Place this wick into an edematous canal and apply antibiotic/hydrocortisone drops onto it. The wick swells and helps to reduce edema by the antimicrobial and anti-inflammatory effects of the solution and through pressure exerted against the walls as it expands. Leave wicks in place until the patient is followed up in 24 to 48 hours for removal and further debridement.

**Antibiotic Therapy and Follow-up**

Antibiotic ear drops most frequently consist of some combination of neomycin and polymyxin, but an acetic acid solution is another acceptable first-line therapy. Ear drops are instilled as 2 to 4 drops 4 times daily for 7 to 10 days. Hydrocortisone may be added to either the antibiotics (Cortisporin suspension or solution) or the acetic acid (VoSol HC). Cortisporin otic *solution* (clear appearing) is harmful to the middle ear if it passes through the tympanic membrane. At times it is difficult to distinguish between a ruptured

tympanic membrane secondary to otitis media and severe otitis externa in a child. Therefore, the cloudy appearing Cortisporin *suspension* is recommended in any case of suspected or known tympanic membrane perforation.

Inform patients to avoid water for the full course of treatment and to apply their ear drops immediately if water does contact the ear canal. Follow up severe cases in 24 to 36 hours and repeat debridement if needed. Generously administer oral opioids for the first 24 to 48 hours, as this condition can be quite painful.

Systemic symptoms or localized cellulitis requires administration of broad-spectrum antibiotics. A cautious approach to treating the mild to moderate case of otitis externa in the immunocompromised patient without toxic reaction is to add oral ciprofloxacin for greater coverage of *Pseudomonas*. Promptly admit suspected cases of malignant otitis externa and begin an IV anti-pseudomonal antibiotic. In addition, immediately consult an otolaryngologist specialist for possible surgical debridement. Patients with Ramsay Hunt syndrome should be admitted for administration of IV acyclovir. Treat otomycosis by swabbing the canal with a cotton-tipped applicator saturated with an antifungal solution (such as clotrimazole or boric acid/alcohol) in an effort to remove debris. Repeat this if necessary on follow-up in 3 to 7 days. Do *not* administer corticosteroids in cases of known fungal otitis externa.

**Foreign Bodies of the Ear Canal**

Despite its small size, the EAC may play host to a number of types of foreign bodies. [16] [17] Living insects account for the majority of foreign bodies found in adults. Children frequently place food (e.g., peas, beans), organic matter (e.g., grass, leaves, flowers), and inorganic objects (e.g., beads, rocks, dirt) into the ear canals during play, and they often fail to admit this to parents. Button batteries may cause significant tissue destruction in a matter of hours, and it is vital to immediately obtain otolaryngologic consultation for removal if the button battery is not easily extracted. Symptoms of foreign body retention are usually ear pain, fullness, or impaired hearing in the adult, whereas the pediatric patient may not present until an associated otitis externa with a purulent discharge has developed. Tinnitus, vertigo, significant hearing loss, or bleeding from behind the object should raise a high suspicion for an associated tympanic membrane rupture.

As previously described, the anatomy of the external auditory canal predisposes to the entrapment of foreign bodies in either a lateral or a deeper position. Removal of more medial objects can be much more painful and anesthesia is usually required. Even the most cooperative patient may become difficult after feeling pain during manipulation of the ear canal. It is probably impossible to adequately immobilize the head of an uncooperative awake child to delicately extract a foreign body. Some authorities claim local anesthesia makes extracting foreign bodies even more difficult because of soft tissue distortion, although swelling should be minimal if proper amounts of anesthetic are used. A more realistic concern is that if the foreign body is deeply or firmly embedded, the patient should be referred early for removal under an operating microscope, before canal trauma and swelling mandate admission for removal under general anesthesia. Conscious sedation (preferably an analgesic-sedative combination

or dissociative anesthetic) can aid in the removal of foreign bodies in the distraught child by preventing further struggling and potential canal trauma. The care provider must weigh the inherent risks of conscious sedation against those of general anesthesia and the cost of hospital admission.

Before initiating removal, the clinician should set realistic limits on the number of attempts to be made. Even the best clinician can become too aggressive as frustration builds with failed attempts to extract the object. Early consultation with an otolaryngologist should not be considered a failure in cases of difficult foreign bodies. Indeed, with the proper equipment and experience, most objects can be atraumatically removed.

**Procedures**

Most approaches to foreign body removal are anecdotal and are found in the literature as case reports or case series rather than as prospective clinical trials. The clinician should be familiar with several techniques, as the most appropriate choice can vary depending on depth of impaction or the size, shape, and consistency of the object. *Irrigation* is the least invasive option and the techniques and related complications are explained in detail earlier in this chapter (see Cerumen Removal). Deeply embedded vegetable matter (such as beans, peas, or seeds) should not be irrigated, as swelling may occur and make extraction more difficult. Irrigation works particularly well with small rocks, dirt, or sand that lies deep in the canal next to the tympanic membrane.

**Suction-tip catheters.**

These devices can also be used, but the patient must be informed of the impending noise to prevent sudden movements from a startle reflex. Place either the blunt or soft plastic tip against the object and slowly withdraw. If using a suction instrument with a thumb-controlled release valve (as with the Frazier suction [Fig. 68-18]) , remember to cover the port to activate the suction.

**Manual instrumentation.**

This approach may be attempted with a variety of instruments (Fig. 68-21) . Illumination and magnification are accomplished by either the diagnostic or operating head of a fiberoptic otoscope. An assistant should hold the pinna back and out so that the examiner may hold the otoscope with one hand and manipulate the instrument with the other. A speculum and either a head lamp or head mirror/light source can also provide illumination, but magnifying loupes are usually required for adequate visualization. Use small alligator forceps to remove objects with edges that can be grasped, but avoid trying to encircle an impacted round foreign body, as this may cause trauma to the canal wall. A small right-angle hook is another choice. Place the tip past the object, rotate it 90°, and then pull the object from the canal. Fine-tissue or Adson forceps, curettes, and skin hooks are other instruments that are used occasionally.

**Small Fogarty catheters.**

Small Fogarty catheters (biliary or vascular) may be used in a manner similar to that described later in the chapter for nasal foreign body removal. [18] Attach the catheter tip to a 2-mL syringe and gradually inflate the balloon once the tip is past the object; then drag the foreign body out along with the balloon. Immediately deflate the balloon if sudden pain occurs, because tympanic membrane rupture is a potential complication.

**Cyanoacrylate (Superglue).**

This compound may be used in small amounts applied to the tip of a thin paintbrush, a straightened paper clip, or the blunt end of a wooden cotton-tipped applicator. [19] Place the tip against the object, allow it to dry, then carefully withdraw the foreign body. Minor complications are possible if the tip dries against the canal wall (abrasion, excoriation) or if the glue spills or drips onto the wall (creating a new foreign body).

**Dissolution of Styrofoam.**

*Styrofoam impaction* in the ear canal can be problematic. Application of acetone in a very small amount (0.1 mL) was reported to effectively dissolve deep-seated Styrofoam in a child's ear canal. [20] The ear was irrigated immediately after carefully dripping the acetone directly onto the Styrofoam, and no significant complications of the canal or tympanic membrane were noted. The potential ototoxic effects of acetone in the middle ear have not been studied; therefore, do not perform this technique if any suggestion or history of tympanic membrane perforation exists.

**Removal of insects.**

Cockroaches are the most commonly found *live insect* as an intra-aural foreign body; treatment consists of instillation of various substances into the ear canal to first immobilize or kill the bug. This helps retrieval by allowing for a stationary target and also halts the disturbing and painful movement of the insect. Controversy exists about which agent most effectively accomplishes this. Mineral oil has traditionally been used, although lidocaine has been reported to paralyze roaches and to allow for easier extraction than the more viscous mineral oil. An in vitro comparative study showed that immersion in mineral oil and 2 or 4% lidocaine solution killed roaches in <60 seconds (27 and 41 seconds, respectively). [21] The roaches struggled less in the viscous oil than in the lidocaine, which did not appear to cause paralysis. Other substances (Auralgan, isopropanol, water, succinylcholine, hydrogen peroxide) were shown to be ineffective in killing the roaches in a reasonable amount of time. Once disabled, insects may be removed with mechanical extraction as previously described, and pieces can be suctioned out if fragmentation occurs. Mineral oil is safe, but lidocaine has been reported to cause vertigo and middle ear symptoms in patients with tympanic membrane perforations. [22]

**Follow-up/Complications**

Hearing should be evaluated before and after foreign body removal, especially in patients with suspected tympanic membrane or middle ear injuries. Examine both the opposite ear and nose of children to search for the rare but possible second foreign body. Minor lacerations or excoriations of the canal usually heal quickly with or without antibiotic ear drops, so long as the canal is kept clean and dry. Document preexisting canal trauma or suspected tympanic membrane rupture before attempts at removal; otherwise, this may falsely be attributed to iatrogenic causes at a later date. Most patients with foreign bodies that cannot be removed in the emergency setting can be safely referred to an otolaryngologist the next day. Exceptions that require immediate consultation include severe pain, suspected tympanic membrane rupture, embedded button batteries, or a concomitant canal infection.

## Auricular Hematoma

Auricular hematomas occur after a shearing force to the ear, most commonly in wrestlers. A subperichondrial hematoma forms, separating the perichondrium from the cartilage. Recurrent or untreated injuries allow the development of new cartilage, which subsequently deforms the auricle (cauliflower ear).

**Procedure**

The treatment of an auricular hematoma involves complete evacuation of the subperichondrial hematoma and reapproximation of the perichondrium to the cartilage.

**Needle aspiration.**

Aspiration of auricular hematomas is performed by perforating the hematoma with a 20-ga needle (Fig. 68-22) . The hematoma is "milked" between the thumb and forefinger until the entire hematoma is evacuated. A pressure dressing is subsequently applied. Frequently reexamine the ear for reaccumulation of the hematoma. Reaccumulation of blood requires reaspiration. Because of the possibility of inadequate evacuation and recurrent hematomas, the authors do not recommend needle aspiration.

**Incision.**

The auricular hematoma, if less than 7 to 10 days old, may be incised along the natural skin folds. Anesthetize the pinna using local infiltration of 1% lidocaine (without epinephrine) or by an auricular block (described earlier). Incise the skin with a No. 15 blade at the edge of the hematoma, following the curvature of the pinna (Fig. 68-23) (Figure Not Available) . Gently peel the skin and perichondrium off the hematoma and underlying cartilage. Completely evacuate the hematoma and irrigate the remaining pocket with normal saline.

**Aftercare.**

After removal of the hematoma, apply antibiotic ointment and reapproximate the perichondrium to the cartilage via a pressure dressing. A compression dressing may be applied to the ear as described in Figure 68-24 . An alternative technique is to suture dental rolls over the area (see Fig. 68-23) (Figure Not Available) . [23] To accomplish this, pass 4-0 nylon suture through the entire thickness of the ear over the hematoma. Wrap the suture around a dental roll on the posterior aspect of the ear and then pass the needle back through the pinna. Wrap and tie the suture around a second dental roll on the anterior aspect of the pinna. A second suture may be placed to secure a third dental roll. The dressing should firmly re-approximate the perichondrium to the cartilage without vasculature compromise. Remove the dressing in 1 week.

Prescribe anti-staphylococcal antibiotics and instruct the patient to inspect the wound frequently for evidence of vascular compromise and/or infection. Reevaluate the wound in 24 hours for recurrence of the hematoma. Infection is treated with bandage removal, surgical drainage, and IV antibiotics. Refer patients with auricular hematomas of >7 days' duration to a surgeon, as the new perichondrial growth must be debrided to prevent auricular deformation.

# NOSE

## Anatomy

The nose consists of the vestibule, nasal septum, lateral wall, and the nasopharynx. The vestibule is the anteriormost portion of the nares, which is composed of skin and contains the hair follicles. The nasal septum is the midline structure, which is composed of cartilage anteriorly and of bone posteriorly. The lateral wall of the nose contains the superior, middle, and inferior turbinates as well as the auditory tube opening.

Three major arteries supply the nose and conjoin via anastomoses. The sphenopalatine artery emerges from the sphenopalatine foramen, which is located at the posterior aspect of the middle turbinate (Fig. 68-25) (Figure Not Available) . This is the most common source of posterior epistaxis. This artery supplies the turbinates laterally and the posterior septum. The anterior and posterior ethmoidal arteries branch off the ophthalmic artery and penetrate the cribriform plate to supply the superior nasal mucosa. The superior labial branch of the facial artery completes the triad, supplying the nasal septum and vestibule. The watershed area on the anterior septum, also known as Kiesselbach's plexus, is the most common source of anterior epistaxis (Fig. 68-26) (Figure Not Available) .

## Anesthesia

Apply local anesthetic and vasoconstrictors on cotton swabs. Placement of these swabs is illustrated in Figure 68-27 (Figure Not Available) . If a larger area of anesthetic is required, use cotton pledgets. Figure 68-28 explains the procedure of making pledgets.

Soak each pledget in anesthetic or vasoconstricting substance and then squeeze the excess fluid out of the pledget. Be aware of the total amount of drug being administered and stay within recommendations for the maximum safe dosage. Place each pledget horizontally on the floor of the nasal cavity, stacking the next pledget on top. Three pledgets are usually required to pack the nasal cavity. These can be replaced with new pledgets in 5 minutes if the desired anesthetic effect is not achieved. Hurricaine spray may also be used as a topical anesthetic. Remind the patient that any excess anesthetic may numb the throat but will not inhibit swallowing.

As with all drugs, review the maximum dose allowed before administering the anesthetic (see Chapter 31) . Always use the smallest amount of anesthetic required to obtain adequate analgesia. The maximum dose of lidocaine without epinephrine is 3-5 mg/kg up to a dose of 300 mg. The maximum dose of lidocaine with epinephrine is 5-7 mg/kg up to a dose of 400 mg. The maximum dose for cocaine is 3 mg/kg for mucosal application up to a dose of 200 mg. Remember that these are guidelines and that any patient can have a severe reaction with less than the total dose. For a 60-kg person, the maximum total dose of lidocaine would equal 300 mg (60 kg × 5 mg/kg = 300 mg). A 1% solution (10 mg/mL) would allow for a total of 30 mL to be administered (30 mL × 10 mg/mL = 300 mg). A 2% solution (20 mg/mL) would allow for only 15 mL to be administered (15 mL × 20 mg/mL = 300 mg). Cocaine is packaged in a 4% solution (40 mg/mL), allowing only 5 mL for a mucosal application to a 70-kg patient (3 mg/kg × 70 kg = 210 mg; 5 mL × 40 mg/mL = 200 mg, which is the maximum total dose). Always be familiar with the side effects and potential complications of the drugs being administered. Cocaine can induce tachycardia, hypertension, irregular respirations, seizures, and hyperpyrexia (especially in children). Lidocaine will manifest its antiarrhythmic and membrane stabilization effects.

## Examination

Examination of the nares is relatively straightforward. When using a nasal speculum, insert it into the naris with the handle parallel to the floor and slowly open the blades in the superior-to-inferior direction. Stabilize your hand on the patient's nose to prevent damage to the mucosa due to unexpected movement (Fig. 68-29) (Figure Not Available) . When attempting to visualize the nasal passageway, remember to have the patient keep the floor of the nose parallel to the ground. Tilting of the head only allows for a view of the anterosuperior area (Fig. 68-30) . A nasopharyngoscope may be used to view the nasal passageway as well, and its use is described in the previous section on examination of the pharynx.

## Epistaxis

Nasal hemorrhage commonly presents to the ED. Identification of the source of bleeding and subsequent control are paramount to the treatment of epistaxis. Although this can be frightening to both physician and patient, a systematic approach with the proper equipment will lessen the anxiety of the situation. The purpose of the procedure is to tamponade the bleeding. If the source is anterior, this may be the final treatment. For posterior bleeds, these are generally temporizing maneuvers until a definitive hemostatic procedure can be completed by a consultant. The procedures can be

performed in the ED with proper lighting and the equipment listed below. Controlling epistaxis may be a time-consuming process without the proper equipment or the cooperation of the patient.

In preparation for any procedure to treat epistaxis, evaluate the patient's hemodynamic status by assessing vital signs and orthostatic symptoms and quantifying blood loss. Also determine if the patient has any underlying medical problem, such as angina or chronic obstructive lung disease, which may be exacerbated due to hypovolemia or anemia. If the patient is symptomatic in any of these areas, or if the blood loss is deemed significant, start a large-bore IV line and administer fluid boluses. Obtain a complete blood count and consider a type and screen. Coagulation studies should be undertaken in patients taking anticoagulant therapy, those with underlying hematologic abnormalities, or those with recurrent epistaxis.

Many patients with epistaxis are hypertensive as well. No direct correlation has been proven between hypertension and epistaxis. Most authors now consider hypertension to be a stress response instead of an inciting event. [24] Therefore, hypertension does not require treatment until the bleeding is controlled and the anxiety of the situation has resolved. However, any patient exhibiting other signs of a hypertensive emergency needs immediate treatment in addition to control of the epistaxis.

**Indications/Contraindications**

Any continuing episode of epistaxis can be treated with the following techniques. Massive facial trauma with the possibility of a basilar skull fracture would preclude the use of a transnasal balloon, as it may travel into the skull cavity.

**Equipment**

- Chair with headrest or gurney with inclinable back

- Headlight with light source, head mirror

- Wall suction with multiple suction catheters

- Gloves, mask, and gown for physician

- Gown or drapes for patient

- Topical anesthetic

- Topical vasoconstrictor

- Nasal speculum

- Tongue depressors

- Small red rubber catheters

Bayonet forceps

Scissors

Kidney basin

Gauze (4 × 4 in., 2 × 2 in.)

Dental rolls or cotton

No. 2 surgical silk ties

1.2-cm wide Vaseline gauze or 0.5-in. wide Nu-Gauze packing

Antibiotic ointment

Silver nitrate sticks or electrocautery

Pediatric Foley catheters (12 Fr)

Rhino Rocket, nasal tampons

Dual balloon pack

**Epistaxis Examination**

As most patients are frightened by continued epistaxis, reassure the patient that you will control the bleeding. Drape the patient with a gown to protect his or her clothing from the bleeding. Have the patient hold an emesis basin to collect any continued bleeding and as a precaution to emesis of swallowed blood. Patients with epistaxis can be quite anxious, and manipulation of the nose can be quite painful. Therefore, sedation/analgesia with appropriate physiologic monitoring should be considered when extensive manipulation is anticipated.

Have the patient sit upright in the sniffing position with the neck flexed and head extended. The base of the nose should remain parallel with the floor. Position yourself in front of the patient, level with the patient's nose after putting on a face shield, gown, and protective gloves. Allow the patient to clear the nose of any blood clots by forceful blowing or, alternatively, you may suction the passageway until it is free of clots. If the bleeding is minimal, attempt to identify the bleeding source. If the bleeding is too profuse for visualization, administer a topical anesthetic and vasoconstrictor. A 4% cocaine solution would be ideal, but it is not commonly stocked in EDs; however, 2 to 4% lidocaine with epinephrine (or lidocaine supplemented by Neo-Synephrine) can be used.

Insert the nasal speculum into the naris and use the suction catheter to evacuate any blood. Do not hesitate to reapply anesthetic or vasoconstrictor if the desired results have not been achieved. As most cases of anterior epistaxis occur in Kiesselbach's plexus, inspect this area closely for areas of bleeding, ulceration, or erosion. If the

patient presents with a history of epistaxis but is no longer bleeding, gentle stroking of the anterior nasal mucosa with a cotton swab or having the patient forcefully blow the nose may reveal the bleeding source. If no source is found and the bleeding has ceased, the authors suggest packing the nose only if the epistaxis is recurrent. If no anterior source is found and bleeding continues down the posterior pharynx, assume a posterior source and pack the nose with an anterior and posterior pack.

**Cautery**

After identifying an anterior source of bleeding, there are several options to obtain hemostasis (Fig. 68-31) . *Silver nitrate sticks* may cauterize the area. Remember that silver nitrate sticks will not cauterize an actively bleeding source; therefore, hemostasis must be achieved first. Start by cauterizing above the bleeding source first to avoid the flow of blood. Cauterize around the bleeding source in a circular fashion. This technique should provide enough hemostasis to allow direct cautery of the source. Wipe away any excess silver nitrate to prevent inadvertent cautery of other areas of the nose. If this restarts the bleeding, the initial cautery was insufficient. *Electrocautery* will work in the same manner, but the cauterization will penetrate more quickly than the silver nitrate sticks. Care must be taken to prevent inadvertent septal perforation due to overaggressive or repeated cautery. Cautery works well for a small circumscribed area of bleeding.

If this is the initial bleed and hemostasis is achieved, no packing is necessary. If this is a recurrent bleed within 72 hours of another, or if cautery does not provide hemostasis, the anterior cavity should be packed. If hemostasis is accomplished, apply Vaseline or antibiotic ointment to the area to prevent desiccation. Do not administer aspirin or nonsteroidal anti-inflammatory drugs for 4 days after epistaxis. If bleeding recurs at home, instruct the patient to pinch the nostrils closed for 20 minutes. Instruct the patient to return to the ED if this maneuver is unsuccessful or the bleeding is profuse.

**Anterior Nasal Packing**

*Anterior gauze packing* is placed to complete hemostasis, prevent desiccation, and protect the area from trauma. However, improperly placed packing may further abrade the area, dislodge prematurely, or migrate into the posterior pharynx. Anterior packing must be placed with adequate analgesia, proper visualization, and deliberate movements. The packing is applied in an "accordion" fashion so that each layer extends the entire length of the nasal cavity.

Coating the packing with antibiotic ointment aids in its placement and helps prevent toxic shock syndrome secondary to nasal packing. Proper placement of the speculum allows visualization of the floor of the nasal cavity. Lay a strip of 1.2-cm wide (0.25- or 0.5-in. Nu-Gauze) gauze across the nasal floor, with the starting end of the gauze at the naris (Fig. 68-32) . Replace the speculum over the layer of gauze, gently packing it to the floor of the nose. Measure the gauze to twice the length of the nasal cavity. Grasp the gauze at the midpoint and insert this point to the posterior aspect of the nasal cavity. This allows placement of the gauze without movement of the underlying layer. Continue

this pattern, replacing the speculum after each layer until the cavity is filled.

An alternative to anterior nasal packing is the *nasal tampon* (Merocel) or the Epistat II nasal catheter (Xomed Surgical Products, Jacksonville, Fla) (Fig. 68-33 *A* and *B*). Place these products into the anterior nasal cavity along the floor of the nose. Contact with moisture will cause them to swell. It is sometimes necessary to place two tampons side by side before inserting them, to fill the nasal cavity. Any packing in the anterior nasal cavity may obstruct drainage of the paranasal sinuses or block the nasolacrimal ducts. In addition, because it is a foreign body, it will stimulate mucus production and act as an impetus for infection. Antibiotics should be prescribed with any packing left in the nose after emergency treatment because of the risk of toxic shock syndrome.

**Posterior Nasal Gauze Packing**

The patient has posterior epistaxis if no source of bleeding is found anteriorly and the patient continues to hemorrhage down the posterior pharynx. Posterior epistaxis may respond to topical vasoconstrictors. However, anterior nasal packing will not provide hemostasis, as it will not cover the source of bleeding. A posterior pack directly compresses the sphenopalatine artery and prevents the passage of blood or anterior packing into the nasopharynx.

The *posterior nasal gauze pack* is the classic method of treating posterior epistaxis. However, because balloon devices are easier to use and are less distressing to the patient, posterior nasal packing is less commonly used. To place a posterior nasal gauze pack, anesthetize the patient's nares and posterior pharynx with topical anesthetic. Prepare a roll of gauze with two No. 2 silk ties secured around the middle and extending in opposite directions. One set of ends will be used to place the posterior pack and the second will remain extruding from the oral cavity to remove the pack. Place a No. 10 red rubber catheter through the bleeding nostril (Fig. 68-34) . When it is seen in the posterior pharynx, grasp it with forceps and guide it out of the mouth. Attach it to one set of ends of the silk ties secured to the gauze pack. Retract the red rubber catheter, thus carrying the No. 2 silk tie through the nasopharynx and out of the nose. Grasp the suture and pull the pack into the nasopharynx. Guide the pack swiftly into the oral cavity and nasopharynx with the other hand. Attach the silk tie that remains in the oropharynx to the patient's cheek to aid in removal or rescue of the posterior pack. Use the silk ties exiting the nostril to maintain the position of the posterior pack. Pack the anterior passage as described for anterior epistaxis. Secure the silk ties over a gauze pad or dental roll. Patients with this type of posterior pack are admitted to the hospital.

**Inflatable Balloon Packs**

Inflatable balloons come in two varieties. The *Foley catheter* is often used as a posterior pack because of its availability, ease of use, and successful tamponading effect. [25] Insert a 12 Fr Foley catheter through the bleeding naris into the posterior pharynx (Fig. 68-35) . Inflate the balloon half way with about 5 to 7 mL of normal saline or water. Slowly pull the Foley into the posterior nasopharynx and secure it against the posterior aspect of the middle turbinate. Finish inflating the balloon with another 5 to 7 mL of normal saline or water. If there is pain or inferior displacement of the soft palate, deflate

the balloon until the pain resolves. Complete inflation of the balloon before proper placement causes the balloon to remain too posterior in the nasopharynx, thus failing to achieve hemostasis. [26] Place a short section of plastic tubing over the catheter and secure it with a nasogastric tube clamp or umbilical clamp. Be careful not to exert undue pressure on the nasal alar, as this may cause necrosis.

The second type of inflatable balloon pack is the pre-made *dual balloon tamponading system*. Goitschach Nasostat (Sparta Surgical Corp, Hayward, Calif) and Xomed Epistat (Xomed Inc, Jacksonville, Fla) are examples of some available devices. The *dual balloon pack* has a posterior balloon that inflates with about 10 mL of air and an anterior balloon that inflates with about 30 mL of air (Fig. 68-36) (Figure Not Available) . Each device may vary slightly (Fig. 68-37) . After appropriately anesthetizing the naris, place the lubricated pack along the floor of the affected naris as far back as possible. Inflate the posterior balloon about half way with air and then pull the balloon into place up against the posterior aspect of the middle turbinate. Complete the inflation of the posterior balloon with air. If the patient complains of pain or if the posterior soft palate deviates downward, deflate the balloon until the symptoms are relieved. Maintain the position of the balloon and inflate the anterior balloon with up to 30 mL of air. Again, halt the inflation if the patient experiences increasing pain or deviation of the nasal septum. Some authors suggest packing the opposite naris to prevent this lateral deviation. A small piece of gauze is placed between the nose and external catheter hub to decrease skin irritation. Generally, healthy patients given this type of pack are treated as outpatients, and the device is removed in 2 to 3 days.

**Complications**

Care of the posterior nasal packing is of particular concern. Posterior nasal packing is uncomfortable and often painful. Complications associated with posterior packing include infection, dysphagia, hypoventilation, tissue necrosis, and dislodgment. Therefore, any patient with a posterior pack should be admitted to the hospital for sedation and monitoring. Rebleeding may also be seen with early pack removal; one series found pack removal within 48 hours to increase the risk of rebleeding. [27]

*Infection* risk with posterior packing includes toxic shock syndrome, nasopharyngitis, and sinusitis. The packing blocks the sinus ostia, preventing proper drainage of the sinuses. In addition to coating the packing with antibiotic ointment, broad-spectrum antibiotics should be administered. *Dysphagia* due to the packing can lead to poor oral intake, and IV fluid hydration may be required.

A significant decrease in $Pa_{O_2}$ (7.5 to 11 torr) and increase in $Pa_{CO_2}$ (7 to 13 torr) is seen in patients with nasal packing who are treated with sedation. [28] This physiologic adaptation is even more worrisome in patients with underlying lung disease. With the risk of *hypercarbia* and *hypoxia*, patients with lung disease with posterior nasal packs should be closely monitored in an intensive care setting.

*Tissue necrosis* of the nasal ala, nasal mucosa, and soft palate has been described secondary to improper placement or padding. The risk of necrosis increases with the

duration of the packing, so all packing should be removed in 3 to 5 days.

If the *posterior pack becomes dislodged*, it will fall into the oropharynx with the risk of asphyxiation, vomiting, and aspiration. The patient, as well as nursing personnel, needs to be familiar with the technique for removing the pack. To accomplish this, cut the anterior sutures that exit the naris from the gauze roll if they have not already broken. Grasp the sutures exiting the mouth and guide the packing out of the nasopharynx. It may be necessary to manually extract the packing with forceps or digits.

*Toxic shock syndrome* has been described with nasal packing. [29] The syndrome is caused by a toxin released by *Staphylococcus aureus*. Sudden onset of vomiting and diarrhea with high fever as well as development of an erythrodermic rash heralds the onset of the disease. Untreated, the disease can advance into shock and multisystem organ dysfunction. Therefore, in addition to coating the gauze with antibiotics to decrease the local bacterial concentration, broad-spectrum antibiotics should be given to any patient with nasal packing. Any symptoms of toxic shock syndrome should prompt the removal of the packing and admission to the hospital for fluid hydration and IV nafcillin or vancomycin therapy.

## Septal Hematoma

Trauma to the anterior portion of the nasal septum may cause a hematoma to form between the perichondrium and cartilage. If untreated, the hematoma may cause complications including septal perforation, septal abscess, and cartilage destruction, with resultant saddle-nose deformity.

Diagnose a septal hematoma by inspecting the nasal septum for swelling, pain, and a fluctuant area. Direct palpation may be necessary, as newly formed hematomas may not yet be ecchymotic. Inspect both sides, as bilateral hematomas are possible. The absence of nasal obstruction does not rule out a septal hematoma.

### Drainage

Treatment of a septal hematoma consists of evacuation of the clot with subsequent reapproximation of the perichondrium to the cartilage. To drain the hematoma, *incise* the mucosa horizontally over the hematoma after adequate anesthesia is achieved (Fig. 68-38) . Suction out all clot and then irrigate with normal saline. Excise a small amount of mucosa to prevent premature closure of the incision and place a section of a sterile rubber band to act as a drain. The nostril should then be packed, as in anterior epistaxis, to reapproximate the perichondrium to the cartilage.

Give the patient broad-spectrum antibiotic therapy. Inspect the septum daily for signs of infection, recurrent hematoma, or necrosis. Recurrent hematomas should be evacuated. When there is no further hematoma for a 24-hour period, remove the drain. Pack the affected naris for 1 more day to complete the apposition of the perichondrium to cartilage where the drain has been. Any evidence of infection should prompt admission

for IV antibiotics and surgical debridement.

## Nasal Fracture

Nasal fractures present with symptoms ranging from mild swelling to epistaxis to periorbital ecchymosis with obvious deformity. As with any trauma to the head, coexistent intracranial injury or neck injury must be evaluated first. In the evaluation of nasal trauma, rule out the existence of a septal hematoma or cerebrospinal fluid rhinorrhea. In most cases, the swelling and soft tissue deformation prevent adequate evaluation and/or treatment. Radiographs are not routinely recommended as they will not alter the course of treatment or injury. [30] Have the patient apply ice to the area and keep the head elevated to treat the soft tissue swelling. Refer the patient to an otolaryngologist for reexamination and definitive treatment in 3 to 5 days. Stress to the patient the importance of being evaluated again in less than 10 days so that the bones do not set in a malaligned state.

### Nasal Fracture Reduction

Simple fractures with minimal local swelling can be treated with closed reduction. To minimize potential litigation, obtain written consent and take prereduction and postreduction photographs. Inform the patient that the outcome is not guaranteed, as impacted fractures may not reduce and greenstick fractures may deform again after reduction. Any swelling may obscure the extent of the deformity or the degree of reduction.

Anesthetize the mucosa as described above (see Figs. 68-27 (Figure Not Available) and 68-28) . Topical anesthetic is usually adequate; however, infiltration with 1% lidocaine without epinephrine may be used adjunctively. For infiltrative anesthesia, inject the lidocaine either deep to the nasal fracture by entering intranasally or externally into the fracture site for a hematoma block. The latter approach is usually quite uncomfortable for the patient.

Asch forceps or a scalpel handle is advanced into the naris with the dominant hand (Fig. 68-39) (Figure Not Available) . Apply pressure in an anterosuperior direction at a right angle to the ridge of the nasal bone. The other hand manipulates the nasal fracture in an anteroinferior direction. Firm, constant pressure is maintained until the bone shifts back into its original position. Assess the reduction for malalignment or subsequent displacement secondary to a greenstick fracture. If either occurs, refer the patient to an otolaryngologist.

Exterior splint dressings can be applied to maintain reduction. Some authors believe this will mask an incomplete reduction or adversely manipulate the reduction during placement. Remove the splint in 7 to 14 days. [31] As in most closed fractures, antibiotics are not indicated. Epistaxis or direct evidence of an open fracture should prompt referral to an otolaryngologist and initiation of broad-spectrum antibiotics.

**Nasal Foreign Bodies**

Nasal foreign bodies frequently present in the pediatric patient, but it is not uncommon to find them in psychiatric or mentally retarded populations as well. Usually a family member has witnessed the event or the patient actually complains of discomfort from the foreign body. Maintain a high level of suspicion, however, in patients who present with unilateral purulent nasal discharge, unilateral sinusitis, or recurrent unilateral epistaxis, as retained foreign bodies can often initially fail to cause pain or other symptoms.

Types of nasal foreign bodies vary widely and often include food (e.g., meat, nuts, beans), beads, jewelry, hardware (e.g., nuts, screws), and even certain living larvae or worms. Alkaline button batteries may cause significant mucosal burns, ulcerations, necrosis, and even septal perforation in hours to days. [32] It is imperative to promptly remove these batteries before tissue damage occurs from leakage of battery contents, electrical currents, and direct pressure.

Nasal foreign bodies often come to rest on the floor of the anterior or middle third of the nose. Metallic or calcified objects may show up on x-ray, but physical examination remains the most reliable means for diagnosis. Maxillary, ethmoid, or sphenoid sinusitis may also accompany foreign body retention. Plain radiographs or facial computed tomographic scanning may be of value in detecting sinusitis, although they are usually not necessary in the acutely retained object.

Failure to remove nasal foreign bodies results in admission for removal under anesthesia; therefore, it behooves emergency medicine physicians to be skilled in this procedure. Admission incurs increased cost, inherent procedural risks, and psychological stressors for both the parents and patients. Like auricular foreign bodies, the removal of nasal foreign bodies can be both frustrating and time consuming. Irrigation cannot be used, as fluid will pass through the nasopharynx.

**Nasal Foreign Body Removal**

A cooperative patient is essential; therefore, young children often require general anesthesia for more posterior foreign bodies. While conscious sedation may aid in removal and preclude the need for admission and general anesthesia, the possible increase in aspiration risk must be considered with use of agents that blunt protective airway reflexes. Before attempting removal, anesthetize and vasoconstrict the affected naris, as previously described in the chapter. Obtain assistance to stabilize the patient's head, and immobilize younger patients as required. The more cooperative patients should be placed in the "sniffing" position, and a head lamp should be used for proper illumination.

Use *alligator forceps* or *bayonet forceps* to retrieve more anteriorly lodged foreign bodies with edges that are amenable to grasping. *Wire loops, right-angle hooks,* or even a properly bent *paper clip* may be carefully passed by the object and rotated, allowing it

to be pulled from the naris (see Fig. 68-18) . Direct mucosal trauma and epistaxis may occur with any of these methods. Foreign bodies with smooth, rounded edges that are difficult to grasp or to pass instruments around may be extracted with a *suction-tip catheter* in a similar manner as that described earlier for EAC foreign bodies.

Objects that cannot be removed with anterior instrumentation may be removed with *balloon catheters*. Several case series have depicted Fogarty catheters as being highly effective in removing nasal foreign bodies (Fig. 68-40) . [33] [34] A No. 4 or 5 vascular Fogarty catheter, a 12 Fr Foley catheter, and a No. 6 biliary Fogarty catheter have all been described for this use in the literature (the biliary catheter reportedly is less apt to rupture). The patient lies supine after proper vasoconstriction and anesthesia of the affected naris. With a 5-mL syringe attached, and the catheter lubricated with lidocaine gel, the tip is passed above the object and into the nasopharynx. The balloon is then inflated with air or water (approximately 2 mL in small children and 3 mL in older children) with the thumb controlling the syringe plunger and, thus, balloon size. The catheter is slowly withdrawn until resistance is felt, and then the object is removed. Complications mentioned in the literature are limited to occasional mild posttraumatic bleeding only, but the theoretical risk of airway obstruction by the balloon or aspiration from further displacement of the object should be considered.

Another approach to the posteriorly placed nasal foreign body is blowing the object out with *air pressure*. One technique requiring no instrumentation is performed by lying the child supine and occluding the unaffected nostril (Fig. 68-41). As in mouth-to-mouth resuscitation, air is then exhaled by the examiner until resistance (from the patient's epiglottis shutting) is felt.  Air is then briskly blown into the mouth which produces an outward pressure behind the object. This either moves it within grasping reach or pops it completely out of the naris. The patient's parent may also be talked through this procedure, which can provide for a less frightened and more cooperative patient. A variation on this method includes using a bag-valve mask instead of the examiner's mouth to provide the air pressure, and application of the Sellick maneuver to prevent air from passing down into the esophagus. [37] Although theoretical complications would include possible barotrauma to the tympanic membrane or those seen with positive-pressure ventilation (pneumothorax, mediastinal emphysema), no reported complications have been published in regard to these two techniques.

# Chapter 69 - Emergency Dental Procedures

**James T. Amsterdam**

Patients with a variety of general dental, oral, and maxillofacial emergencies may present to any emergency unit. Emergencies may range from an agonizing toothache to massive maxillofacial trauma or infection. Most general dental emergencies can be evaluated and managed initially by the emergency physician; however, pediatric dental emergencies and dentoalveolar trauma may require immediate dental consultation and early follow-up. In addition, consultation is essential in maxillofacial trauma or in certain dental infections in which a seemingly minor problem may have potential life-threatening implications, including airway compromise, septicemia, and dehydration. Management of oral and facial pain, dentoalveolar trauma, dental infection, and maxillofacial trauma requires an understanding of the anatomy of the stomatognathic system and the relevant anatomy will be discussed. Intraoral and extraoral local anesthesia can be very useful in the diagnosis and management of dental emergencies; this topic is covered in Chapter 33 . This chapter concludes with an overview of the oral manifestations of systemic disease that are of particular importance to the emergency physician.

## ANATOMY

### Stomatognathic System

The muscles of mastication are divided into 2 groups: the supramandibular muscles, or elevators of the mandible, and the inframandibular muscles, or depressors. The most important elevating muscles are the masseters, the medial pterygoids, and the temporalis. The bilateral simultaneous function of this group is to move the condyle of the mandible superiorly and posteriorly. The muscles involved in the depressor function of the mandible are the lateral pterygoids, the digastric muscles, the geniohyoid, and the mylohyoid. Unilateral contraction of the lateral pterygoid muscle causes movement of the mandible to the opposite side. If both lateral pterygoids contract simultaneously, the mandible is depressed, causing the jaw to open in a downward and forward movement.

The mandible is essentially formed bilaterally by 2 rami: the horizontal portion and the ascending portion (Fig. 69-1) (Figure Not Available) . The ascending ramus of the mandible extends up to form 2 processes: the coronoid process, which extends anteriorly, and the more important condylar process, which extends posteriorly. The temporomandibular articulation is a diarthrosis joining the mandibular fossa and the articular tubercle of the temporal bone with the condyle of the mandible. A fibrous connective tissue articular disk or meniscus intervenes between the articulating bones. A joint capsule surrounds the temporomandibular joint (TMJ). The capsule consists of an outer fibrous layer, which is strengthened on its lateral surface to form the TMJ and the capsular ligaments. The capsular ligaments reinforce the capsule and function to limit mandibular movement. A small amount of synovial fluid may be found in the articular spaces. Frequently,trauma to the mandibular condyle produces pain resulting from extension or torquing of these ligaments, which should be distinguished from pain

caused by a fracture in this area.

**Teeth**

A tooth has been described as a homogeneous body of dentin surrounding a central pulp--the neurovascular supply--from which the microporous dentin is nourished and was initially derived. The pulp continuously lays down additional dentin throughout life. The tooth may also be divided into coronal and root portions. The enamel-covered coronal portion is the part that is normally seen in the mouth. The root portion of the tooth, which serves to anchor it, is covered with cementum, a substance that is much softer than enamel (Fig. 69-2) .

There are numerous classifications for the teeth. The permanent dentition generally consists of 32 teeth, which comprise 4 types--incisors, canines, premolars, and molars (Fig. 69-3) (Figure Not Available) . If one begins from the midline and counts backward, one will find 1 central incisor, 1 lateral incisor, 1 canine, 2 premolars, and 3 permanent molars in the normal dental anatomy. The third molar is commonly referred to as the wisdom tooth. Agenesis, or absence, of any of these teeth can occur occasionally. In addition, a patient can have extra, or supernumerary, teeth, which are somewhat small and unusually shaped. There are many methods of notation in the literature for numbering or classifying teeth. Although some systems are more universal than others, it is perhaps best for the emergency physician simply to describe the type of tooth and the location involved in a particular emergency (e.g., an upper right second premolar or a lower left canine). The following dental nomenclature may be of use to the emergency physician:

> *Facial:* That part of a tooth that faces the oral vestibule, or the cheek and the lips. In the area of incisors to canines, this surface is called the *labial* surface; for premolars and molars, it is referred to as the *buccal* surface.

> *Oral:* That part of a tooth that faces the tongue or the palate, usually referred to as the *lingual* surface of the tooth.

> *Approximal:* The contacting areas of adjacent teeth. The area closest to the midline is called the *mesial* surface, and the area toward the posterior aspect of the mouth is referred to as the *distal* surface.

> *Occlusal:* Biting surfaces of the premolars and the molars.

> *Incisal:* Biting surface of the canines and incisors.

> *Apical:* The tip of the root.

> *Coronal:* Toward the biting surface of the tooth.

### Periodontium

The normal periodontium can be divided into 2 major components: the gingival unit and the attachment apparatus. The *gingival unit* is composed of the soft tissues investing the teeth and the alveolar bone. The *gingiva* is covered by a keratinized, stratified squamous epithelium. It extends from the free gingival margin to the mucogingival junction. Apical to the mucogingival junction is the *alveolar mucosa,* which is covered by a nonkeratinized, stratified squamous epithelium and is continuous with the mucosa of the lip and the cheek.

In healthy individuals, the gingiva is attached tightly to the tooth. From a level that is coronal to the margin of the alveolar bone and extending to the level of the cementoenamel junction, connective tissue fibers from the gingiva insert into the cementum of the root.

Coronally to the epithelial attachment is a space bounded on 1 side by enamel and on the other by a continuation of the gingival epithelium. This space is called the *gingival sulcus.* This is the cuff that is formed around the necks of the teeth by the gingival tissues. The gingiva lining this space is not attached to the tooth and is therefore called *free gingiva.* The gingiva apical to the base of the gingival sulcus is called *attached gingiva.* In the healthy periodontium, the gingival sulcus is rarely >3 mm in depth.

The *attachment apparatus* is, as the name implies, the group of structures that attach the teeth to the jaws. It consists of the cementum covering the root, the alveolar bone surrounding the root, and the periodontal ligament. The periodontal ligament is composed of collagen fibers that insert on 1 end in the alveolar bone and on the other end in the cementum. It is important to note that the union of the tooth to the alveolar bone is not a direct calcific union, but a fibrous attachment. The anatomy of the dental unit (crown and root) and the periodontium is illustrated in cross section in Figure 69-2 .

## DENTAL ALVEOLAR TRAUMA

### Fractures of Teeth

The simplest type of dental trauma involves the fracture of anterior teeth. The management of dental fractures is based on (1) the extent of the fracture in relation to the pulp of the tooth and (2) the age of the patient. A classification system, the Ellis system, was developed to describe the anatomy of fractures of teeth. The emergency physician may  alternatively use a descriptive classification of traumatic injuries to teeth and supporting structures.

#### Ellis class I fractures.

The Ellis class I fracture involves only the enamel portion of the tooth (Fig. 69-4) . This is generally a minor problem and requires immediate intervention only if a sharp piece of tooth is causing trauma to soft tissues. In such situations, the rough edge may be

smoothed with something as simple as an emery board, or the patient may be referred at his or her convenience to a general dentist for more definitive management. What is perhaps most important is for the emergency physician to reassure anxious parents that with plastic enamel bonding materials, a cosmetic restoration of the tooth is possible. It would be inappropriate for the emergency physician to attempt immediate restoration of these teeth; however, no irreversible damage will occur from the smoothing of rough edges. These fractures are not painful and do not result in sensitivity to heat or cold.

**Ellis class II fractures.**

The Ellis class II fracture is a more complicated fracture in that it involves not only the enamel, but also the exposure of dentin. On inspection, dentin is identified by its pinkish or yellow appearance, as opposed to the white hue of enamel. The patient with exposed dentin may frequently complain of sensitivity to hot or cold or even air. The immediate treatment of the Ellis class II fracture is dictated by the age of the patient (Table 69-1) (Table Not Available) . Because, as the tooth matures, the pulp continues to produce a larger amount of dentin while the pulp itself shrinks in size, the dentin that is exposed in the Ellis class II fractures in patients <12 years of age is closer to pulpal tissue.

Dentin is a microtubular structure that can permit the passage of microorganisms from the oral environment directly to the pulp. Hence, contamination and resulting inflammation of the pulp can be anticipated in affected patients if dentin is exposed to the oral environment for >24 hours. Therefore, because of the possibility of damage to the pulp, the management of Ellis class II fractures in patients <12 years of age requires immediate placement of a dressing on the exposed dentin. The dressing not only provides pain relief, but also helps prevent infection.

A simple dressing that the emergency physician can apply consists of a calcium hydroxide resin paste (Dycal), which is available from dental supply companies (Fig. 69-5) . Calcium hydroxide paste is prepared by mixing small (equal) amounts of base and accelerator from 2 tubes with an applicator. The exposed dentin is dried with a piece of gauze,
and a small amount of calcium hydroxide is placed on the exposed area with a cleansed applicator instrument; the tooth surface must be perfectly dry, or the Dycal will not adhere. The tooth is then covered with a small piece of aluminum foil or, preferably, "dental-adhesive dry" foil. Dycal will set in approximately 2 minutes, more quickly if exposed to humidity. Dycal is easily removed by the dentist. Patients are advised not to eat solid foods to prevent dislodging of the Dycal dressing.

More sophisticated techniques involve covering the tooth with the plastic bonding materials mentioned previously; an aesthetic restoration will then result. The patient treated by the emergency physician requires referral within 24 hours. Patients with simple class II fractures (i.e., patients >12 years old who have a greater dentin-to-pulp ratio) may be advised to avoid extremes in temperature and to seek dental care the following day. A protective dressing need not be routinely applied. Patients with severe Ellis class II fractures (which may usually be recognized because of their larger exposed areas of pinkish- or yellowish-tinged dentin) should be treated with a dressing in a manner similar to that for younger patients. Analgesics may also be required, depending

on the degree of sensitivity of the patient. It should be noted that correct management of Ellis class II fractures may obviate the need for root canal therapy. It may be advisable to warn any patient who has sustained trauma to the anterior teeth, no matter how minor, that disruption of the neurovascular supply to the tooth may have occurred. The long-term complication of the initial trauma may be necrosis of the pulp or resorption (dissolving) of the root.

**Ellis class III fractures.**

Ellis class III fractures of the teeth involve, in addition to fracture of enamel and exposure of dentin, actual exposure of the pulp. One may differentiate the Ellis class III fracture from the Ellis class II fracture by gently wiping a tooth clean with a piece of gauze to remove any blood that may be present from soft tissue trauma. The tooth is then examined for any red blush of dentin or frank drops of blood that may extrude from the pulp. A patient may complain of exquisite pain; however, on occasion the tooth may be in shock from disruption of the neurovascular supply, in which case the patient feels little sensitivity in the tooth.

Ellis class III fractures are true dental emergencies and require immediate consultation with a general dentist or endodontist (root canal specialist) (Fig. 69-6) (Figure Not Available) . Ultimate treatment will consist of the total removal of pulpal tissue (pulpectomy). Alternatively, in the case of primary teeth, partial amputation of pulpal tissue (pulpotomy) may be performed. A delay in either of these procedures will result in significant pain and probable abscess formation. Some reports have recommended the use of the endodontic barbed broach for the removal of exposed pulp in the emergency department. [3] A barbed broach, when twisted in the root canal, engages the remaining pulp; when the broach is removed, the pulp is generally attached. However, even in the hands of an endodontist, the use of this instrument is difficult, and it is prone to breakage in the root canal. A broken instrument in a root canal is difficult to remove and may necessitate extraction of the tooth. Therefore, emergency physicians and other nondentists generally should not attempt to use this instrument. If a dentist is not immediately available, the tooth may be temporarily covered with aluminum or, preferably, dental dry foil so as to minimize pulpal irritation and pain.

Because of bleeding or other sources of moisture, it may be difficult to apply Dycal to these fractures effectively. Analgesics should be prescribed, and the patient should be told to see a dentist as soon as possible. It is preferred to neither prescribe nor apply any of the over-the-counter topical dental analgesic preparations. Although these agents may give the patient temporary relief from pulpal pain, they often cause soft tissue damage because of their irritant effects, and they are caustic to the tooth. Use of these agents has been known to result in sterile abscesses. In all cases of tooth fracture, the soft tissue should be palpated for tooth fragments and radiographed if swelling limits the examination and if one has not accounted for tooth fragments.

## Subluxation and Avulsed Teeth

The same force that may have resulted in the fracture of anterior teeth may also result in actual loosening of the tooth in its socket. This is called *subluxation*. Traumatized

teeth should always be examined for subluxation by applying pressure with the fingers or with 2 tongue blades on each side of the tooth. The tooth is wiggled in a back-and-forth motion. A more subtle indication that teeth have been traumatized is the appearance of blood in the gingival crevice of the tooth. Teeth that are minimally mobile usually heal well if the patient is kept on a soft diet for 1 to 2 weeks. Teeth that appear grossly mobile to the eye require stabilization as soon as possible. The techniques for stabilization are described later. Although stabilization procedures are usually performed by a general dentist or an oral and maxillofacial surgeon, the techniques that are described can be used by the emergency physician who is trained in such procedures. As a temporary measure for teeth that are very loose, it is often useful to have the patient bite gently on a piece of gauze to keep the tooth in place, pending examination by a dentist or an oral surgeon.

**Avulsed and Intruded Teeth**

Teeth that have been completely avulsed from the socket constitute a true dental emergency. If the patient is unaware of the location of the missing tooth, a complete *intrusion* of the tooth below the level of the gingiva must be ruled out with a radiograph (Fig. 69-7) (Figure Not Available) . An intruded tooth has been forced back into the alveolar bone, implying disruption of the supporting structures and possible fracture of the alveolar bone. Intrusion may be missed by a superficial examination, and one should not automatically conclude that all spaces in dentition following trauma represent avulsed teeth. Dice and coworkers have reported a case in which an intruded tooth was initially thought to be a fractured tooth; facial cellulitis and subsequent periodontal infection developed as a result of the misdiagnosis. [4] Intruded primary teeth ("baby teeth") in the absence of infection are allowed to erupt for 6 weeks before repositioning is considered. Intruded permanent teeth are surgically repositioned with a forceps within 24 to 48 hours and are then stabilized. Failure to diagnose intruded teeth may also result in cosmetic deformity.

As in other cases of dental alveolar trauma, the management of an avulsed tooth depends on the age of the patient and the length of time that the tooth has been absent from the oral cavity. Fully avulsed primary anterior teeth in the pediatric patient age 6 months to 5 years *are not replaced into their sockets.* Loss of these primary anterior teeth poses no threat to normal development and alignment of permanent teeth. Reimplanted primary teeth have a high tendency to ankylose, or fuse to the bone itself. The most serious consequence of an ankylosed primary tooth is facial deformity in the child. As growth continues, it may hinder eruption of the permanent tooth, and as time progresses, ankylosed teeth are more difficult to surgically remove. Temporary prosthetic replacement of avulsed primary teeth is easily accomplished if a cosmetic effect is desired.

In general, *permanent* teeth should be replaced in their sockets as soon as possible. Care must be taken to ensure that the tooth does not become dehydrated and that the remaining periodontal ligament fibers are disturbed as little as possible. The transport medium is also important in terms of pH and osmolarity to preserve the cells of the periodontal ligament fibers. [5] A percentage point for successful reimplantation is lost every minute that the tooth is absent from the oral cavity. This time interval can be

extended from 4 to 24 hours if the tooth is placed in a medium consisting of a pH-balanced cell culture fluid, such as Hank's solution. A system called the *Save-A-Tooth system* (Biological Rescue Producers, Inc., Pottstown, Pa) contains the cell-preserving fluid in a break-resistant, sterilized container that does not need to be refrigerated. [6] [7] An avulsed tooth is simply dropped in the system's basket, which sits in the fluid, and the cap is replaced. When the tooth is needed, the basket is lifted out of the container. Teeth that have been absent from the oral cavity for >20 minutes should also be placed in this fluid for at least 30 minutes to rehydrate the periodontal ligament cells prior to replacement.

Therefore, when a call is received about an avulsed tooth, the first question that should be asked is the age of the patient. If it is determined that the tooth is permanent, the parent or patient should be instructed to replace the tooth immediately, if possible. If there is gross debris on the tooth, the tooth can be rinsed under cool, running tap water prior to being reimplanted in its socket. If actual reimplantation is not possible, the patient should be advised to bring the tooth to the emergency unit as quickly as possible, preferably in a "Save-A-Tooth" container (Fig. 69-8) (Figure Not Available) or a cup of milk. Alternatively, the alert, older patient may be allowed to place the tooth in his or her own mouth to bathe in saliva, but care should be taken that the tooth is not swallowed or aspirated. In all cases, one should attempt to prevent dehydration of the avulsed tooth, because teeth that become dehydrated have the poorest prognosis for healing.

An avulsed tooth should be reimplanted as soon as possible; the initial procedure is relatively simple. [7] The avulsed tooth is held by the crown at all times. It is rinsed under saline or under running water to remove gross debris but is *not* scrubbed. Scrubbing damages remaining periodontal ligament fibers and adversely affects reattachment. Ideally, if the "Save-A-Tooth" system is available in the emergency department, the avulsed tooth can be cleansed by soaking in this system. Indeed, if the tooth has been avulsed for >20 minutes, it should be soaked in the preserving solution for 30 minutes. If the patient has other, more serious injuries, the tooth can remain in Hank's solution until reimplantation can be accomplished. The socket is then inspected. Blood clots or bone fragments, which may prevent reimplantation, should be irrigated or removed by gentle suction. When reimplantation is delayed (>30 minutes), local anesthesia is recommended (see below).

The socket is suctioned and debrided of all blood and foreign matter, and the tooth is immediately reimplanted. Generally, the tooth can be forced into its original position with the operator's thumb. The socket should not be sharply scraped, because this may damage the periodontal ligament or the attachment fibers. If the tooth does not fully sit in the socket as compared with the alignment of the adjacent teeth, it is often because the socket contains a blood clot or the injured gingiva prohibits implantation. These conditions can often be remedied. If there is confusion as to the position of the tooth after reimplantation, the procedure should stop at this point. The patient should then gently bite on a piece of gauze until seen by a general dentist or an oral or maxillofacial surgeon, or the tooth can be transported in the Hanks solution to the dentist. Large gingival lacerations may be sutured at this juncture.

**Prognosis for Patients with Avulsed Teeth**

When a tooth is avulsed, the neurovascular supply to the tooth is completely disrupted. If the tooth is reimplanted within a few minutes, there may be some restoration of the neurovascular supply, but most avulsions result in hypoxia and ultimate necrosis of the pulp. Therefore, almost all reimplanted teeth require subsequent root canal therapy within a short period (i.e., 7 days). The purpose of root canal therapy is to (1) debride the pulp, (2) render the tooth insensitive to pain, and (3) fill and seal the pulp chamber with an inert material. This inert material prevents infection or chronic inflammation, which may discolor the tooth or interfere with stabilization of the tooth by the periodontal ligament.

The object of immediate reimplantation is not to keep the tooth alive, but to keep the periodontal ligament alive, thus ensuring a retained functional tooth. Healing of the periodontal ligament is variable following reimplantation. In addition, some resorption of the root surface always follows replantation. The degree of resorption varies and may even result in ankylosis of the tooth with surrounding bone. Although the long-term prognosis favors retaining an avulsed tooth if timely treatment is available, the patient should always be advised of the possibility of losing the tooth in a few months to a number of years following reimplantation. In general, immature permanent teeth have a better prognosis for survival than do older teeth.

**Stabilization Techniques**

Avulsed teeth require immediate stabilization so that they do not exfoliate. Although stabilization is normally performed by a general dentist or an oral or maxillofacial surgeon, there are situations in which it may be performed by the emergency physician. Stabilization is indicated in the case of a single avulsed tooth that has been placed back into the socket with satisfactory alignment. Satisfactory alignment of the tooth is judged both by visual inspection and by a report from the patient that there is no prematurity of occlusion when the jaw is closed. Even a millimeter of extrusion of a reimplanted tooth may cause occlusal disharmony in some patients, and final occlusal adjustment should not be performed by the emergency physician.

Any tooth stabilized by the emergency physician should be evaluated by a general dentist or an oral or maxillofacial surgeon within 24 to 48 hours. Several techniques are available to the emergency physician for the stabilization of a single avulsed tooth. The application of Erich arch bars is perhaps the oldest technique used for stabilization of avulsed teeth. These arch bars are also used for stabilization of mandibular and maxillofacial fractures. Figure 69-9 (Figure Not Available) shows the application of the Erich arch bar. Application of the arch bar is not a simple technique and should not be performed by the nondentist. [8]

A temporary and readily available measure to stabilize avulsed or subluxated teeth in the emergency unit by nondentists has been described. [9] A temporary splint that has been accepted by the Council on Dental Therapeutics of the American Dental Association [10] is made using the commercially available Coe-pak (Coe Laboratories,

Inc., Chicago). Coe-pak, a zinc oxide-eugenol preparation that sets to semihardness, is prepared from tubes that contain a base and a catalyst (Fig. 69-10) (Figure Not Available) . Following reimplantation of the tooth, the splint material is applied in a soft, clay-like consistency and is molded over the gingival line, in the front and rear of the tooth, and into the spaces between the teeth. A liquid diet is possible with the splint in place, and the patient should be directed to see a dentist within 24 hours.

Avulsed teeth are stabilized for approximately 10 days to 2 weeks and are then brought back into function. However, if teeth are reimplanted by an emergency department physician, the patient should be seen by the dentist in 24 to 48 hours. As in any type of dentoalveolar trauma, general precautions that should be taken to avoid long-term complications are explained to the patient. When there are concomitant alveolar fractures, stabilization of avulsed or subluxated teeth serves to stabilize not only the teeth, but also their alveolar bone. In this situation, therapy is directed toward the conservation and healing of bone, and therefore stabilization is left for a minimum of 6 weeks, recognizing the risk of possible ankylosis of the teeth. The indiscriminate loss of alveolar bone leads to much more difficult prosthetic restoration of this area than with the removal of an ankylosed tooth. Generally, prophylactic antibiotics (phenoxymethyl penicillin or erythromycin, 250 to 500 mg orally 4 times a day) are used when avulsed teeth are reimplanted in the oral cavity, but their benefit is unproven. Tetanus prophylaxis should also be instituted when needed.

**Lacerations Associated with Dentoalveolar Trauma**

Subluxated or avulsed teeth are frequently accompanied by associated lacerations of the gingiva, the mucosa, the lips, should preferably precede definitive closure of any soft tissue laceration. The lips and the oral mucosa undergo constant manipulation during the stabilization procedures for teeth; therefore, carefully placed sutures may be torn, increasing the existing soft tissue injury and making aesthetic closure more difficult. Plastic closure, once dental stabilization has been first performed, may then be left undisturbed.

Gingival avulsions should be repaired in approximately their original position with fine silk sutures (Fig. 69-11) . Small lacerations may be left open to heal. Gingiva is very friable, and suturing may be difficult. The suture may be passed between teeth using the suture needle and then passed back between the teeth again like dental floss and tied in the front anchoring the buccal and lingual flaps; or the suture may be anchored to the mucosa on the other side of the teeth. When appropriate, patients with large gingival avulsions should be referred to an oral surgeon.

A frequently encountered problem is that of the through-and-through laceration resulting in an open communication between the skin and the oral cavity. This may result from a tooth being forced through the upper or lower lip. Occasionally, pieces of a fractured tooth are found imbedded in the soft tissue. Their presence should be suspected any time a tooth is chipped or avulsed. Devitalized tissue should be removed by sharp debridement, and the area should be irrigated under pressure. After appropriate debridement and irrigation, it is best to close mucosal lacerations larger than 0.5 cm with sutures. Smaller lacerations may be left alone. Mucosal lacerations can be closed

with 4-0 Dexon or Vicryl or 3-0 to 4-0 black silk sutures; gingival lacerations are closed with 4-0 black silk. The cut ends of nylon sutures are very irritating, and therefore nylon should not be used. Large, open intraoral mucosal lacerations result in much discomfort for the patient and frequently become infected from the accumulation of debris.

Patients with sutured intraoral lacerations are advised to keep the area clean by rinsing with warm saline and swabbing locally with hydrogen peroxide. Lip sutures may be covered with a thick coating of petrolatum jelly or antibiotic ointment. Patients are given the usual wound precautions and are checked within 24 to 48 hours. A certain amount of edema may be found when the wound is checked; in addition, a whitish granulation tissue, resembling pus, may have developed. The emergency physician should not immediately assume that this means the area is infected. Significant pain usually signifies infection, however. If there is any suspicion of infection, the patient should be rechecked at 24-hour intervals until the edema has resolved. Frank infection should be treated with penicillin and hot compresses. Occasionally, sutures may need to be removed to promote drainage. Like patients with reimplanted avulsed teeth, individuals with through-and-through lacerations should be given tetanus prophylaxis; antibiotic coverage is often prescribed. Penicillin or erythromycin is advocated by many. [11] Skin sutures are frequently removed in 3 to 5 days to minimize scar formation. Intraoral sutures are removed in 5 to 7 days.

## HEMORRHAGE

Oral hemorrhage may occur spontaneously from the gingiva or, more commonly, may be the result of dental treatment, especially surgical extraction of teeth. Patients with this complaint frequently present at night, when their dentist or oral surgeon is not immediately available. A patient presenting with a bleeding gingiva should be questioned about any recent dental scaling, curettage, or other procedures. Such bleeding usually responds to peroxide mouth rinses and local pressure with gauze. In patients with advanced periodontal disease, small remnants of missed granulation tissue may ooze continuously for hours. Spontaneous gingival hemorrhage without a history of recent dental therapy may be the initial presentation of a systemic process (e.g., leukemia or coagulopathy). A decision to investigate such hemorrhage with laboratory testing is based on the extent of the hemorrhage, the age of the patient, and other information obtained from the history and physical examination.

Most commonly, patients present with bleeding following dental extraction. Postextraction bleeding most often responds to sustained pressure, which can be produced by having the patient bite on gauze. Patients frequently report that they have already been doing this for hours. One should then ask whether the patient has been spitting excessively, smoking cigarettes, or using straws, each of which may create negative intraoral pressure and promote bleeding. Negative intraoral pressure removes blood clots from sockets and aggravates postextraction bleeding.

The procedure for the management of postextraction bleeding is a very systematic one. If clots are present, they should be removed with suction or wiped with gauze. Patients are then instructed to bite on gauze for 15 to 20 minutes. If bleeding continues after 15 to 20 minutes, local anesthesia consisting of 2% lidocaine (Xylocaine) with 1:100,000 or

1:50,000 epinephrine is infiltrated in the area of the socket until the tissue blanches (turns white). Gauze pressure is then reapplied. The epinephrine reduces bleeding, and the lidocaine allows the patient to bite without pain. Continued bleeding after 20 minutes may respond to the placement of a small piece of surgical foam or Gelfoam in the socket. This is then secured with a 3-0 black silk suture.

Sustained vigorous oozing after all of the aforementioned procedures have been performed warrants a screening coagulation profile, consisting of a complete blood cell count with differential, prothrombin time and partial thromboplastin time, and a platelet count. Postextraction bleeding is often caused by aspirin use. The patient must be questioned about all medications that may contain aspirin. Postextraction bleeding may also be the initial manifestation of a coagulopathy, such as hemophilia, especially in younger individuals. In some instances, postextraction bleeding results from improper surgical technique or flap design or lack of a sufficient number of sutures. Such flaps may need to be revised and resutured.

Following treatment, the emergency physician should warn the patient to avoid all liquids and solid foods for 2 hours and to avoid extremes in temperature, excessive spitting, smoking, or the use of straws or aspirin. If bleeding occurs at home, gauze pressure should be used.

The patient should be advised of the possibility that a *dry socket* will develop in 2 to 3 days. The patient becomes aware of a dry socket when excruciating pain develops in the area of the socket and a foul odor or taste occurs in the mouth after a day or two of no pain. Patients should know that the pain of a dry socket is easily managed by their dentist or an emergency physician. Application of local anesthesia to the area of the involved tooth, gentle irrigation of the socket, and application of an iodoform pack dipped in eugenol or Campho-Phenique or a commercial sedative dressing relieves the pain. The packing is placed gently in the socket, avoiding manipulation of the walls of the socket. A dry socket is a localized alveolar osteitis. Because of the high incidence of osteomyelitis secondary to scraping of a dry socket to initiate bleeding, aggressive debridement of the dry socket is contraindicated.

Patients with dry sockets are frequently given oral antibiotics; penicillin or erythromycin is preferred. The use of topically applied antibiotics is not indicated because of the increased incidence of sensitivity reactions. The dressing is replaced at 24-hour intervals until the patient is pain free.

In addition to dental extractions, bleeding is frequently seen after periodontal (gingival) surgery. The tissue involved in the surgical site is usually covered with a surgical dressing, which may be dislodged by bleeding. Bleeding following periodontal surgery will generally respond to gauze pressure. It should be noted, however, that periodontal surgical dressings are extremely important for wound healing, and incorrect placement of the pack can result in treatment failure. Therefore, the periodontist should be informed immediately that bleeding has occurred and should see the patient as soon as possible.

# DRAINAGE OF AN INFECTION OF DENTAL ORIGIN

Acute infection of the oral cavity and the jaws can be minor or life threatening. The most common dental infection is the periapical abscess, or the acute alveolar abscess, which usually begins in the periapical region of the tooth as a result of nonvitality or degeneration of the pulp. One can usually easily manage these infections by treating the tooth with endodontics or extraction. [12]

Periodontal and pericoronal infections are generally more difficult to manage. Most intraoral infections form an abscess and drain intraorally. When the infection is well contained, drainage of these areas is generally easy. Extension of this same infection to the fascial planes of the head and neck, however, may result in much more serious infection in the parapharyngeal space or may track exteriorly to drain at the surface of the skin (Fig. 69-12) (Figure Not Available) . Drainage of an infection of dental origin by the emergency physician should be limited to well-confined intraoral abscesses requiring intraoral drainage and fluctuant extraoral swellings that require drainage externally by an incision on the face.

## Pulpal Infection (Abscessed Tooth)

Although physical and chemical injuries to teeth result in pulpal necrosis and infection, dental infection most frequently is the result of carious (decay) exposure of the pulp. Destruction of the enamel and the dentin by caries opens a portal to the pulp for oral microorganisms. Before invasion of the pulp by microorganisms, the affected tooth usually becomes sensitive. Invasion of the pulp produces either a localized or a generalized pulpal infection. If the portal of entry into the pulp is adequate to allow spontaneous drainage, the patient may be asymptomatic. If drainage is obstructed, rapid involvement of the entire pulp results in pulpal necrosis. The patient can experience moderate to severe pain that has been ranked second only to that of renal colic. Untreated inflammation progresses through the teeth and extends into the periapical region; irritation in this area produced by inflammatory products in the necrotic pulp may result in the formation of periapical granuloma. This process may be asymptomatic and persists as long as drainage through the tooth continues.

Treatment consists of removing the infected pulp and obliterating the pulp chamber, allowing the tooth to remain (root canal therapy), or extracting the infected tooth and draining the periapical region. Antibiotic therapy is indicated if drainage cannot be established when the infection has perforated the cortex and spread into the surrounding soft tissue. Frequently, physical examination reveals a grossly decayed tooth. Alternatively, no apparent pathologic condition may be seen, or many teeth may appear decayed. One may localize the offending tooth by percussing individual teeth with a tongue blade; in most cases, tapping the involved tooth elicits a sharp pain.

In most minor dental infections, oral phenoxymethyl penicillin in doses of 250 to 500 mg 4 times a day is the drug of choice. Erythromycin 250 to 500 mg 4 times a day, clindamycin (Cleocin) 150 to 300 mg 4 times a day, and cephalexin (Keflex) or cephradine (Velosef) 250 to 500 mg 4 times a day are alternatives. Analgesics can be

prescribed. If the infection has broken through the cortex and there is subperiosteal extension of the infection with swelling, incision and drainage is the treatment of choice, as in any abscess.

## Periodontal Infection

Periodontal disease is a progressively destructive bacterial process involving the supporting structures of the teeth, which include the gingiva, the periodontal ligament, and the alveolar bone. Unlike the relatively confined pulp chamber, inflammatory exudate produced in periodontal infection usually drains freely, and the patient experiences little, if any, discomfort. Significant symptoms may not be apparent for many years. If for any reason drainage from the infected area is interrupted, the inflammation becomes acute and is similar to an acute periapical infection that spreads to the soft tissue. The lack of a carious lesion in the involved tooth and a dental radiograph help in differentiating these 2 processes. In most cases, acute periodontal infections tend to remain in the intraoral soft tissues rather than spread to the face and the neck.

Immediate treatment of periodontal infections includes drainage of the infected tissue (see later discussion), which may require removal of the involved tooth. Antibiotic therapy is usually instituted only if drainage cannot be achieved or if spread to tissues of the face and the neck has occurred. Follow-up periodontal therapy is needed to prevent recurrence. Warm saline rinses frequently promote drainage in periodontal areas, and antibiotics are prescribed if there are systemic manifestations. The condition usually does not require urgent referral. Frequently, scaling and curettage of the area relieve the abscess. In the emergency unit, however, incision and drainage of the abscess are generally preferred.

## Pericoronal Infection

Pericoronitis occurs when debris and microorganisms become trapped under soft tissues that partially overlie the crown of a tooth, usually in an erupting or partially impacted third molar (wisdom tooth). A localized infection that drains from under the tissue becomes established. If drainage is interrupted by sudden swelling of the overlying tissue, caused either by trauma from an impacted third molar or by the inflammatory process itself, the entrapped exudate will spread through other pathways, usually into the pterygomandibular or submasseteric spaces (see Fig. 69-12) (Figure Not Available) . The underlying bone is generally not involved. Clinically, marked trismus secondary to irritation of the masseter or the medial pterygoid muscles predominates. The pericoronal tissues are erythematous and swollen. Digital pressure in the area often elicits pain and produces a small amount of exudate under the infected flap.

Treatment includes antibiotics in virtually all cases. Removal of the impacted tooth or the infected tissue ensures good drainage. Frequent irrigations with warm saline during this period are beneficial and should be instituted immediately. An oral or maxillofacial surgeon should be consulted within 24 to 48 hours. Fluctuant swelling is amenable to incision and drainage. Soft tissue dissection should be performed with caution, because the space extends posteriorly in the retropharyngeal area. Incisions must be made with

great care in this region because of the proximity of the internal carotid artery, which may have been moved anteriorly with tissue swelling.

In many instances, progression of oral infection may cause acute facial cellulitis. The extent of the cellulitis, of course, is dependent on the virulence of the organism and the resistance of the host. In general, cellulitis from an odontogenic infection arising from the maxillary teeth involves the lower half of the face and the neck. This pertains only to the earlier stages of infection, because in many instances the entire side of the face may be involved, regardless of the origin of infection. In the nondebilitated host, most untreated odontogenic infections tend to localize and drain spontaneously (usually extraorally).

## Technique of Incision and Drainage

### Intraoral Technique

Before attempting incision and drainage [13] of an intraoral abscess, the emergency physician should first determine whether the infection or abscess is a simple one. The patient should have minimal trismus and should be able to open the mouth widely to allow inspection of the pharynx. The area of maximal fluctuance is anesthetized superficially with either a topical anesthetic spray, such as benzocaine-tetracaine-butamben-benzalkonium (Cetacaine), or (better) an injection of 2% lidocaine (Xylocaine) with 1:50,000 epinephrine until tissue blanching occurs. One should always remember that it is difficult to obtain profound anesthesia in an infected site with topical or local anesthetics. Superficial anesthetic techniques are used so as not to track infection more distally with a long needle. When regional nerve blocks distant to the area of infection are possible, they should be considered (see Chapter 33) .

The required equipment for incision and drainage consists of the instruments found in a standard incision-and-drainage tray (Fig. 69-13) . A No. 11 scalpel blade is recommended, as are a mosquito hemostat and drain material (such as ¼-inch iodoform gauze or a small 3-cm fenestrated Penrose drain). Antiseptic cleansing of the area to be drained is generally not necessary. A small 1-cm incision is made superficially over the area of fluctuance, with the point of the scalpel blade always facing toward the alveolar bone (Fig. 69-14) . Blunt dissection is then carried out with a mosquito hemostat to avoid any vascular structures. Cultures of draining pus may be obtained at the discretion of the clinician but are usually not required. However, cultures are recommended for complicated abscesses and when the patient is immunocompromised. The drained area is copiously irrigated.  If possible, one places the iodoform gauze or the Penrose drain by packing the site and securing 1 end of the gauze or the drain with a black silk suture (4-0) to prevent aspiration of the drain.

The patient is instructed to continue warm salt-water rinses hourly for the next 24 to 48 hours and to rinse several times during the night. The drain is removed in 24 to 48 hours, and intraoral rinsing is continued every 4 hours for another day. Patients generally begin taking oral antibiotics during the course of this therapy. Although the emergency physician may manage the initial phase of the dental infection, referral to a

dentist or an oral or maxillofacial surgeon is required for definitive therapy of the infection.

**Extraoral Technique**

If the dental infections described in the preceding section do not drain intraorally, they may spread to the face. The approach to drainage of these abscesses is similar to that of other soft tissue abscesses (see Chapter 40) . However, the emergency physician must determine that the infection, although it has an extraoral spread, is a simple one. The patient should have no trismus, and the retropharynx should be adequately visualized. Drainage of an infection of dental origin on the face requires more attention and care because of the cosmetic consequences of the procedure (Fig. 69-15) .

The patient is placed in a reclining position and is externally draped well so as to prevent drainage of purulence on the patient's clothing, the stretcher, and other materials in the treatment area. The skin is cleansed with a scrub, prepared with povidone-iodine solution, and draped in an appropriate manner. The skin is anesthetized superficially with 2% lidocaine (Xylocaine) and 1:100,000 epinephrine.

It is important to note that the incision in this case will not be made over the area of maximal fluctuance but inferiorly to the area of infection in a zone of *healthy* skin. A 1.0- to 1.5-cm incision that follows the natural tissue line as closely as possible is made through skin and subcutaneous tissue; blunt dissection with a mosquito hemostat is then carried out toward the area of infection to establish drainage. In compromised patients, a culture should be taken, and the area should be gently irrigated with saline. A Penrose or gauze drain should be placed. The area is covered with a gauze dressing, and the patient is instructed to remove the dressing 4 times a day and apply heat to promote drainage in this zone.

It is important to note that this is one of the few indications for the application of warm compresses to the face in the presence of dental infection. In general, all attempts should be made to establish drainage intraorally, but this procedure is used when extraoral drainage is inevitable. Any facial infection of dental origin that requires 24 hours of heat to obtain maximal fluctuance for drainage extraorally can probably be managed after that time with intraoral drainage. Obviously, scarring results from any extraoral drainage. Therefore, the procedure should be avoided if possible, but if it is necessary, the incision is made over healthy tissue.

## COMPLICATED HEAD AND NECK INFECTIONS

The emergency physician is often responsible for the actual incision and drainage of simple dental infections. When the infections described previously extend to the fascial compartments of the head and the neck, they immediately fall into the serious and complicated category (Fig. 69-16) . Toxic febrile patients with marked trismus require immediate attention to airway and early institution of IV antibiotics. The patient should immediately be referred to the oral and maxillofacial service for admission.

An uncommon complicated infection of dental origin seen by the emergency physician is Ludwig's angina. This infection is a bilateral, board-like swelling involving the submandibular, submental, and sublingual spaces, with elevation of the tongue. Emergency physicians frequently see affected patients before elevation of the tongue, during the initial manifestations of the infection. In the early stages, Ludwig's angina may appear deceptively benign (Fig. 69-17 A). Brawny induration is characteristic, and there is no fluctuance present for incision and drainage. Infection is commonly caused by hemolytic *Streptococcus* organisms, although it may be a mixed *Staphylococcus-Streptococcus* infection or a combination of aerobic or anaerobic organisms. The presence of anaerobes commonly accounts for the presence of gas in the tissues. Chills, fever, difficulty in swallowing, stiffness of tongue movements, and trismus are common presenting signs. Respiration becomes increasingly difficult as the tongue is elevated, and the oral pharynx becomes edematous (Fig. 69-17 B). Progression to airway obstruction may be rapid, occurring within only a few hours.

Treatment consists of high-dose IV antibiotic therapy. Intubation or tracheostomy should be considered in the acute stage to maintain the airway if respiration becomes embarrassed. Constant observation is important, since the airway may become obstructed without much warning. Although hospital admission (preferably in a surgical intensive care setting) is mandatory, surgical intervention may be necessary only if antibiotic therapy is not successful. The most common locations of dental infection in this condition are the lower second and third molar teeth; pus formation usually occurs medially or on the lingual aspect of the mandible. In Ludwig angina, as in any parapharyngeal space infection, mediastinal descent can occur because of the communication of the parapharyngeal space with the visceral space.

**Therapeutic Considerations**

The most important therapeutic modality for pyogenic orofacial infections of odontogenic origin is surgical drainage and removal of necrotic tissue. The need for definitive restoration or extraction of the infected teeth, the primary source of infection, is readily apparent. Antibiotic therapy, although important in halting local spread of infection and preventing hematogenous dissemination, cannot substitute for evacuation of pus.

Penicillin remains the antibiotic of choice for treating orofacial infections of odontogenic origin. *Bacteroides fragilis*, which is highly resistant to penicillin, is not normally a resident in the oral cavity; however, this organism has been recovered in 15% to 20% of anaerobic pleuropulmonary infections and is presumably related to aspiration of oropharyngeal flora. It is interesting to note that penicillin has remained effective in such cases, despite recovery of this organism as part of the mixed flora.

Cephalosporins, particularly cefoxitin (Mefoxin), may be excellent alternatives for penicillin-allergic patients, because the action of these agents against oral-obligate anaerobes is comparable to that of penicillin, and they also are effective against certain aerobic bacteria. The usual cephalosporin dosage is 1 to 2 g IM or IV every 6 hours. Clindamycin (600 mg IM or IV every 8 hours) is also highly effective, especially against anaerobes, when used in a controlled fashion and when possible side effects are

monitored. Erythromycin is generally active against most indigenous oral bacteria but is comparatively less active against anaerobic and microaerophilic streptococci, *Fusobacterium*, and anaerobic gram-negative cocci. Chloramphenicol, although highly active against obligate anaerobes, is potentially toxic and should be reserved for situations in which the pathogenic role of *B. fragilis* is of prime importance or for use as an alternative agent in patients allergic to penicillin, cephalosporins, or clindamycin.

# DISORDERS OF THE TMJ AND RELATED STRUCTURES

## Mandibular Dislocation

In acute dislocation of the mandible, the condyle moves too far anteriorly in relation to the eminence and becomes locked (Fig. 69-18) (Figure Not Available) . Subsequent muscular trismus prevents the condyle from moving back into the temporal fossa. Spasm of the external pterygoid, masseter, and internal pterygoid muscles, as well as the associated edema, results in extreme discomfort and anxiety for the patient. It is difficult for the patient to verbalize a complaint because he or she cannot close the mouth. Predisposing factors include anatomic disharmonies between the fossa and the interior articular eminence, weakness of the capsule forming the temporomandibular ligaments, and torn ligaments. Dislocation is likely to occur during maximum opening, such as during yawning, laughing, or "popping" of the mandible in an open position. Although the TMJ is a double joint, dislocation may occur bilaterally or unilaterally. The jaw may be locked open symmetrically or may deviate to the side opposite the side of dislocation. Palpation of the TMJs may reveal them to be anterior to the articular eminence. In the face of trauma, radiographs should be taken to rule out fracture, since the clinical picture of both of these conditions is similar and similar occlusal disturbances are produced. Radiographs may not be necessary on an emergency basis if there is no history of trauma or if the condition is recurrent. [14]

### Technique for Reduction

If one appreciates the anatomy of the TMJ, the proper sequence for manual manipulation to reduce the dislocation is clear (see Fig. 69-18 (Figure Not Available) *D*). Following dislocation, the powerful masseter muscles may be in tremendous spasm. For a smooth reduction, it is mandatory to relieve the patient's pain and muscle spasm with slow IV injection of a benzodiazepine, with or without an opioid (see Chapter 35) . Some clinicians advocate direct injection of the condylar area with a local anesthetic (Fig. 69-19 (Figure Not Available) *A*). When the patient is sufficiently relaxed and analgesia is obtained, the physician faces the patient and grasps the mandible with both hands--one on each side--with the thumbs (which have been wrapped with gauze alone or tongue blades wrapped in gauze) facing the occlusal surfaces of the posterior teeth. The fingertips are placed around the inferior border of the mandible in the region of the angles. Some prefer to have the patient seated in a chair or on the floor with the patient's back against the wall. Alternatively, the patient may be in a recumbent position (Fig. 69-19 (Figure Not Available) *B* and *C*). Downward pressure is slowly and steadily applied to free the condyles from their anterior position to the eminence. The chin is then pressed backward after the jaw has been forced downward, and the mouth is closed while the condyle returns to its position in the fossa. In cases of severe muscle

spasm, the jaw may snap back quickly. Therefore, protection of the thumbs is essential (see Fig. 69-19) (Figure Not Available) .

Following the procedure, the patient should be instructed to stay on a soft diet for 1 week, to avoid wide opening of the mandible, and to take analgesics and muscle relaxants. Local heat may also provide relief. Chronic dislocators or patients who suffer acute recurrences may be helped by a bandage applied around the head holding the mandible to the maxilla for 2 weeks to prevent maximum opening, but this is rarely used. Very severe cases may require intermaxillary wiring and fixation for complete control with the use of Erich arch bars (described in Dental Alveolar Trauma). Patients who have suffered dislocation of the TMJ should be referred to an oral or maxillofacial surgeon for follow-up, since chronic dislocation may require a surgical alteration of the eminence for relief.

## Temporomandibular Myofascial Pain Dysfunction Syndrome

The temporomandibular myofascial pain dysfunction syndrome, or simply the TMJ syndrome, is a complex neuromuscular disturbance possibly resulting from and definitely aggravated by occlusal disturbances and disharmonies between occlusal relations and the anatomy of the TMJ. Other entities, such as trauma, psychologic tension, and neuromuscular habits (e.g., bruxism and clenching), contribute to the problem. Patients who present to the emergency unit frequently complain of unilateral facial pain. The pain is fairly nonspecific and is generalized to the region of the TMJ. The pain is of a dull nature in most patients and increases throughout the day with continued jaw motion. Clinical examination frequently reveals spasm of the masseter muscle externally and the internal pterygoid muscle intraorally. There is usually limitation of opening. Radiographs of the TMJ are usually normal unless there is an associated TMJ degenerative disease. When the diagnosis of TMJ syndrome is suspected, it is important for the emergency physician to rule out acute otalgia or pain of odontogenic origin. [15]

### Treatment

Severe trismus associated with TMJ syndrome may be treated by the emergency physician locally with the application of a refrigerant anesthetic spray, such as ethyl chloride, to the face. The skin of the patient's face around the masseter muscle at the angle of the mandible is covered with a light coating of petrolatum jelly. A towel is placed over the midline of the face to protect the region of the eye, and ethyl chloride is gently sprayed at the angle of the mandible in a rotary fashion from a distance of approximately 10 inches. The physician should take care not to produce frostbite of the tissues. The patient is instructed to open and close the mouth gently as the refrigerant spray is being applied. Frequently, this breaks the muscle spasm. Diazepam may also be of use. Physiotherapy is continued at home and consists of application of moist heat for 15 minutes 4 times a day. The patient should stay on a soft diet for approximately 2 weeks. Analgesics such as nonsteroidal anti-inflammatories, with or without muscle relaxants, are also effective.

Patients should be referred to a general dentist, a periodontist, or a periodontal

prosthodontist for follow-up and a course of therapy consisting of occlusal adjustment, if indicated. It is possible that some patients may have to be referred to an oral or maxillofacial surgeon for an intra-articular injection of cortisone or, rarely (in the most intractable cases), surgery (high intracapsular condylectomy). The various methods described here should always be attempted by a dentist before intra-articular injection of steroids is considered. Although useful, the intra-articular injection of steroids in the TMJ may be associated with a high incidence of subsequent fibrosis.

## CONCLUSION

Although patients having dental complaints do not represent a high percentage of emergency visits, individuals with dental emergencies frequently do present to the emergency unit. The most common procedures available to the emergency physician in the management of general dental emergencies have been described in detail in this chapter. Although many procedures, such as the stabilization of a reimplanted avulsed tooth, are more easily and perhaps better performed by a dentist or an oral or maxillofacial surgeon, in some cases this type of consultation may not be readily available for several days. Emergency physicians can render a great service to the patient in these cases by performing whatever stabilization is possible for the reimplanted tooth. The majority of procedures described in this chapter are useful for the emergency physician and should be performed whenever indicated. The emergency physician should feel free to call on dental colleagues for further demonstration and explanation when necessary.

# Chapter 70 - Vital Sign Measurement

**Jody Riva Lewinter, Thomas E. Terndrup, Terry M. Williams, Robert K. Knopp**

Documentation of temperature, pulse, and respiration is recommended for all emergency department (ED) patients, except for those with the most minimal of complaints. In patients with a pulse, blood pressure should generally be obtained. These measurements provide a unique, objective, capsule assessment of the patient's clinical condition. Vital signs are indicators of the severity of illness and may dictate the urgency of required intervention. Deteriorating vital signs are an important indicator of a deteriorating physiologic condition, whereas improving values provide reassurance that an unstable patient is responding to therapy. Hence, when a patient undergoes treatment over an extended time, selected vital signs, particularly previously abnormal ones, should be repeated. In some circumstances, the monitoring of selected vital signs should be continuous.

Vital signs should be measured and recorded at intervals dictated by the patient's clinical state (e.g., before and after fluid resuscitation, invasive procedures, or administration of medications with cardiopulmonary effects) or with any sudden change in the patient's clinical status. In addition, an abnormal vital sign can direct the physician toward a group of diagnoses or a particular organ system for further evaluation. An abnormal vital sign may constitute the patient's entire complaint, as in the febrile infant, or be the only indication of the potential for serious illness, as in the patient with resting tachycardia. For all of these reasons, accurate determination and interpretation of vital signs are mandatory.

In the ED, the accurate assessment and management of abnormal vital signs must reflect the priorities of resuscitation. Determination of airway patency with respiratory rate and pattern assumes first importance. Establishing the presence and quality of an arterial pulse is the second vital sign to be assessed, followed by blood pressure. Blood pressure and pulse are often evaluated in conjunction, as a measure of blood volume. Although body temperature is the last vital sign to be monitored during resuscitation, it has especial importance for patients suffering from thermal regulation failure (see Chapters 71 and 72) . This chapter is organized according to the priorities of patient resuscitation and evaluation.

Pulse oximetry and capillary refill are considered by some to represent additional "vital signs" in ED patients. The use of pulse oximetry is discussed in Chapter 6 . The assessment of capillary refill may be beneficial in children for determination of the adequacy of perfusion.

## BACKGROUND

Early pulmonary medicine was dominated by the concepts of Herophilus (4th century B.C.) and Galen (131 to 200 A.D.), whose belief in the humoral theory of medicine dictated that the lungs functioned as a cooling device and site for generation of body humors. The pulmonary circulation was correctly described in the 13th century by Ibnan-Nafis;

however, his observations passed unnoticed.

Respiratory physiology did not progress until the significance of the pulmonary circulation was recognized by Harvey in 1628. It was not until the 1700s that advances in physics and chemistry allowed the identification of the gases involved in respiration. [1]

Sphygmology, or palpation of the pulse, was first appreciated by Herophilus. He believed that interpreting the pulse required a knowledge of both music and geometry and defined the characteristics of the pulse as size, frequency, force, and rhythm. Chinese physicians (2nd century B.C.) timed the pulse by the respiratory rate of the examiner, believing that 4 pulsations per respiration was a normal rate for adults. The study of pulses was greatly influenced by Galen, who expanded the subject into a rather complex and obscure art form, writing no fewer than 18 books on the subject. [2]

Blood pressure was first measured directly in 1733 by Hales, who recorded the arterial pressures in a mare by cannulation with a brass pipe and a blood-filled glass column. [3] Frank used large-bore catheters connected to a rubber membrane in a 1903 manometer. [4] The invention of inflatable cuff manometers (Riva-Rocci, 1896) and the discovery of the arterial phase sounds (Korotkoff, 1905) allowed for the development of indirect blood pressure measurement. [3] [4]

The earliest recorded references to fever are from 6th century B.C. Akkadian cuneiform inscriptions, which appear to have adapted an ancient Sumerian icon of a flaming brazier to denote both fever and the local warmth of inflammation in a single ideogram. Clinical thermometry was introduced by Sanctorius in 1625. Mercury column thermometers were introduced by Fahrenheit in 1714. Although their routine use was supported by Boerhaave, thermometry

| TABLE 70-1 -- Normal Values for Vital Signs of Infants and Children (Mean ± SD) | | | | | |
|---|---|---|---|---|---|
| | Age | | | | |
| Parameter | 0-2 mo | 3-12 mo | 1-6 yr | 7-12 yr | 13-18 yr |
| Breaths/min | -- * | -- * | 24 ± 3 | 19 ± 2 | 17 ± 3 |

| | | | | | |
|---|---|---|---|---|---|
| Pulse/min | 126 ± 20 | 131 ± 20 | 88 ± 9 | 70 ± 8 | 64 ± 7 |
| Systolic BP | 72 ± 10 | 95 ± 15 | 93 ± 13 | 100 ± 10 | 112 ± 12 |
| Diastolic BP | 51 ± 9 | 53 ± 10 | 55 ± 10 | 63 ± 10 | 67 ± 10 |

* For data on children 0 to 35 months, see Table 70-2 (Table Not Available) .
As an estimate, for children 1 to 10 years: 2 × age (in years) + 90 mm Hg = 50th percentile for systolic BP.

was not established as routine clinical practice until the 1870s.

## NORMAL VALUES

The range of normal, resting vital signs for specific age groups must be recognized by the clinician to enable identification of abnormal values and their clinical significance. Normal ranges for vital signs also may be influenced by sex, race, pregnancy, and residence in an industrialized nation. These ranges have not been validated in ED patients, who may have many reasons for vital sign abnormalities that include anxiety, pain, and other forms of distress, in addition to altered physiology from disease states.

Published vital sign norms for children are not as well accepted as for adult patients. In Tables 70-1 and 70-2 (Table Not Available) , we report normal vital signs for children by age group as means and standard deviations. In Table 70-1 , the values for pulse and blood pressure for 0- to 2-month-olds are adapted from studies of newborn populations (i.e., <7 days). [6] [7] [8] During the newborn period, normal arterial blood pressure rises rapidly. Values for pulse and respiration in children older than 3 years reflect an average of male and female values for 0- to 1-, 3-, 9-, and 16-year-old populations. [9] The values for blood pressure reflect an average of male and female values for the 1- to 6-month and 3-, 9-, and 16-year-old populations. [8] Recent studies have reassessed reference values for respiratory rates in children. Table 70-2 (Table Not Available) reflects the age-related changes and the effect of state of wakefulness in the respiratory rates of children ages 0-3 years. [11] Hooker and colleagues measured resting respiratory rates in pediatric ED patients up to age 18 years. [10] They noted considerable patient variability and somewhat higher respiratory rates than are shown in Table 70-2 (Table Not Available) .

For the adult population, normal values for blood pressure are well established. Although there is an increase in systolic blood pressure with age, normotensive or normal systolic blood pressure is defined as 90 to 140 mm Hg, and normotensive or normal diastolic blood pressure is defined as 60 to 90 mm Hg.

The normal limits for resting heart rate of 60 beats/min and 100 beats/min were established by consensus in 1928 by the New York Heart Association. [13] Recent data indicate that 45 beats/min and 95 beats/min better define the heart rate limits of normal sinus rhythm in adults of all ages. Spodick recommends that the operational definition for the limits of resting heart rate in adults should be 50 beats/min and 90 beats/min. This view is widely supported among cardiologists. [15]

*There is currently no consensus on what constitutes a normal adult respiratory rate*. The majority of studies on respiratory rate support 16 to 24 breaths/min as the norm for adults.

Pregnancy results in alteration of the normal adult values for pulse and blood pressure. Respiratory rate is unchanged, although the physiologic hyperventilation of pregnancy is well recognized. This is a result of increased tidal volume and decreased residual and expiratory reserve volumes. [16] Resting pulse rate increases through pregnancy to 10 to 15% over baseline values. Norms for systolic and diastolic blood pressure are dependent on patient positioning. When the pregnant patient is sitting or standing, systolic pressures are essentially unchanged. Diastolic pressures decline until approximately 28 weeks' gestation, when they begin to rise to nonpregnant levels. When the pregnant patient is in the lateral decubitus position, both systolic and diastolic pressures decline until the 28th week and then begin to rise to nonpregnant levels (Table 70-3) (Table Not Available) .

## RESPIRATION

Respiratory frequency reveals only part of the clinical picture. The pattern, effort, and volume of respiration may be more indicative of altered respiratory physiology. An abnormality in respiration may be a primary complaint or a manifestation of other systemic disease.

### Physiology

Breathing is initiated and primarily controlled in the medullary respiratory center in the brainstem. The respiratory center is modulated by the pneumotaxic and apneustic centers in the pons. The pneumotaxic center serves as the limiter of length of the inspiratory signal and therefore can greatly increase or decrease respiratory rate.

In addition to being modified by other areas of the brainstem, the medullary respiratory center is modified by voluntary centers in the cerebral cortex; pulmonary stretch receptors of the airways; type J or juxtapulmonary capillary receptors of the pulmonary capillaries; arterial baroreceptors of the carotid sinus; and receptors found in skeletal muscle, tendons, and joints. Central and peripheral chemoreceptors also influence respiratory rate. [18]

### Indications and Contraindications

Generally, all ED patients should have respiratory rate documented during their evaluation. Repeated assessment and documentation of the patient's respiratory status is indicated in patients who present with an abnormal respiratory rate or a complaint referable to the airway or breathing.

The only contraindication to a careful measurement of respiratory rate is in the scenarios of respiratory distress, apnea, or upper airway obstruction that require immediate therapeutic intervention. A measurement of respiratory rate and effort should be performed as soon as patient care demands allow it in these circumstances.

Observation and palpation of chest movement are the techniques most frequently used to monitor respiratory frequency and amplitude noninvasively. Discussion of inductive plethysmography and other noninvasive monitors are beyond the scope of this chapter. Periodic manual measurements as described below generally suffice for ED patients.

## Procedure

Respiratory rate is the number of inspirations per minute. Generally, respiratory rate is best measured with the patient unaware that breathing is being observed, because awareness makes the patient conscious of the breathing pattern, which may alter the rate. Commonly, examiners count respirations while appearing to count the pulse. The respiratory rate is most accurately determined by counting for a full minute. Because the frequency is much less than the pulse, and breathing is less regular, an inaccurate measurement is more likely to occur if a 15-second interval is used.

Infants, in addition to being principally nasal breathers, are predominantly diaphragmatic breathers, and an infant's respiratory rate is easily determined by observing or palpating excursion of the chest or the abdominal wall. [19]

## Complications

There are no inherent complications from measuring respiration by observation. Problems related to the measurement of respiratory rate are generally due to failure to recognize a patient in obvious respiratory distress or failure to monitor respiratory rate in a patient who may be at risk for respiratory depression (e.g., in the case of sedative-hypnotic or narcotic overdose).

## Interpretation

### Respiratory Rate

A limited number of studies have examined respiratory rates. Hutchinson evaluated respiratory rates in 1897 healthy males at rest and found that 91% had respiratory rates between 16 and 24 breaths/min. He also noted that 30% had exactly 20 breaths/min. [20] Hooker and colleagues note that current texts vary considerably in their definitions of a

normal respiratory rate and cite published values that range from 8 to 20 breaths/min.

Hooker and associates, in the only study that specifically investigated normal respiratory rates in an ED, measured respiratory rates in 110 afebrile ambulatory patients without respiratory complaints (53 females and 57 males). [21] They report a mean rate of 20.1 breaths/min. For patients whose respiratory rate was measured again before release from the department, no significant difference was noted between the initial and subsequent respiratory rates. When analyzed by sex, females had a mean respiratory rate of 20.9 breaths/min and males had a mean respiratory rate of 19.4 breaths/min, a statistically significant difference. The researchers concluded that a normal respiratory rate in the adult patient population was 16 to 24 breaths/min. [21]

Recent studies, performed in young children, have provided additional information on normal resting and sleep state respiratory rates in children younger than 7 years. Respiratory rates obtained with a stethoscope were higher than those obtained by observation (mean difference, 2.6 breaths/min in awake and 1.8 breaths/min in asleep children). Smoothed percentile curves demonstrated a larger dispersion at birth (5th percentile, 34 breaths/min; 95th percentile, 68 breaths/min), while at 36 months of age (5th percentile, 18 breaths/min; 95th percentile, 30 breaths/min) dispersion was less.

Gravelyn and Weg compared changes in respiratory rates with respiratory dysfunction in 46 postoperative patients and found that 9 patients had respiratory rates >24 breaths/min. Of these, 5 patients had developed infection or congestive heart failure and 1 patient demonstrated an elevated respiratory rate in response to pain. In the remaining 35 patients, only 1 had respiratory dysfunction and a normal respiratory rate. [22] Bell and colleagues, using data from the Urokinase-Streptokinase Pulmonary Embolism Trials, found that 92% of patients with pulmonary emboli have a respiratory rate of >16 breaths/min. [23] Unfortunately, many normal patients have a resting respiratory rate of >16 breaths/min.

**Respiratory Pattern and Amplitude**

Abnormal respiratory patterns may be characteristic of metabolic or central nervous system pathologic conditions. Hyperventilation and hypoventilation may result from an extensive differential diagnosis including primary pulmonary disorders, such as pneumonia or chest wall pain. Respiratory disturbances also occur secondary to other disease processes. For example, *Kussmaul respiration* describes the hyperventilation pattern seen in diabetics with ketoacidosis. Abnormal respiratory patterns in adults can be used in differential diagnosis or in determining the location of central nervous system lesions.

Respiratory patterns in children must be observed carefully. In infants, periodic breathing, which may be normal, must be distinguished from apnea. By definition, periodic breathing consists of three or more respiratory pauses >3 seconds in duration, with <20 seconds between pauses. There is no associated bradycardia or cyanosis. This contrasts with apnea, which is a particular problem in preterm infants. Apnea is defined as a respiratory pause of >20 seconds, and it may be associated with bradycardia and hypoxia. [19] Periodic breathing and apnea are believed to be disorders

on a continuum, both stemming from abnormal physiologic control of respiration. However, periodic breathing is felt to be a benign disorder, whereas infants with symptomatic apneic episodes resulting in an apparent life-threatening event (ALTE) are thought to be at increased risk for sudden infant death syndrome.

# PULSE

The pulse is examined primarily to establish cardiac rate and rhythm. However, palpation of peripheral pulses yields clues to cardiac disease, such as aortic insufficiency, and information about the integrity of the peripheral vascular supply. Doppler ultrasound provides a noninvasive method of assessing blood flow in the ED. It has utility in the location of a pulse, in the assessment of fetal heart tones beyond the first trimester, for evaluation of peripheral lower extremity vascular insufficiency, and for the evaluation of blood pressure in infants or in patients with low-flow states.

### Physiology

Blood flowing into the aorta with each cardiac cycle initiates a pressure wave. Blood flows through the vasculature at approximately 0.5 m/sec; however, pressure waves in the aorta move at 3 to 5 m/sec. Therefore, palpated peripheral pulses represent pressure waves, not blood flow.

### Indications and Contraindications

The evaluation of pulse presence and rate is indicated in every patient who presents to the ED. The necessity of repeated evaluations is dictated by the clinical complaint and status of the patient. Pulse assessment is essential in all patients with potential peripheral vascular insufficiency.

No contraindications exist to assessment of pulse, but a few cautionary notes about the examination of the carotid pulse should be kept in mind: Concurrent bilateral carotid artery palpation should be avoided, as this maneuver could endanger cerebral blood flow. In addition, massage of the carotid sinus, found at the bifurcation of the external and internal carotid arteries at the level of the angle of the mandible, may result in reflex slowing of the heart rate (see Chapter 10) . To avoid inadvertent carotid sinus massage, the pulse should be palpated at or below the level of the thyroid cartilage. A risk of precipitating a cerebrovascular event by vigorous palpation of the carotid artery is present in adults with atherosclerotic disease. This risk may be minimized by prior auscultation of the carotid artery. If a bruit is present, avoid palpation of the carotid pulse in that patient.

### Equipment

Assessment of the pulse may be performed by the clinician at the bedside with any timepiece that has a second-hand display. This allows simultaneous assessment of all the characteristics of the pulse. If continuous monitoring is deemed necessary, bedside cardiac monitors can constantly monitor heart rate and rhythm. Pulse oximetry (see

, although primarily intended to measure oxygen saturation, also may be used to monitor the pulse rate. In a critical care situation, more sophisticated invasive monitoring techniques are available (see for arterial pressure measurement and rate assessment.

## Procedure

Pulses are palpable at numerous sites, although for convenience, the radial pulse at the wrist is routinely used. The examiner should use the tips of the first and second fingers to palpate the pulse. The two advantages to this technique are (1) that the fingertips are quite sensitive, enabling the pulse to be easily located and counted, and (2) the examiner's own pulse may be erroneously counted, if the thumb is used instead of the first and second fingers. Pulses are also easily palpated at the carotid, brachial, femoral, posterior tibial, and dorsalis pedis arteries. Palpation of the pulse at the brachial artery may facilitate the appreciation of pulse contour and amplitude. It is located at the medial aspect of the elbow and is more easily palpated when the elbow is held slightly flexed. [25] Pulse rate is ideally determined by counting the pulse for 1 minute, particularly if any abnormality is present.

In newborns, direct heart auscultation and umbilical palpation are the methods of choice to determine heart rate. Instantaneous changes in newborn heart rates are best indicated for the resuscitation team by the examiner tapping out each heartbeat. [26] In unstable children, palpation of central arteries, particularly femoral and brachial pulses, is recommended over palpation of more peripheral arteries.

## Interpretation

### Pulse Rate

Individual physiology must be considered in pulse interpretation. In infants and children, pulse rate must be interpreted with reference to age. Pulse varies with respiration, increasing with inspiration and slowing with expiration. This is known as a *sinus dysrhythmia* and is physiologic.

Although bradycardia is defined as a heart rate of <60 beats/min in adults, a well-conditioned athlete may have a normal resting heart rate of 30 to 40 beats/min. [27] As discussed earlier, a redefinition of bradycardia to <50 beats/min and tachycardia to >90 beats/min has been proposed.

The clinician must consider whether an abnormal pulse rate is a primary or secondary condition. The examination of the entire set of vital signs is instrumental in discerning the cause for the abnormal rate. For example, hyperthermia causes a sinus tachycardia. An increase in heart rate of 18 beats/min can be expected for each degree centigrade and 10 beats/min for each degree Fahrenheit of elevated temperature. [17] Drug fever, typhoid fever, and central neurogenic fever are suggested when no corresponding tachycardia is found in a patient with elevated body temperature. Hypothermia, with its

reduced metabolic demands, may be associated with bradycardia.

Clinical evaluation of the patient with an abnormal pulse rate dictates a consideration of medications the patient may be taking or the presence of a mechanical pacemaker. Digitalis compounds, beta-blockers, and antidysrhythmics may alter the normal heart rate and the ability of this vital sign to respond to a new physiologic stress. These cardioactive medications may be the cause of the patient's heart rate abnormality.

**Heart Rhythm**

In addition to determining the pulse rate, information about the regularity of the pulse is obtained during palpation. An irregularly irregular pulse suggests atrial fibrillation or flutter with variable block, and accurate assessment of the pulse should be obtained by auscultation of apical cardiac sounds. The apical pulse is frequently greater than the peripheral pulse, reflecting inadequate filling time and stroke volume, with resultant nontransmitted beats. A greater pulse deficit generally reflects more severe disease.

**Pulse Amplitude and Contour**

Amplitude and contour of the pulse are generally assessed simultaneously. Figure 70-1 (Figure Not Available) compares normal and abnormal pulse amplitudes and contours. Accurate examination and description provides additional clinical information. Superimposition of one pathophysiologic state on another may modify the pulse. For example, sepsis may manifest with variable pulse amplitude, depending on the stage in the development of the disease at which the patient presents. Early in sepsis, cardiac output increases and vascular resistance decreases, causing bounding pulses. In advanced sepsis or septic shock, falling cardiac output and increased vascular resistance are seen, and pulses are diminished. [28]

**Pulses During Cardiopulmonary Resuscitation**

Palpated "femoral pulses" during chest compression may represent either forward arterial blood flow or "to-and-fro" movement of blood from the right heart to the venous system. A carotid pulse is preferred when assessing the adequacy of chest compressions during cardiopulmonary resuscitation (see Chapter 16) .

# ARTERIAL BLOOD PRESSURE

Changes in arterial blood pressure over time may be an indication of the success of treatment or the worsening of the patient's overall condition. An abrupt reduction in the patient's arterial blood pressure is usually an indication of the need for immediate intervention or reconsideration of therapy. The technique of arterial cannulation and direct intra-arterial blood pressure monitoring is discussed in Chapter 19 . This section discusses indirect blood pressure monitoring. Discussions of the specific use of the Doppler device for pulse and blood pressure measurement and the measurement of orthostatic blood pressure and pulse changes follow this section.

## Physiology

The arterial blood pressure indicates the overall state of hemodynamic interaction between cardiac output and peripheral vascular resistance. The arterial blood pressure is the lateral pressure or force exerted by the blood on the vessel wall. The arterial blood pressure indirectly measures perfusion, where blood flow equals the change in pressure divided by resistance. [4] However, because peripheral vascular resistance varies, a normal blood pressure does not confirm adequate perfusion. [29] Mean arterial blood pressure can be estimated by adding one third of the pulse pressure (i.e., the difference between the systolic and diastolic blood pressure) to the diastolic pressure.

## Indications and Contraindications

Blood pressure measurement and documentation are essential for most ED patients seen for the first time. Patients with minor ambulatory complaints not related to the cardiovascular system may not receive blood pressure measurements in the ED. Frequent monitoring of the blood pressure is necessary for patients with hemodynamic instability.

In low-flow states, Doppler measurement of blood pressure may be obtained rapidly. Repeated measurements will provide an evaluation of the adequacy of resuscitation in patients whose blood pressure cannot be auscultated by standard techniques. Placement of a catheter for direct intra-arterial measurement of blood pressure has a higher risk of complications, but it may be performed safely in the ED (see Chapter 19). In particular, direct measurement of arterial pressure during pulseless electrical rhythms may help to discriminate between severe shock and an otherwise nonresuscitatable status. [31]

Relative contraindications to specific extremity blood pressure measurement include an arteriovenous fistula, ipsilateral mastectomy, axillary lymphadenopathy, lymphedema, and circumferential burns over the intended site of cuff application.

## Equipment

The equipment required for indirect blood pressure measurement includes a sphygmomanometer (cuff with inflatable bladder, inflating bulb, controlled exhaust for deflation, and manometer) and a stethoscope or Doppler device (for auscultation) or an oscillometric device. To ensure an accurate reading, the sphygmomanometer cuff should be of an appropriate size for the patient. The width of the bladder should be 40% of the distance of the midpoint of the limb (i.e., from the acromion process to the lateral epicondyle). The length of the bladder should be 80% of the midarm circumference or twice the recommended width. [30]

Manometers in common use are either an aneroid or a mercury gravity column. Both types of manometers are convenient for bedside use, although the mercury gravity column must be placed vertically to ensure accurate measurements. An aneroid

manometer uses a metal bellows that elongates with the application of pressure. This elongation is mechanically amplified, transmitting the motion to the indicator needle.

Manometers require annual servicing. Mercury columns may require the addition of mercury to bring the edge of the meniscus to the zero mark. The air vent or filter at the top of the mercury column also should be checked for clogging. The aneroid manometer should be calibrated against a mercury column at least yearly. If the aneroid indicator is not at zero at rest, the device should not be used. [35]

Automatic sphygmomanometers may improve physiologic monitoring with alarm and self-cycling capabilities. They offer indirect arterial blood pressure measurement with little pain and lack the risks associated with invasive arterial lines. [36] Various manufacturers use oscillometric (Dinamap 845, Applied Medical Research), Korotkoff sound (Pressurometer [Avionics]; Diasyst-T [Siemens Co]), and ultrasonic (Arteriosonde, Hoffmann-LaRoche Co) techniques. Oscillometric blood pressure monitors detect motion of the blood pressure cuff transmitted from the underlying artery. A sudden increase in the amplitude of arterial oscillations occurs at systolic pressure and mean arterial pressure, and an abrupt decrease occurs at diastolic pressure.

Dinamap blood pressures obtained in 29 hemodynamically stable children (mean age, 18 months) demonstrated a smaller mean error (systolic, -0.24 vs 3.26 mm Hg) than auscultatory measurements in 20 children (systolic, -1.65 vs 6.68 mm Hg) using direct radial arterial pressures for comparison. [37] Park and Menard also found less variability with the Dinamap vs the auscultatory method in children. [38] Similarly, in adult patients, good correlation was found with mean diastolic and systolic arterial pressures using Dinamap. [39] Automatic devices do not provide a continual monitoring of blood pressure, and the static digital readouts may fail to pick up sudden hypotension.

**Procedure**

Indirect blood pressure measurements may be obtained at the patient's bedside by palpation, auscultation, Doppler, or oscillometric methods. The technique is straightforward and accurate when well-maintained, calibrated equipment is used by practitioners who follow accepted standards. The patient may be lying or sitting, as long as the site of measurement is at the level of the right atrium and the arm is supported.

Palpation of arterial blood pressure requires cuff inflation to 30 mm Hg above the level at which a palpable pulse disappears. Once properly inflated, the examiner should palpate directly over the artery and deflate the cuff at 2 to 3 mm Hg per second. The initial appearance of arterial pulsations is reported as the palpable blood pressure. The same technique may be used with the Doppler device with the Doppler auditory signal replacing the palpated pulse. Arterial pressure measurement by palpation and Doppler yields only systolic blood pressure estimates.

When auscultating the blood pressure at the brachial artery, the blood pressure cuff is applied about 2.5 cm above the antecubital fossa with the center of the bladder over the artery. [32] The bell of the stethoscope is applied directly over the brachial artery but with as little pressure as possible. [40] The systolic arterial blood pressure is defined as the

first appearance of faint, clear, tapping sounds that gradually increase in intensity (Korotkoff phase I), whereas the diastolic blood pressure is defined as the point at which sounds disappear (Korotkoff phase V). In children, phase IV defines the diastolic blood pressure (Fig. 70-2) (Figure Not Available) . [8] Phase IV is marked by a distinct, abrupt muffling of sound when a soft, blowing quality is heard. Measurement by auscultation over the brachial artery is preferred because of accepted standardization of measured values. Alternate sites include the radial, popliteal, posterior tibial, or dorsalis pedis arteries, although any fully compressible extremity artery may be used. Studies correlating direct and indirect blood pressure measurements have demonstrated a good correlation between these methods.

The accuracy of palpatory, Doppler, and oscillometric methods has also been demonstrated. However, when phase I and V Korotkoff sounds are used, indirect methods typically underestimate systolic and diastolic pressure by several millimeters of mercury. [41] [48] In addition, during shock, palpatory and auscultatory methods underestimate simultaneous direct arterial pressure measurements. [49] The flush method, in which return of color after deflation of the cuff is used for estimating blood pressure in infants, may underestimate systolic blood pressure by up to 40 mm Hg. [48] This method is unreliable and is not recommended.

**Complications**

Complications of indirect blood pressure measurement are minimal when the proper procedure is followed. Inadvertent prolonged application of an inflated blood pressure cuff may result in false elevation of diastolic pressure and in ischemia distal to the site of application, with attendant complications. Invasive blood pressure monitoring is associated with a number of potential problems (see Chapter 19) .

**Interpretation**

Normal blood pressure increases with decreasing distance from the aorta. The blood pressure tends to increase with age and is generally higher in males. Individual factors that influence blood pressure include body posture, emotional or painful stimuli, environmental influences, vasoactive foods or medications, and the state of muscular and cerebral activity. Exercise and sustained isometric muscular contraction increase blood pressure in proportion to the strength of the contraction. [4] A normal diurnal pattern of blood pressure consists of an increase throughout the day, with a significant, rapid decline during early, deep sleep. [50]

Normal lower limits for systolic blood pressure for infants and children can be estimated by adding 2 times the age (in years) to 70, with the result expressed in millimeters of mercury. The 50th percentile for a child's systolic arterial blood pressure from 1 to 10 years of age can be estimated by adding 2 times the age (in years) to 90 mm Hg. Children older than 2 years are considered hypotensive when systolic blood pressure is <80 mm Hg. [51] Children, in particular, are able to maintain mean arterial blood pressure until very late during shock. [52] Thus the finding of a normal blood pressure in a child with signs of poor perfusion should not dissuade the emergency physician from appropriate treatment. Adults are considered hypotensive if the systolic blood pressure

is <90 mm Hg. When accompanied by signs of shock, immediate treatment is indicated. In patients with shock, blood flow cannot be reliably inferred from heart rate and blood pressure values.

**Hypertension**

Adults are hypertensive if either the systolic or the diastolic pressure consistently exceeds 140 or 90 mm Hg, respectively. [55] [56] The applicability of population norms for hypertension in a stressful emergency situation is controversial. One should not make diagnostic or therapeutic decisions based solely on an abnormal initial measurement. Patients with hypertension require repeat measurement to assess whether ED therapy is required. Because sustained hypertension may be seen in more than a third of initially hypertensive ED patients, careful evaluation and follow-up are required. [57]

One study of 48 hospitalized patients found that during a physician visit, 94% experienced a mean peak increase in systolic pressure (27 ± 2 mm Hg), diastolic pressure (15 ± 2 mm Hg), and heart rate (16 ± 2 beats/min). The response peaked at approximately 4 minutes and abated at about 10 minutes after initiation. [58] By using noninvasive, ambulatory blood pressure recordings, investigators at New York Hospital found that 21% of 292 patients had "white coat" hypertension. These patients were (1) more likely to be recently diagnosed as hypertensive, (2) female, (3) younger, and (4) to have had their office blood pressure measured by a physician. [59]

Recent ED data indicate that patients with stroke have spontaneous reductions in blood pressure during the first 90 minutes after onset of symptoms (mean change in systolic and diastolic readings, -29 mm Hg and -10 mm Hg, respectively). [60]

**Measurement Errors**

Erroneous blood pressure measurements may result from several factors.  Falsely low blood pressure may be caused by using an overly wide cuff or by rapid cuff deflation. [62]  Falsely high blood pressure may be caused by the use of an overly narrow cuff, anxiety, pain, tobacco use, exertion, an unsupported arm, or slow inflation of the cuff.

In 470 unselected adults, investigators at Duke University found no spurious effect of cuff size in 350 patients weighing <95 kg and with an arm circumference <35 cm. However, in 120 patients weighing >95 kg and with an arm circumference >35 cm, the use of a large cuff reclassified 33% of those with systolic hypertension to borderline, 62% of those with borderline systolic hypertension to normal, and 79% of patients with borderline diastolic hypertension to normal. [63] Of note, 41% of adults observed at the University of Pittsburgh required nonstandard size cuffs, and use of small cuffs was associated with a mean error of 8.5 and 4.6 mm Hg in the systolic and diastolic pressures, respectively.  Hypotensive patients have unreliable Korotkoff sounds. However, Doppler measurements are well correlated with direct arterial systolic pressure in hypotensive patients. [65]

An auscultatory gap can be appreciated in hypertensive patients and may mislead the

examiner. It is heard during the latter part of phase I and should not be confused with diastolic readings. Auscultation until the manometer reading approaches zero should prevent misinterpretation. In patients with aortic insufficiency or hyperthyroidism, in persons who have just finished exercising, and in children younger than 5 years of age, the measurement of diastolic blood pressure should occur at Korotkoff phase IV.

Irregular heart rates also may interfere with accurate blood pressure determination. A second or third reading, with 2 minutes of deflation between recordings, should be used to obtain an average when premature contractions or atrial fibrillation is present. Ultrasonic methods may be more accurate during shock states and in infants for systolic blood pressure measurement. [65]

Dewar demonstrated that hemiplegic patients may exhibit different blood pressures in the affected and unaffected arm. [66] A flaccid extremity tended to yield lower systolic and diastolic pressures, whereas a spastic extremity tended to yield higher values than the extremity with normal motor tone. Although these differences are generally small, it is preferable to monitor blood pressure in the unaffected limb.

**Pulse Pressure**

Increased pulse pressure (i.e., 60 mm Hg) is commonly observed in anemia, exercise, hyperthyroidism, arteriovenous fistula, aortic regurgitation, and patent ductus arteriosus. A narrowed pulse pressure (20 mm Hg) may be a manifestation of hypovolemia, increased peripheral vascular resistance, or decreased stroke volume.

**Differential Brachial Artery Pressures**

A difference in bilateral brachial artery pressures up to 10 mm Hg may be normal, but it is uncommon. Hashimoto and colleagues found that only 1.4% of elderly patients had a systolic brachial blood pressure difference of >10 mm Hg, although 6.5% had a difference exceeding 7.5 mm Hg. [67] Most patients with subclavian steal syndrome, supravalvular aortic stenosis, and aortic dissection have a 15 mm Hg difference in contralateral brachial artery systolic pressures.

**Pulsus Paradoxus**

Normal respiration decreases the systolic blood pressure by approximately 10 mm Hg during inspiration. Pulsus paradoxus occurs when there is a >12 mm Hg decrease in the systolic blood pressure during inspiration. Pulsus paradoxus may occur in patients with chronic obstructive pulmonary disease, pneumothorax, severe asthma, and pericardial tamponade. [68]

To measure a paradoxical pulse, the patient should be lying comfortably, at a 30° to 45° angle, and breathing normally, in an unlabored fashion (unusual conditions in a patient suspected of cardiac tamponade). [69] The blood pressure cuff is inflated well above systolic pressure and is slowly deflated until one first hears the systolic sounds that are synchronous with expiration (Fig. 70-3) . Initially, one will hear the arterial pulse only

during expiration, and it will disappear during inspiration. The cuff is then further deflated until arterial sounds are heard throughout the respiratory cycle. A paradoxical pulse can be palpated if it is very large. During palpation the pulse may completely disappear during inspiration. When present, this technique is a quick bedside confirmation of the possibility of severe tamponade. Palpation for this purpose is best done at peripheral arteries, such as the radial or femoral.

An alternative approach to measurement of pulsus paradoxus is to use a finger arterial pressure monitor (Finapres; Ohmeda, Englewood, Colo) and to subtract the peak systolic blood pressure during expiration from the lowest systolic blood pressure during inspiration. [70] The pulsus paradoxus obtained with this technique was found to have less variability (when compared to intra-arterial measurements) than with manual measurements. Furthermore, pulsus paradoxus obtained using the finger pressure monitor correlates well with the pulmonary index score in asthmatic children. [71] Changes in the pulsus paradoxus were found to correlate with other markers of clinical status and admission decisions.

If the difference between these inspiratory and expiratory pressures is >12 mm Hg, the paradoxical pulse is high. [72] Most patients with proven tamponade have a difference of 20 to 30 mm Hg during the respiratory cycle. This may not be true of patients with very narrow pulse pressures (typical of advanced tamponade), who have a "deceptively small" paradoxical pulse of 5 to 15 mm Hg. The relative decrease in pulsus paradoxus occurs because the paradoxical pulse is a function of actual pulse pressure, and the inspiratory systolic pressure may be below the level at which diastolic sounds disappear. [69] For this reason, the ratio of paradoxical pulse to the pulse pressure is a more reliable measure. A paradoxical pulse >50% of the pulse pressure is abnormal. [69]

Pulsus paradoxus has been correlated with the amount of impairment of cardiac output by tamponade. In atraumatic patients, a 15% pulsus paradoxus in the presence of relative hypotension was found in 97% of patients with moderate or severe tamponade and in only 6% of patients with absent or mild tamponade. A similar study of right ventricular diastolic collapse by echocardiography found that an abnormal pulsus paradoxus had a sensitivity of 79%, specificity of 40%, positive predictive value of 81%, and negative predictive value of 40%. [75] The absence of a paradoxical pulse does not rule out tamponade (see Chapter 15) .

**Shock Index**

The ratio of the pulse rate over the systolic blood pressure has been suggested as a measure of clinical shock. The shock index (SI) has a normal range of 0.5 to 0.7. Rady and colleagues demonstrated that an SI of >0.9 was more commonly associated with acute illness requiring immediate treatment (56% vs 45%) or hospital admission (85% vs 45%) than was an SI of <0.9. [76] However, the presenting pulse rate alone had nearly the same predictive power. Further, Rady and coworkers demonstrated that although the SI appeared to correlate with left ventricular stroke work index, it had little correlation with systemic oxygen transport in hemorrhagic and septic shock.

# DOPPLER ULTRASOUND FOR EVALUATION OF PULSE AND BLOOD

# PRESSURE

## Principles of Doppler Ultrasound

Doppler ultrasound is based on the Doppler phenomenon: the frequency of sound waves varies depending on the speed of the sound transmitter in relation to the sound receiver. Doppler devices transmit a sound wave that is reflected by flowing erythrocytes, and the shift in frequency is detected. Frequency shift can only be detected for blood flow >6 cm/sec.

### Indications and Contraindications

Doppler ultrasound is commonly used in the ED for the measurement of blood pressure in low-flow states, evaluation of lower extremity peripheral perfusion, and assessment of fetal heart sounds after the first trimester of pregnancy. Doppler sensitivity allows the detection of systolic blood pressure down to 30 mm Hg in the evaluation of a patient in shock. In the patient with peripheral vascular disease in whom there is concern about the adequacy of peripheral perfusion, the ankle/brachial index provides a rapidly obtainable, reproducible, and standardized assessment. [78] Fetal heart sounds provide a baseline assessment of any patient with 12 weeks' gestation in whom there is possible abdominal trauma or fetal distress due to a complication of pregnancy.

The use of Doppler ultrasound in the evaluation of deep venous thrombosis is a valuable tool; however, it requires specific training and experience to attain proficiency. Discussion of this topic is beyond the scope of this chapter.

### Equipment

A nondirectional Doppler device has a probe that houses 2 piezoelectric crystals. One crystal transmits the signal and the other receives it. Reflected signals are converted to an electrical signal and fed to an output that transforms them to an audible sound. Two commonly used Doppler units are the pocket Doppler stethoscope (model BF4A, Medsonics, Inc, Los Altos, Calif) and the ultrasonic Doppler flow detector (model 811, Parks Medical Electronics, Aloha, Ore) (Figs. 70-4 (Figure Not Available) and 70-5) (Figure Not Available) .

Probes with a frequency of 2 to 5 MHz are best for detecting fetal heart sounds. Frequencies of 5 to 10 MHz are appropriate for limb arteries and veins. The probes should be monitored periodically for electrical damage and integrity of the crystal. Sphygmomanometers used in conjunction with the Doppler device should be calibrated periodically, as described in the section on blood pressure evaluation.

### Procedure

The Doppler probe is placed against the skin using an acoustic gel as an interface. The gel ensures optimal ultrasound signal transmission and reception and protects the crystals. In an emergency, water-soluble lubricant (e.g., Surgilube or K-Y jelly) may be

substituted for commercial acoustic gel. The probe is angled at 45° along the length of the vessel to optimize frequency shifts and signal amplitude.

In the evaluation of peripheral perfusion, a sphygmomanometer cuff is placed proximal to the arterial pulse and inflated. The probe is placed over the arterial pulse and the cuff is slowly deflated. The pressure at which flow is first heard is the systolic pressure.

In the evaluation of peripheral vascular disease, the ankle/brachial index is determined. Both brachial arteries are examined at the medial aspect of the antecubital fossa. The probe is angled until the most satisfactory signal is obtained. The cuff is inflated and slowly deflated until the systolic pulse is heard. The procedure is repeated for the posterior tibial and dorsalis arteries of both lower extremities.

In the evaluation of fetal heart tones, variable positioning of the fetus may require examination at several locations over the uterus and angling of the probe to search for the optimal signal. It is best to begin in the mid-suprapubic area and to explore the uterus via angulation of the probe. Once tones are located, the probe can be moved along the abdomen to reach a position closer to the origin of the sound. Fetal heart tones are distinguished from placental flow by the discrete quality of the fetal heart tones and the rate of placental flow, which matches the maternal pulse.

**Interpretation**

As noted earlier, in low-flow states, Doppler ultrasound can detect a blood pressure as low as 30 mm Hg. The ankle/brachial index of each limb is calculated by dividing the higher systolic pressure of the posterior tibial or the dorsalis pedis artery of the limb by the higher of the systolic pressures in the brachial arteries. In normal individuals, the index should be >1.0. Patients with claudication have values between 0.6 and 0.8. Values <0.5 imply severe impairment and are consistent with rest pain or gangrene. [78] Patients with ankle/brachial index values of 0.9 have been found to have increased cardiovascular morbidity and mortality. [79] Segmental lower extremity pressure measurements may help to identify the level of obstruction (Figs. 70-6 (Figure Not Available) through 70-8). [80] Obese patients, diabetic patients, or patients with calcified vessels that are not compressible may have abnormally high systolic pressures (e.g., 250 to 300 mm Hg) and indices that do not accurately reflect flow.

Normal fetal heart tones should be between 120 and 140 beats/min. Fetal tones may be heard as early as the 12th week of gestation.

# ORTHOSTATIC VITAL SIGNS MEASUREMENT

Orthostatic vital signs are used to evaluate patients with fluid loss, hemorrhage, syncope, or autonomic dysfunction. They are also used to assess the patient's response to therapy. The emergency physician is often concerned with the accurate detection of acute blood loss or volume depletion. When the clinical syndrome of shock exists, assessment of a blood volume deficit poses little difficulty. It is preferable, however, that volume loss be detected before loss of physiologic compensation and clinical shock

occurs. This section addresses the utility of orthostatic vital signs in the detection and monitoring of acute volume depletion.

Many techniques have been advocated to assess volume status. Unfortunately, most of these procedures lack a database against which to judge their reliability. Methods that have been recommended include evaluation of the following parameters: skin color; skin turgor; skin temperature; supine, serial, and orthostatic vital signs; neck vein status; transcutaneous oximetry; and hemodynamic monitoring (e.g., monitoring of central venous pressure) (see Chapter 24) . Serial vital sign measurements have been used for assessing blood loss, but they do not reliably detect small degrees of blood loss. *Up to 15% of the total blood volume can be lost with minimal hemodynamic changes or any alteration of the supine vital signs.* [81] A decrease in the pulse pressure occurs with acute blood loss, [83] but the patient's baseline blood pressure values are often unknown. Clinical examination of neck veins adds useful information but is less precise than measurement of central venous pressure. Most clinicians use skin color, temperature, and moisture as a reflection of skin perfusion and sympathetic tone but not as an accurate guide to circulatory volume, because the vasomotor tone of the skin is affected by numerous diseases as well as by emotional and environmental factors. Capillary refill has been advocated as an ideal noninvasive test for hypovolemia, but it has not been found to be accurate in adults [84] (see the following discussion regarding its use for children).

The ideal test for determining volume status would rapidly and accurately detect volume depletion of 5% or more using a noninvasive technique. At present, no such test exists. Orthostatic vital signs meet the criteria of being noninvasive and easily used at the bedside. However, *in patients with acute blood loss of <20% of total blood volume, orthostatic vital signs lack both sensitivity and specificity.* [85] Further, ethanol ingestion exaggerates postural pulse changes, thus mimicking the hemodynamic changes seen with acute blood loss. [86]

The medical literature is replete with unsubstantiated claims regarding what constitutes a positive or negative orthostatic test, and its value for estimating volume status may be overstated. Some authors [87] [88] have stated that postural hypotension or postural tachycardia occurs with varying degrees of hypovolemia, but they do not define specific criteria for a positive test. Other sources (without documentation) have perpetuated the notion that relatively small changes in the orthostatic blood pressure or the pulse are reliable in detecting hypovolemia. For example, Hayes and Briggs state erroneously that "a decrease of 10 mm Hg or more on assuming the sitting position indicates significant hypovolemia." [89]

In this section, the physiologic compensatory mechanisms that are activated by hypovolemia and postural tilting and the clinical use of orthostatic vital signs to detect acute volume loss are discussed.

**Physiologic Response to Hypovolemia**

Acute blood loss decreases the pressure gradient between the venules and the right atrium. A fall in this pressure gradient decreases venous return. [90] As a result, cardiac

output falls, and clinical manifestations of shock ensue. Several homeostatic mechanisms are initiated by acute blood loss (Table 70-4) . The dominant compensatory mechanism in shock is a reduction in the carotid sinus baroreceptor inhibition of sympathetic outflow to the cardiovascular system. This increased sympathetic outflow results in several effects: (1) an arteriolar vasoconstriction, which greatly increases total peripheral vascular resistance; (2) a constriction of venous capacitance vessels, thereby increasing venous return to the heart; and (3) an increase of heart rate and force of contraction, which helps to maintain cardiac output despite significant volume loss. [91] These sympathetic reflexes are geared more for the maintenance of arterial pressure than for the maintenance of cardiac output (Fig. 70-9) (Figure Not Available) . The value of

| **TABLE 70-4** -- Homeostatic Mechanisms in Hemorrhagic Shock |
|---|
| Sympathetic reflex compensation |
|   Arteriolar vasoconstriction |
|   Venous capacitance vasoconstriction |
|   Increased inotropic and chronotropic cardiac activity |
|   Central nervous system ischemic response |
| Selective increase in cerebral and coronary perfusion by means of local autoregulation |
| Increased oxygen unloading in tissues |
| Restoration of blood volume |

| Renin-angiotensin-aldosterone axis activation |
| --- |
| Antidiuretic hormone secretion |
| Transcapillary refill |
| Increased thirst resulting in increased fluid intake |
| Increased erythropoiesis |

sympathetic reflex compensation is illustrated by the fact that 30 to 40% of the blood volume can be lost before death occurs while these reflexes are intact. When the sympathetic reflexes are absent, loss of only 15 to 20% of the blood volume may cause death. [91]

Several other reflexes maintain cardiac output in the presence of volume loss. The central nervous system ischemic response stimulates the sympathetic nervous system after the arterial pressure falls below 50 mm Hg and is responsible for the second plateau on the arterial pressure curve (see Fig. 70-9) (Figure Not Available) . [91] Other compensatory mechanisms that tend to restore the blood volume to a normal level include the release of angiotensin and antidiuretic hormone, which cause arteriolar vasoconstriction and conservation of salt and water by the kidneys. [92] A fluid shift from the interstitium to the intravascular space occurs that helps to restore blood volume over a longer period (1 to 40 hours).

When blood loss results in anemia, part of the loss in oxygen-carrying capacity is countered by an increase in tissue oxygen extraction. [95] Finally, the lost red blood cell mass is slowly replaced by erythropoiesis.

Several investigators have examined the changes in blood pressure and pulse that occur in the supine patient with blood loss. Collectively these studies have shown variable individual hemodynamic responses to acute blood loss of up to 1 L. The frequent inability to detect significant volume loss with supine vital signs and the observation that patients with acute volume loss frequently develop syncope on arising led to the investigation of the use of orthostatic vital signs to detect occult hypovolemia.

**Physiologic Response to Postural Changes**

When an individual assumes the upright posture, complex homeostatic mechanisms compensate for the effects of gravity on the circulation to maintain cerebral perfusion. These responses include (1) baroreceptor-mediated arteriolar vasoconstriction, (2) venous constriction and increased muscle tone in the legs and the abdomen to augment venous return, (3) sympathetic-mediated inotropic and chronotropic effects on the heart, and (4) activation of the renin-angiotensin-aldosterone system. [96]

These compensatory mechanisms preserve cerebral perfusion in the upright position with minimal changes in vital signs. Currens found that when normal subjects stand, the pulse increases by an average of 13 beats/min, no change or a small drop is seen in systolic blood pressure, and either no change or a small rise occurs in diastolic blood pressure. [97] These changes have been confirmed by others.

In patients with *vasodepressor syncope*, the normal compensatory reflexes that preserve cerebral perfusion with postural changes are altered. The normal increased sympathetic tone on standing is paradoxically inhibited, and an exaggerated enhancement of parasympathetic activity (bradycardia) occurs, which can lead to syncope. [100]

Few data exist on the effect of acute blood loss on postural vital signs. One early study [83] looked at 23 young adult volunteers from whom 500 to 1200 mL of blood was withdrawn. They found no reliable change in the postural blood pressure, but a consistent postural increase in the pulse of 35 to 40% was noted after a 500-mL blood loss. In the 6 subjects who were bled approximately 1 L, only 2 were able to tolerate standing; each of them had a postural increase in pulse of >30 beats/min. The other four subjects experienced severe symptoms on standing, followed by a marked bradycardia and syncope if they were not allowed to lie down.

Knopp and colleagues [85] phlebotomized 450 to 1000 mL of blood from healthy volunteers. By using the criterion of a pulse increase of 30 beats/min or the presence of severe symptoms (syncope or near syncope) during a supine-to-standing test, they were able to distinguish accurately between a 1000-mL blood loss and no blood loss. Changes in blood pressure and pulse were not evaluated in the symptomatic subjects. In this study population of 100 normal healthy volunteers with acute blood loss, the sensitivity and specificity using the aforementioned criteria for detecting a 1000-mL blood loss (Table 70-5) were both 98%, giving an accuracy of 96% (2% false-negative results and 2% false-positive results). The investigators were unable to consistently detect a blood loss of 500 mL by using these criteria.

**Variables Affecting Orthostatic Vital Signs**

Many conditions affect the compensatory mechanisms that allow us to assume the upright posture (Table 70-6) (Table Not Available) . [96] Because of decreased vasomotor tone, limited chronotropic response, and other factors, the elderly have a

higher incidence of orthostatic hypotension, which can lead to syncope

| |
|---|
| **TABLE 70-5** -- Summary of Orthostatic Tilt Testing [*] |
| **Test Procedure** |
| 1. Blood pressure and pulse are recorded after patient has been supine for 2-3 min |
| 2. Blood pressure, pulse, and symptoms are recorded after patient has been standing for 1 min; the patient should be permitted to resume a supine position immediately should syncope or near-syncope develop |
| **Positive Test** |
| 1. Increase in pulse of 30 beats/min or more in adults, *or* |
| 2. Presence of symptoms of cerebral hypoperfusion (e.g., dizziness, syncope) |

* The predictive ability of orthostatic vital signs to assess volume status is often overestimated in clinical practice. This suggested guide is based on the ability of the pulse change and patient symptoms to distinguish between no acute blood loss and a 1000 mL acute blood loss in healthy, previously normovolemic volunteers (sensitivity of 98% for detecting 1000 mL acute blood loss). [85]This guide may not be applicable to elderly patients, sick children, medicated patients, and those with autonomic dysfunction.

and fall-related injury. [101] One should note that drugs that antagonize the normal autonomic compensatory mechanisms can also produce orthostatic changes. These changes can be severe enough to produce frank syncope, especially in the elderly. However, in one study of *euvolemic* adult volunteers, orthostatic changes in patients with diabetes or in those using various antihypertensive agents were similar to changes in normal adults. [102]

Even in normal subjects, passive tilting generates a high incidence of orthostatic syncope. [103] Patients with chronic anemia (and a compensated blood volume) seem to have the same postural response as normal subjects. [104] Most of the conditions that

affect postural blood pressure regulation involve a pathologic condition that affects the sympathetic nervous system. Orthostatic hypotension caused by autonomic insufficiency is usually not accompanied by tachycardia, whereas the orthostatic hypotension produced by acute volume depletion is commonly accompanied by a pronounced reflex tachycardia.

As noted in Table 70-6 (Table Not Available) , many conditions, diseases, and medications have been implicated as a cause of abnormal orthostatic vital sign changes. Most variables have been poorly studied. In the elderly, orthostatic vital sign changes in *volume-depleted* patients have not been studied. In one study of *normovolemic* nursing home patients 62 years or older, 39 of 476 (8%) had a drop in systolic blood pressure of >20 mm Hg along with a drop in diastolic blood pressure of >10 mm Hg. [105] As expected, this postural blood pressure change was more common in patients taking cardiovascular or psychotropic drugs.

Ethanol ingestion exaggerates postural pulse changes up to 8 hours following ingestion, [86] thus mimicking the hemodynamic changes seen with acute blood loss. However, in the setting of ethanol intoxication and trauma, one must be vigilant for associated occult hemorrhage and not reflexively assign tachycardia to being a result of intoxication alone.

The utility of orthostatic vital signs in children has been questioned. Horam and Roscelli found that healthy adolescents had heart rate changes of 21.5 ± 21.2 beats/min with orthostatic measurements made after 2 minutes of standing. [106] They found similar variation in the systolic blood pressure change (+19 to -17 mm Hg). Bergman and colleagues found that 25% of clinically normovolemic children had a postural increase in pulse of >20 beats/min and 11% had a postural fall in systolic blood pressure of >20 mm Hg. [107] However, children with fever and diarrhea were included in this "normal" study group. Another study comparing mildly dehydrated children with normal children found a significant difference in the orthostatic rise in pulse between the two groups. [108] Using near-syncope or a change in heart rate of >25 beats/min, orthostatic vital signs have a specificity of 95%, a sensitivity of 75%, and a predictive value of 92% in detecting mild clinical dehydration in children. [108] No difference in orthostatic blood pressure was found between normal and dehydrated children. Considering resting tachycardia as a positive sign of dehydration increased the predictive value of the test. The investigators concluded that in the appropriate clinical setting, an orthostatic increase in pulse >25 beats/min constitutes a positive tilt test, and an orthostatic pulse increase of <20 beats/min constitutes a negative test for hypovolemia. [108]

Another complicating factor in interpreting orthostatic vital signs is the development of *paradoxical bradycardia* in the presence of blood loss. Bradycardia in the face of hemorrhage has generally been considered a preterminal finding of irreversible shock, but bradycardia has been documented in hypovolemic, yet conscious, trauma patients. Several of the early studies [82] [83] noted that when orthostatic syncope occurred, it was accompanied by hypotension and often bradycardia. Many central nervous system factors can contribute to *vagal-mediated* syncope in ED patients with acute traumatic blood loss. These factors include pain, the sight of blood, stress, and nausea. Several investigators  have described women with hemoperitoneum secondary to ruptured

ectopic pregnancy who were hypotensive but did not have tachycardia. Jansen reviewed other cases of this relative bradycardia that occurred in hypotensive patients with acute intraperitoneal bleeding and postulated a parasympathetic mechanism triggered by the presence of free blood in the peritoneal cavity. [111] This bradycardia may be reversed with atropine, but *aggressive fluid replacement is the treatment of choice,* because anecdotal reports mention serious ventricular arrhythmias when atropine was used in this setting. [112] Paradoxical bradycardia has also been described in patients with abdominal or thoracic trauma or arterial bleeding from extremity wounds. [112] This paradoxical bradycardia may be more frequently associated with rapid and massive bleeding, whereas patients with a more gradual blood loss tend to have a more typical tachycardiac response. When the patient's clinical presentation is consistent with volume loss or shock, the clinician should not allow the absence of tachycardia to change the assessment.

## Indications and Contraindications

When the volume status of a patient is assessed by use of orthostatic vital signs, several points should be remembered. Many factors influence orthostatic blood pressure including age, preexisting medical conditions, the use of medication, and autonomic dysfunction (see Table 70-6) (Table Not Available) . Data relating the effect of *blood loss* to orthostatic vital signs are limited to phlebotomized healthy volunteers. Great care must be used when extrapolating these data to patients with anemia, dehydration, or painful trauma. The clinician must consider the clinical condition of the patient as well as the orthostatic vital signs in evaluating a patient for volume depletion.

Orthostatic vital signs are indicated as part of the evaluation of any patient with known or suspected volume loss or a history of syncope, except in the presence of the following contraindications: The use of orthostatic vital signs is unnecessary and dangerous in a patient with supine hypotension or the clinical syndrome of shock. Orthostatic vital sign evaluation also is contraindicated in patients with a severely altered mental status, in the setting of possible spinal injuries, and in patients with lower extremity or pelvic fractures.

The use of medications that block the normal vasomotor and chronotropic response to orthostatic tests also represents a contraindication to use of this test for assessment of volume status. However, when the patient's volume status is believed to be adequate and the clinician seeks to determine if specific medications may have affected the patient's ability to respond to postural changes, the test may be useful. In the latter situation, the primary finding may be the feeling of near-syncope with little or no change in vital signs.

Orthostatic vital signs are often used to assess a patient's response to therapy. In patients receiving intravenous rehydration therapy, serial orthostatic vital signs are widely used to judge the end point to therapy prior to release. Johnson and colleagues used this technique to demonstrate that the individual orthostatic vital signs response to saline infusion in women with hyperemesis gravidarum was associated with other measures of rehydration, including weight gain and decreased urine specific gravity. [113] Although the individual improvement in orthostatic vital signs in response to rehydration

was of clinical value, the presenting orthostatic vital signs were considered insufficient for use as the sole indicator of clinical dehydration in this population.

## Technique

Once the decision to obtain orthostatic vital signs has been made, the blood pressure and pulse are recorded after the patient has been in the supine position for 2 to 3 minutes (see Table 70-5) . The patient should rest quietly. No painful or invasive procedures should be performed during the test. Anxiety, fever, and other causes of resting tachycardia may make the test uninterpretable. [107]

The patient is then asked to stand, and the examiner should be prepared to assist the patient if severe symptoms or syncope develops. A supine-to-standing test is more accurate than a supine-to-sitting evaluation. Knopp and coworkers found that the supine-to-sitting test was not reliable for detecting 1000 mL of blood loss (55% false-negative results). [85] If severe symptoms develop (defined as syncope or extreme dizziness requiring the patient to lie down) on standing, the test is considered positive and should be terminated. If the patient is not symptomatic, the blood pressure and pulse should be recorded after the patient has been standing for 1 minute. This interval resulted in the greatest difference between the control and 1000-mL phlebotomy groups in the study by Knopp and colleagues. [85]

## Complications

The possible complications of orthostatic vital sign assessment can be avoided if the aforementioned contraindications and precautions are remembered. Complications include syncope with a resulting fall and injury and the possibility of exacerbating an existing fracture or spinal cord injury.

## Interpretation

Criteria for positive orthostatic vital sign changes are either tachycardia greater than a specific threshold (see below) or symptoms of cerebral hypoperfusion (e.g., near-syncope). Although blood pressure changes may be seen, they are too variable to be used as an indicator of blood volume loss. Although specific population-based thresholds for pulse rate and blood pressure changes have some value for identifying patients at high risk for significant volume loss, great individual variability limits the use of this technique as a screening test. That is, a volume loss of 500 mL (and occasionally more) may be associated with a negative orthostatic vital sign assessment (see below). [114] However, the use of serial measurements to ascertain the response to therapy of patients considered at risk for volume loss appears to have clinical utility. [113]

In the setting of possible blood loss, if the patient has a pulse rise of 30 beats/min or severe symptoms and if other complicating factors have been excluded, then blood loss is highly likely (2% false-positive rate). [85] The presence of a negative test indicates only that an acute blood loss of 1000 mL is unlikely (2% false-negative rate); a blood loss of

500 mL cannot be excluded (43% false-negative rate).

In children, postural near-syncope or an orthostatic pulse increase of 25 beats/min may be a predictor of mild dehydration. The accuracy of these criteria is increased by the addition of resting tachycardia. [108] However, one cannot quantify the amount of volume depletion with this test in children.

Criteria for significant orthostatic blood pressure changes cannot be definitively set for the following reasons: (1) in the study by Knopp and coworkers, a lack of correlation between blood pressure in the phlebotomy and control groups was seen [85] ; (2) a large variability in postural blood pressures has been found in the adult ED population ; (3) results of studies using passive tilt tables cannot be extrapolated to the bedside use of orthostatic vital signs; (4) studies using healthy patients with acute blood loss may not reflect the orthostatic changes that are seen in the elderly or those with chronic bleeding, dehydration, and various other medical problems; and (5) many of the studies of orthostatic changes never used a gold standard (measurement of actual volume loss) in their determinations. Because of the lack of agreement about the degree of postural blood pressure change that constitutes a positive test result, the most reasonable definition may be any postural fall in blood pressure that results in symptoms of cerebral hypoperfusion.

# CAPILLARY REFILL

The capillary refill test is a measurement of the time interval from the release of nailbed or soft-tissue pressure (sufficient to blanch the nailbed or superficial soft tissue) until the return to normal coloration. Delayed capillary refill is an indication of reduced skin turgor, often as a result of volume depletion. Measurement of the capillary refill time interval appears to be somewhat accurate in children, but its accuracy in assessing dehydration and reduced perfusion in adults is highly suspect. [84] [119]

**Physiology**

Skin elasticity is the characteristic of skin that allows it to spring back into its original shape after it has been deformed. One sign of decreased elasticity is skin tenting. The normal fullness of blood vessels or capillaries is referred to as *turgor vitalis*. The presence of normal skin turgor is a sign of adequate circulatory perfusion, because the speed of refilling of the capillary bed after compression is responsible for the return of color to the skin. [26]

**Indications and Contraindications**

There are no specific contraindications to performing capillary refill measurements in ED patients. However, the capillary refill time interval should not be obtained in a dependent extremity, a recently burned or injured extremity, or at the site of an infection or acute injury. Frequent monitoring of capillary refill is useful in accessing responses to rapid fluid resuscitation in children. Because capillary refill is available without additional equipment and takes only a few seconds to perform, it is a useful bedside assessment

of perfusion and dehydration.

**Procedure**

The preferred sites for performing capillary refill are the nailbed, the thenar surface of the palm, and the heel. The current standards are best developed for capillary refill obtained at the nailbed. [119] Regardless of the site chosen, the extremities should be positioned at about the level of the right atrium. The minimum pressure necessary to produce blanching yields the most reproducible values. Timing can be performed with a stop watch or simply by counting out "one-thousand-one, one-thousand-two" for approximation of the interval. A repeated measurement should be obtained at the same location as the initial test, because alternate sites may have different capillary refill times.

**Interpretation**

The normal capillary refill interval increases with age, degree of dehydration, and degree of hypoperfusion. Hypothermia, hyponatremia, congestive heart failure, malnutrition, and edema all increase the capillary refill interval.

The main difficulty in interpreting the capillary refill interval is that normal values in healthy patients fall into a wide range. In 30 normal infants from 2 to 24 months of age, the mean capillary refill interval was 0.8 ± 0.3 seconds. Measurements obtained from the nailbed were more reproducible than those from the heel. Dehydration was strongly correlated with a capillary refill time of >3 seconds, and suggested a fluid deficit of >100 mL/kg. [119]

The role of serial capillary refill interval measurements for assessing the response to rehydration in adults is unknown.

However, the test does not appear to be useful for assessing acute blood volume loss. In adults, the capillary refill interval was found to be less sensitive and less specific than orthostatic vital signs for detecting a 450 mL blood loss during blood donation.

# TEMPERATURE

Accurate measurement of body temperature is an essential part of clinical medicine. When taken in the context of other vital signs, abnormalities of core body temperature are excellent guides to the severity of illness.

Detection of abnormal body temperature facilitates proper diagnosis and evaluation of presenting complaints. The inability of any patient to maintain normal body temperature is indicative of a vast number of potentially serious disorders, including infections, neoplasms, shock, toxic reactions, and environmental exposures. [120] [123] Fever in neutropenic, immunocompromised, and intravenous drug-abusing patients may be more reliable than laboratory tests or physician assessment in diagnosing serious illness. [123] Infants are particularly sensitive to thermal stress and may demonstrate lower body

temperatures during asphyxia or necrotizing enterocolitis.  Normalization of body temperature following intervention may have important prognostic and therapeutic implications. [123]

## Physiology

Under normal conditions, the temperature of deep central body tissues (i.e., core temperature) remains within ±0.6 °C or ±1.08 °F. [127] [128] Core body temperature can be maintained within a narrow range while environmental temperature varies from as much as 13 to 60 °C (55 to 140 °F), [129] whereas surface temperature rises and falls with environmental and other influences. Maintenance of normal body temperature requires a balance of heat production and heat loss. Heat loss occurs by radiation, conduction, and evaporation. Approximately 60%, 18%, and 22% of heat loss, respectively, occurs by these methods. Heat loss is increased by wind, water, and lack of insulation (e.g., clothing). Sweating, vasodilation, and decreased heat production serve to decrease temperature, whereas piloerection, vasoconstriction, and increased heat production serve to increase body temperature. Heat production is increased by shivering, fat catabolism, and increased thyroid hormone production.

Temperature control occurs by feedback mechanisms operating through the preoptic area of the hypothalamus. Heat-sensitive neurons in this area increase their rate of firing during experimental heating. Receptors in the skin, spinal cord, abdominal viscera, and central veins primarily detect cold and provide feedback to the hypothalamus, which signals an increase in heat production. Stimuli that change the core body temperature result in reflex changes in mechanisms that increase either heat loss or production. [130]

## Indications and Contraindications

Clinicians generally measure body temperature to know if the patient's body temperature is outside the normal range and as an indication of pathologic conditions that can affect core body temperature. Because actual core body temperature measurement requires the placement of invasive monitors, such as an esophageal or a pulmonary artery probe, clinicians commonly use estimates of core body temperature, which conveniently and safely assess abnormalities of core temperature. Unfortunately, all noncore body sites and methods have inherent accuracy limitations, which physicians have come to accept in assessing most patients.

Oral temperature measurement requires a cooperative adult or child, generally older than 5 years. Patients who are grossly uncooperative, hemodynamically unstable, septic, or in respiratory distress require another method of temperature measurement. This group includes children <5 years and patients who are intubated.

Special techniques of measuring actual core body temperature may be indicated in certain patients in the ED, such as those with profound hypothermia, frostbite, or hyperthermia. Measurement of core body temperature is indicated in these individuals because it serves as an accurate measure of treatment effects.

## Measurement Sites

### Core Body Temperature

It has been demonstrated that the following sites accurately reflect core body temperature and its changes: esophageal (in the distal third of the esophagus), the tympanic membrane (using *direct thermistor contact* at the anterior inferior quadrant of the tympanic membrane), [131] [132] and the pulmonary artery temperature. [133]

Other sites may represent core body temperature under certain conditions. For example (1) the rectum, when the temperature is obtained at least 8 cm from the anus using an indwelling thermistor and the body temperature is relatively constant, and (2) the bladder when measured with an indwelling thermistor. [89] Data on core temperature in pediatric patients is limited and it is unclear if bladder, rectal, or oral temperature is a good measurement of core body temperature in children. [134]

### Peripheral Body Sites Approximating Core Body Temperature

Oral temperature measurement with a digital electronic probe is commonly used for ambulatory patients. [135] Advantages include convenience, timing, safety, and availability. Disadvantages include a variety of factors that have an impact on clinical accuracy and sensitivity. Electronic oral temperature probes must be covered with disposable covers, although these have been shown not to be completely effective in preventing probe contamination with microorganisms. [136] Although there are no absolute contraindications for oral temperature assessment, patients with factors shown to produce unreliable results (see below) require temperature measurement at other sites.

Rectal temperature is often considered the gold standard of body temperature for ambulatory patients and is often routine for children younger than 3 years. [140] Advantages include accuracy, sensitivity, and availability. One intensive care unit study found rectal probe temperatures to demonstrate limited variability or bias when compared with pulmonary artery temperatures. [141] Disadvantages include longer intervals for measurement, safety concerns, and inconvenience. Neutropenia and recent rectal surgery represent relative contraindications to rectal temperature measurement. [142] It may produce autonomic changes in patients with acute myocardial infarction.

Body temperature measured as a function of infrared radiation (IR) detected from the ear, including the auditory canal and tympanic membrane, is easy to use, hygienic, convenient, and quick. [144] The noncontact IR ear thermometer readings correlate well with other methods of body temperature measurement under a variety of clinical conditions. [145] Concerns have been raised over the accuracy of these thermometers in screening for fever in children <3 years of age.  Romano and colleagues found the Thermoscan Pro-1 IR thermometer to perform similar to rectal probe temperature, but the FirstTemp IR thermometer displayed considerably more variability. [141]

Axillary and tactile temperature assessment have been demonstrated to be unreliable and insensitive and should not be used as screening methods for core temperature abnormalities in the ED. Similarly, the use of liquid crystal chemophototropic strips applied to the skin of the forehead are not accurate for single measurement or fever screening. Single-use Tempa-DOT thermometers, which show increasing temperature dot darkening with increasing temperature, have been adopted by many EDs. The sensitivity of these thermometers for fever identification remains to be determined.

## Equipment

Mercury-in-glass thermometers remain popular despite requiring longer equilibration times and having cumbersome cleansing requirements. Electronic methods of temperature measurement are based on the thermocouple principle. Modern electronic thermometers signal once extrapolation of the temperature-time curve occurs. [153] Current in vitro standards call for an accuracy of ± 0.1 °C (± 0.18 °F) over the range of 37 to 39 °C (98.6 to 102.2 °F). [154] Thermistor probes (i.e., small thermocouples with instantaneous readouts) for esophageal and vascular temperature measurement provide continuous temperature readouts when attached to a potentiometer. [5] Thermistor products are available for esophageal, bladder, and rectal probes (Mallinckrodt Medical, Inc, St. Louis; or Yellow Springs Instruments, Yellow Springs, Ohio) with appropriate readout monitors.

Noncontact IR ear thermometers were introduced in 1985. These thermometers were initially used only in hospitals, but they are now sold over the counter for home use. The IR ear thermometers work by incorporating an IR sensor in the field of view of the IR emissions from the ear. Ear IR thermometers generally detect naturally occurring IR emissions over a brief time period, generally <1 sec. The emissions are converted to an electrical analog signal, which is digitized and analyzed by a microprocessor with resultant digital display. [155] The primary determinant of radiation emission is the temperature of blood perfusing this area, and the warmest spot in the auditory canal is the tympanic membrane. Thus, current IR ear thermometers are operator-dependent in the same fashion that otoscopy requires proper positioning to enable the examiner to "see" the tympanic membrane. [156]

A variety of IR ear thermometers are available commercially (Table 70-7) with varying operating temperature ranges, features, and reported accuracy. Clinical data assessing relative performance of the many commercial devices are limited. In one study comparing many of these IR thermometers, the Pro-1 and FirstTemp gave significantly higher readings. [156]

## Procedure

Temperature measurement begins with body site selection. Consideration should be given to the accuracy of using a site to reflect core temperature, the site sensitivity to temperature

** Temperature value, which is added to unadjusted infrared ear thermometer reading to estimate body temperature at specific sites.

changes, convenience, time required, safety, and site availability.

When reusable probes are used, the thermometer end should be covered with a probe cover. Temperature measurement continues with insertion of the temperature probe and probe equilibration with the temperature of local body tissues. Proper placement of temperature probes significantly influences results for oral, rectal, esophageal, and vascular temperatures.

Sublingual oral temperatures should be obtained in either posterior sublingual pocket, with the mouth closed. [158] The patient should be sitting upright or lying, holding the base of the probe with one hand. [137] Rectal temperatures require removal of clothing, lubrication of the probe, and gloving of personnel, and should be obtained with the patient relaxed in the left or right lateral decubitus position. Gentle insertion to 3 to 5 cm should ensure accurate, atraumatic results. [127]

Axillary temperatures are frequently used for neonatal patients in incubators because of convenience. The technique is not indicated unless other sites are unavailable.

Although not commonly used, temperature measurement in a freshly voided urine specimen can validate temperature measurement at other body sites. A nomogram of expected urinary temperatures has been derived from measurements of oral and urinary temperatures in 55 subjects (Fig. 70-10) (Figure Not Available) . [161]

Placement of an esophageal catheter for measurement of core body temperature is similar to placement of a nasogastric or orogastric tube (see Chapter 43) . In this case, the distal tip of the esophageal catheter contains a thermistor to measure body temperature. In normal adults, the catheter is inserted approximately 34 cm deep into the esophagus, with the objective of locating the probe tip at the level at which the esophagus is between the aorta and the left atrium. The catheter is connected to a potentiometer and allowed to equilibrate briefly before a body temperature reading is taken.

For pulmonary artery (PA) catheter assessment of core body temperature, a PA or thermistor-tipped catheter is placed into the PA. A detailed discussion of the placement of PA catheters is beyond the scope of this chapter. Once a PA catheter is in the correct position, the temperature value may be obtained by using the potentiometer attached to the distal thermistor. Because of the risks associated with catheter placement, PA temperatures are generally reserved for patients with another clinical indication for PA pressure monitoring.

**Complications**

Complications associated with axillary, oral, ear IR, and liquid crystal thermometers are rare or unreported. Tympanic membrane perforation and pain have been reported as complications of thermistor probe placement in the auditory canal. Complications associated with rectal temperature measurement are extremely rare, but include rectal perforation, pneumoperitoneum, bacteremia, dysrhythmias, and syncope. Falsely low, but supranormal, rectal temperature measurements may be seen during shock. [162] Rectal temperatures also may lag behind core temperature changes.

Complications associated with esophageal temperature measurement include those associated with placement of an orogastric or nasogastric tube (see Chapter 43) . Confirmation of accurate placement can be verified with a chest radiogram. In addition, spurious temperatures may arise from an improperly calibrated potentiometer, a damaged thermistor, a proximal esophageal location, and during mechanical ventilation or thoracotomy.

**Interpretation**

Normal values for body temperature are affected by the following variables: (1) site and methods used for measurement, (2) perfusion, (3) environmental exposure, (4) pregnancy, (4) activity level, and (5) time of day. Clinicians must interpret body temperature with knowledge of the range of normal values at the intended site of measurement. Although the core body temperature remains nearly constant (37.0 ± 0.6 °C or 98.6 ± 0.18 °F), the surface temperature rises and falls with changes in ambient temperature, exercise, and time of day. The definition of fever varies by the site of

measurement and is defined by a temperature greater than 2 SD above the mean. Fever has been defined as an oral temperature 37.8 °C (100.0 °F), [163] a rectal

temperature 38.0 °C (100.4 °F), [164] or an IR ear temperature 37.6 °C (99.6 °F). [165] Hypothermia has been defined as a core body temperature <35 °C (<95 °F), whereas hyperthermia has been defined as a core body temperature >41 °C (>105.8 °F), with accompanying symptoms and signs. [166] A useful nomogram for conversion of degrees centigrade to degrees Fahrenheit is provided in Figure 70-11 .

Temperature probes that require the transfer of heat energy from local tissues to the temperature probe require a period of equilibration and reliable tissue contact at the intended body site. Acceptable equilibration times for mercury-in-glass thermometers for oral, rectal, and axillary sites are 7, 3, and 10 minutes, respectively. Used in a predictive mode, electronic digital thermometers generally require 30 seconds for oral or rectal temperature equilibration. The predictive mode uses temperature changes vs time to predict an equilibration temperature.

Normal ranges and suggested febrile thresholds for common body sites and methods should be considered in the interpretation of temperature values (Table 70-8) . The interpretation of temperature measurements during clinical assessment must consider the use of antipyretics, level of activity, pregnancy, environmental exposure, and patient age. The duration of antipyresis with acetaminophen or aspirin is 3.5 to 4 hours. When both drugs are given together, the duration of action may be extended up to 6 hours. [167] Body temperature is increased during sustained exercise, during pregnancy and the luteal phase of the menstrual cycle, and in the later afternoon by diurnal variation. Body temperature is generally reduced by advanced age.

The interpretation of temperatures obtained with pulmonary artery or esophageal thermistors is generally straightforward.

* Temperature obtained with a properly positioned pulmonary artery, esophageal, or tympanic membrane thermistor.
For unadjusted ear temperature using Thermoscan Pro-1 (Thermoscan, Inc, San Diego)

Comparison of measured values to the expected normal range should be performed to determine if the patient has an abnormal core body temperature. In addition to improper placement of the thermistor, sources of temperature error include an improperly calibrated potentiometer or thermistor, damaged thermistor, or improper placement. The biomedical staff at the institution should periodically verify readout and calibration of these instruments.

Oral temperature measurements are affected by ingestion of hot or cold liquids, [142] tachypnea, [168] and cold ambient air. [169] Smoking appears to result in little change in oral temperatures. [142] [170] Therefore, before taking an oral temperature, the examiner should inquire about these features and possibly delay taking the temperature. Also, Erickson found a 2.7 °C (4.9 °F) reduction of oral temperature measurement when the probe was placed under the tip of the tongue instead of under the posterior sublingual pocket. [137] When using a mercury-glass thermometer, optimum placement time was found to be 7 minutes for oral temperatures in children. [171]

Axillary temperatures obtained in 108 children by Kresch had a sensitivity of only 33% and a specificity of 98% for fever. [149] Ogren obtained similar results using an electronic thermometer in the axilla. [172] Hence, axillary temperatures should not be used to screen for fever.

When rapid changes in body temperature are occurring, oral and tympanic temperature measurements appear to be more reliable than rectal temperature. In 20 adults examined during open-heart surgery, oral temperatures showed a better correlation with blood temperature during rapid cooling and rewarming. [159] In 12 adults, the average rectal temperature lag during warming was 5.3 minutes during water immersion and 3.8 minutes during exercise. [173] Sublingual (oral) temperature delay (1.3 and 0.9 minutes for the two experiments, respectively) was less than auditory canal delay (1.1 and 4.1 minutes, respectively) in temperature response.

Infrequently, ED patients require constant monitoring of temperature (e.g., in cases of hypothermia or hyperthermia). This can usually be performed using a bladder or esophageal probe attached to a potentiometer. Patients with indwelling central venous or pulmonary arterial catheters may have electronic thermistors inserted into the central circulation to measure core body temperature. As noted above, rectal temperature measurements are less desirable for monitoring patients undergoing rapid core temperature changes. Periodic IR tympanic temperature monitoring may represent one useful option in the hypothermic patient.

The interpretation of ear IR temperatures requires a knowledge of the mode of

thermometer operation and ambient temperature. Cerumen occlusion of the ear canal may produce a falsely low reading. [175] Most IR ear thermometers allow the user to select a mode that allows prediction of the equivalent temperature at other body sites. IR ear thermometers appear moderately sensitive for fever. [146] [147] If these devices are used, the clinician must be aware of the potential for a falsely low temperature and, when in doubt, the measurement should be repeated with a more standard method.

## CONCLUSION

Vital signs must always be interpreted in relationship to each other to obtain a more complete clinical picture. All vital signs are subject to errors in measurement and therefore must be verified when the initial result does not match the clinical presentation. Abnormal vital signs may lead the clinician to a diagnosis, and abnormalities should be explained within the context of the patient's illness.

# Chapter 71 - Procedures Pertaining to Hypothermia

**David Doezema, David P. Sklar**

The spectacular reports of survival after up to 66 minutes of cold water immersion fuel our fascination with hypothermia. [1] [2] The severely hypothermic patient appears at times to lie suspended somewhere between life and death. Generally, physicians continue cardiopulmonary resuscitation (CPR) long past the time other patients would be declared dead, occasionally succeeding in resuscitating a hypothermic patient, who later leaves the hospital neurologically intact.  Unfortunately, the medical literature on treatment of hypothermia is generally characterized by anecdotal reports, patient selection bias, and uncontrolled case series. However, because the condition is relatively rare, this information must be used to augment the individual physician's limited clinical experience.

This chapter critically reviews approaches and procedures appropriate to the management of several categories of hypothermic patients. The recommendations combine treatment efficacy with safety. Before describing procedures and making recommendations, essential terms are defined and the pathophysiology of hypothermia is briefly reviewed.

## DEFINITIONS

*Accidental hypothermia* (AH) has been defined as an unintentionally induced decrease in the core (vital organ) temperature below 35 °C (95 °F). [5] Victims of hypothermia can be separated into the following categories: *mild hypothermia*, 35 to 33 °C (95.0 to 91.4 °F); *moderate hypothermia*, <33 to 28 °C (<91.4 to 82.4 °F); and *severe hypothermia*, <28 to 9 °C (<82.4 to 48.2 °F). Other factors that may be useful in separating groups of patients with AH include the presence of underlying illness,  altered neurologic state on arrival, hypotension, and the need for out-of-hospital CPR. [11] A hypothermia outcome score has been developed that incorporates some of these factors and may permit comparison of outcomes for patient groups treated with different modalities. [11]

Because signs and symptoms may be misleading, mild to moderate hypothermia may easily be overlooked in the emergency department (ED). A common error is failure to routinely obtain a core temperature on all patients at risk. Presenting symptoms such as confusion in the elderly and combativeness in the intoxicated patient may not initially be recognized as symptoms of hypothermia. *Hypothermic patients frequently will not feel cold or shiver*, and a "paradoxical undressing" has been described in confused patients who apparently have the sensation of heat at lowered body temperatures.

## CORE TEMPERATURE MEASUREMENT

Accurate temperature measurement is important to guide diagnostic and therapeutic decisions. Any thermometer that does not record temperatures in the hypothermic range is *inappropriate* for evaluating significant hypothermia. Standard glass/mercury

thermometers generally cannot record temperatures of <34 °C (93.2 °F), although some models are available to record temperatures as low as 24 °C (75.2 °F) (Dynamed, Inc, Carlsbad, Calif). An electronic probe and accompanying calibrated thermometer (Fig. 71-1) (Figure Not Available) is recommended when monitoring this vital sign. A detailed description of core temperature measurement is provided in Chapter 70 .

Core temperature can be estimated with a rectal probe, although rectal temperature often lags behind core temperature. Esophageal probes may be used, although they may be affected by warm humidified air therapy, which is commonly used in severe hypothermia. Other possible sites for temperature measurement include the tympanic membrane and the urinary bladder. [12] Fresh urine temperature can closely approximate core temperature. [13] For monitoring purposes, rectal or bladder probe use is preferred. Although there are excellent correlations between tympanic probe and core temperatures, the role of infrared tympanic temperatures for monitoring the temperature of hypothermic patients is unknown (see Chapter 70) . When a rectal probe is used, it should be inserted at least 10 cm beyond the anal sphincter and its position frequently verified. One should remember that temperature gradients exist in the human body and consistency of monitoring at one or more sites is mandatory. A chart and formula that convert centigrade to Fahrenheit temperatures will assist the clinician in assessing the severity of hypothermia (Fig. 71-2) .

## PATHOPHYSIOLOGY

*Accidental hypothermia* occurs when the body's heat-producing mechanisms cannot keep up with heat loss. Heat production occurs through basal metabolic functions and muscular activity. Heat production can be increased from the basal rate of 100 to 500 kcal/hour by shivering.  Heat loss occurs through radiation, conduction, evaporation, and convection. Vasoconstriction and shunting of blood can preserve core temperature at the expense of a further temperature decrease of the skin. As the core body temperature drops

below 33 °C (91.4 °F), the patient becomes confused and ataxic. [15] Shivering stops at about 32 °C (89.6 °F). Atrial fibrillation occurs frequently as the temperature continues to drop, [16] and the patient loses consciousness. [15] A J-wave in the electrocardiogram often appears before ventricular fibrillation (Fig. 71-3) (Figure Not Available) . Ventricular fibrillation may occur below 29 °C (84.2 °F) and becomes common as the core drops to 25 °C (77 °F). [15] The electroencephalogram flattens at 19 to 20 °C (66.2 to 68 °F), [17] and asystole commonly occurs at 18 °C (64.4 °F) but has been seen at higher temperatures. The lowest recorded temperature for a survivor of AH is 16 °C (60.8 °F).

## INITIAL EVALUATION AND STABILIZATION OF THE HYPOTHERMIC PATIENT

Overall, one must realize that with the reduction of core and cellular temperatures, it is not surprising to find a parallel reduction in all parameters of vital activity, because the enzymatic rate of metabolism itself decreases two to three times with each 10 °C (18

°F) drop and cerebral blood flow decreases 6 to 7% per 1 °C (1.8 °F) drop. Profound hypothermia results in coma, hyporeflexia, fixed and dilated pupils, severe bradycardia, and often unobtainable blood pressure. In severe hypothermia, a pulse may not be palpable and blood pressure measurement may require the use of a Doppler device (see Chapter 70) . Electrocardiographic monitoring provides rate and rhythm status. All patients who have more than minimal impairment require frequent determination of their oxygenation, ventilation, and acid-base status by means of arterial blood analysis.

All patients should have an adequate-bore IV line established for fluid, glucose, and possible drug administration. Most hypothermic patients are *dehydrated*, because fluid intake is reduced and cold causes a diuresis; maintenance IV fluids should be given routinely. Warming of all IV fluids to 40 to 42 °C (104 to 107.6 °F) is reasonable, but the usual volumes administered will not contribute significant calories of heat.

With a mild to moderate reduction in core temperature, the level of mentation correlates with the severity of the AH or associated illness or both. In alcoholics or diabetics, coma at higher core temperatures may be due to unsuspected hypoglycemia, and a trial of glucose by bolus infusion is justified. In the 22 cases of AH reviewed by Fitzgerald, all except 2 patients were alcoholics. [19] The serum glucose level was <50 mg/dL in 41% (9 patients). This study noted glycosuria in 2 patients, even when low serum glucose values were evident, and described a renal tubular glycosuria in AH. Such glycosuria may worsen or cause hypoglycemia; *hence, glycosuria in AH is no guarantee of an adequate serum glucose concentration*. This supports the routine use of supplemental IV glucose unless a normal serum glucose value can be quickly ensured. Also, IV thiamine (100 mg) and a trial dose of 2 mg IV naloxone (Narcan) should be given to *all obtunded victims* to treat potential thiamine deficiency and narcotic overdose, respectively. Although failure to rewarm spontaneously has been noted in victims with hypothyroidism and other endocrine deficiencies, the use of thyroid hormones and corticosteroids is reserved for those patients with suspected thyroid and adrenal insufficiency, respectively.

Antibiotics are not routinely indicated in uncomplicated mild hypothermia. Although there is no consensus or clinical proof on the value of routine antibiotic therapy in severe AH, the inaccuracy of historical, laboratory, and clinical data in distinguishing the infected from the noninfected hypothermic patient has prompted some authors to advocate the routine empirical initiation of broad-spectrum antibiotic therapy on admission of severely hypothermic patients.

## TREATMENT OVERVIEW

The treatment of AH involves support of basic bodily functions (i.e., airway, breathing, and circulation) while preventing further heat loss and augmenting heat production. Although AH may be lethal, the speed and manner of warming the patient may also be harmful by causing or worsening hypotension, a paradoxical decrease in core temperature, [20] [21] and cardiac dysrhythmias. [22] Other complications may include bleeding [23] and infection of surgical incisions. Invasive therapy should be carefully considered and individualized to the severity of the hypothermia and the condition of the patient, and one should avoid the temptation to *overtreat and overmonitor with invasive*

*techniques the otherwise stable hypothermic patient.*

As opposed to the need for rapid temperature correction with heat stroke, a condition in which it is essential to lower the core temperature as rapidly as possible, a more gradual and conservative approach is generally advocated for rewarming the mildly to moderately *hypothermic* patient. Although the ideal rewarming rate is unknown and clearly varies with each case, it is logical to be content with a 0.5 to 2.0 °C (0.9 to 3.6 °F)/hour rise in temperature *in the otherwise stable patient* (Table 71-1) (Table Not Available) . Patients who slowly become hypothermic over hours or days may not tolerate nor require invasive procedures or aggressive therapy.

The patient with severe underlying problems such as hypoglycemia, hyperglycemia, sepsis, adrenal crisis, drug overdose, or hypothyroidism should be treated appropriately for those conditions as well as aggressively for hypothermia, because long-term outcome may depend more on treatment of the underlying illness than the hypothermia. [24] [25]

For patients with AH that is mild, removal of wet clothing followed by *passive external rewarming* with blankets generally suffices. Passive external warming results after the addition of increased insulation, preventing further heat loss so that the body's own mechanisms for heat production can restore normal temperature. The technique is simple; however, the patient must be capable of generating enough body heat for this method to be successful. Patients who cannot shiver, patients who are hypotensive, or patients who are intoxicated or malnourished may not have this capability; however, most patients with mild hypothermia can be warmed gradually with passive rewarming techniques (Fig. 71-4) . Survival rates using passive external rewarming have ranged from 55 to 100%.

For patients in the moderate or severe category of hypothermia, a more aggressive approach may be warranted. The options available are active external rewarming and active core rewarming. Active core rewarming techniques can be further divided into less invasive and more invasive techniques. Generally, the aggressiveness of therapy depends more on the patient's underlying health, hemodynamic status, and response to initial therapy than the initial temperature.

## Active External Rewarming

The application of heat to the skin of the hypothermic patient has been termed *active external rewarming.*

### Indications

Although there is some suggestion that active external rewarming of profoundly hypothermic patients by immersion may be associated with an increase in mortality over other treatments, [11] [20] more recent studies have suggested that this technique is highly effective for mild hypothermia. [28] Other forms of active external rewarming are increasingly used in the ED as adjunctive care of moderately hypothermic, otherwise

healthy individuals. Vasoconstriction limits the ability to increase core temperature using techniques that primarily warm the skin. [29]

Finally, in settings where more aggressive warming techniques are precluded owing to lack of equipment or personnel, active external rewarming (e.g., with body-to-body contact) may be the only option available to the rescuer. However, the rewarming contribution of body-to-body contact appears limited. [30]

**Equipment**

Traditionally, immersion therapy has used a heated (40 to 42 °C) water tank of the type present in most burn units. Generally, all of the hypothermic patient except the extremities and head are immersed (Fig. 71-5) , although immersion of the extremities may hasten rewarming. [28] Alternatively, conduction warming is performed using warm water-filled heat exchange blankets (e.g., Blanketrol; Cincinnati Sub-Zero Products, Cincinnati). A forced warm air convection system (Bair Hugger; Augustine Medical, Eden Prairie, Minn) has been used for postsurgical rewarming [31] and holds promise for AH treatment.

**Technique**

Because profound fluid shifts can occur with conduction warming, the patient should receive supplemental IV fluid [32] that has been warmed to 40 °C, given at a rate sufficient to generate a urinary output of 0.5 to 1.0 mL/kg/hour. An initial fluid bolus of 500 mL of 5% dextrose and normal saline may be beneficial. (Note that blood pressure is not an accurate way to gauge fluid resuscitation, because serious hypothermia is always accompanied by "physiologic" hypotension.) Because patients requiring mechanical ventilation have rarely been subjected to tank immersion, it cannot be recommended for hypothermic patients who require intubation. Rewarming rates ranging from 0.9 to 8.8 °C (1.6 to 15.8 °F)/hour have been reported with immersion therapy. [20] [33]

A heat exchange blanket allows the patient to receive other treatments that may be difficult or impossible to carry out in a tub, such as defibrillation, CPR, or more invasive warming techniques. With this latter form of conduction heating, the heating blanket and overlying cloth sheet is placed under the patient. The blanket temperature is set at 40 to 42 °C, and the measures described under passive rewarming techniques (see Fig. 71-4) are initiated.

Forced-air rewarming (convection) uses a blanket cradle to create an environment through which heated air is blown. Access to the patient is quite good with this system in that the overlying blankets can be raised temporarily to evaluate the patient or perform procedures. One study found this approach superior to a heating blanket. [31] Experience with mild immersion-induced hypothermia in volunteers suggests that the forced-air technique warms at a rate comparable to vigorous shivering, but with less metabolic stress and less afterdrop. [34]

**Complications**

There is concern that surface warming with accompanying vasodilation may produce a relative hypovolemia in the hypothermic patient. A further decrease in the core temperature may occur as the blood courses through still-cold extremities and returns to the heart. In the study by Miller and coworkers, survival with this method was only 36%. [20] However, others have described a 95% survival rate. [33] One study of human volunteers with mild to moderate hypothermia comparing external rewarming versus inhalation with warm air demonstrated superior warming rates using external rewarming without adverse effect. [35]

Importantly, CPR and other advanced cardiac therapy and monitoring are impossible with immersion rewarming. Until studied further, active external rewarming should only be considered in a clinically monitored setting for mildly hypothermic patients who can protect their airway. When using a heating device, the potential for burns to the areas in greatest contact with the heating source should also be monitored.

## Active Core Rewarming

There is evidence that active core rewarming may decrease mortality from *severe* hypothermia exposure compared with other techniques. [11] Several methods have been described, including the use of warm humidified air through an endotracheal tube or mask (Fig. 71-6) , peritoneal lavage, gastric or bladder lavage with warm fluid, thoracic tube lavage, cardiopulmonary bypass (Fig. 71-7) , hemodialysis, and thoracotomy with mediastinal lavage (Fig. 71-8) . These techniques transfer heat actively to the body core, achieving varying rewarming rates. The specific techniques as well as some of the advantages and disadvantages for each procedure are described below.

**Less Invasive Techniques**

**Inhalation of heated humidified $O_2$ or air**

The use of warm humidified oxygen to treat hypothermia was described by Lloyd in 1973. [36] Miller and colleagues reported average rates of rewarming of 0.74 °C (1.3 °F)/hour via mask and 1.22 °C (2.2 °F)/hour via endotracheal tube with heated aerosol at 40 °C. [20] Faster rewarming rates may be accomplished using a maximum safe aerosol temperature of 45 °C (113 °F). The Multicenter Hypothermia Study showed an average first- and second-hour rewarming rate of 1.5 to 2.0 °C (2.7 to 3.6 °F) for mask and endotracheal tube inhalation in severe hypothermia. [37] This rate was somewhat less in moderate hypothermia.  Core rewarming with the technique occurs through the following mechanisms. The warmed alveolar blood returns to the heart, thereby warming the myocardium. The warmed humidified air delivered to the alveoli also warms contiguous structures in the mediastinum by conduction. Finally, warming the inhaled air or oxygen eliminates a major source of heat loss.

**Indications and contraindications**

The use of heated humidified air or oxygen is a simple technique that *should be used routinely*, either by itself or in combination with other methods, in all patients with hypothermia, regardless of severity. If the correct equipment is available, it can be used in the field as well as the hospital. [36] [38] However, one must address the risk of burns during inhalation of warm air in the field environment. [39] Mouth-to-tube ventilation in the intubated hypothermic out-of-hospital patient has the theoretical advantage of providing warm humidified air without special equipment. The ventilating rescuer can inhale oxygen before expiring into the patient's endotracheal tube to provide air with increased oxygen content. There are no contraindications for or reported complications from the use of warm humidified air for hypothermia, and there is no afterdrop. [21]

**Technique**

A heated cascade nebulizer can be used with a mask for patients with spontaneous respirations or with a volume ventilator for intubated patients. It is important to monitor the inspired air to maintain a temperature of approximately 45 °C. [40] Temperatures >50 °C (122 °F) may burn the mucosa, and temperatures <45 °C (<113 °F) do not deliver maximum heat. The air or oxygen must be humidified, and the heater module may need modification, because many units have feedback mechanisms that shut off at a given temperature. As a practical issue, it may be difficult to deliver oxygen at the recommended temperature because of equipment limitations. In our institution, we found that without modification, we could not deliver humidified air at >40 °C. In many cases the air temperature was only 30 °C (86 °F).

**Conclusions**

Studies have suggested that the rewarming rate of inhalation therapy is inferior to that of peritoneal lavage, thoracic lavage, and bath rewarming. [41] However, because inhalation therapy can be combined with any and all other methods of rewarming and because it is relatively noninvasive and inexpensive, it should be considered as the initial treatment of choice for hypothermic patients.

**Peritoneal dialysis**

Peritoneal dialysis (lavage) is an ideal treatment for severe hypothermia because it is available in most hospitals and does not require any unusual equipment or training. Rewarming rates of 1 to 3 °C (1.8 to 5.4 °F)/hour, depending on the dialysis rate, can be achieved without sophisticated equipment that may delay therapy or require transfer of the patient to a tertiary care facility. [37] [42]

Peritoneal dialysis rewarming was first used successfully in a patient in ventricular fibrillation with a temperature of 21 °C (69.8 °F). [43] Since that time, there have been reports of successful rewarming with peritoneal lavage in stable, severely hypothermic patients and unstable hypothermic patients in cardiac arrest. [42] [44] Peritoneal lavage

works through heat transfer from lavage fluid to the peritoneal cavity. The peritoneal great vessels and abdominal organs provide a large surface area for heat exchange. There are few controlled comparisons with other rewarming methods, [41] and failures are probably not reported.

**Indications and contraindications**

Peritoneal dialysis is indicated in any severely hypothermic patient (temperature <28 °C [82.4 °F]). Although theoretically less effective than other techniques that directly warm the thorax in the setting of cardiac arrest, it has been used successfully in that situation. It is particularly useful in hypothermic patients who have overdosed with a dialyzable toxin. Other less invasive methods, such as gastric or bladder lavage or warm nebulized air or oxygen inhalation, may be preferred in stable patients with temperatures >26 to 28 °C (78.7 to 82.4 °F). Peritoneal dialysis should not be performed on patients with previous abdominal surgery and should be used with extreme caution in patients with a coagulopathy after the risks and benefits have been considered.

**Equipment**

The equipment described in Chapter 46 is needed. We recommend using the Seldinger technique with a commercially available disposable kit (e.g., Arrow peritoneal lavage kit, product No. AK-09000, Arrow International, Inc, Reading, Pa) because of the ease of performance and minimal morbidity associated with this procedure.

**Technique**

In the noncritical patient, a coagulation profile should be obtained before the procedure, but immediate initiation is warranted in life-threatening situations. The patient should be supine with a Foley catheter and nasogastric tube in place. After infiltration with lidocaine, an infraumbilical stab incision is made with a No. 11 blade, and an 18-ga needle is placed into the peritoneal cavity directed toward the pelvis at a 45° angle. A standard flexible J-wire is inserted through the needle, and the needle is removed. The 8-Fr dialysis catheter is passed over the wire with a twisting motion, and the wire is removed.

Lavage rates of 4 to 12 L/hour can be achieved with 2 catheters. Fluid is warmed with a standard blood warmer to 40 to 45 °C. We recommend using standard 1.5% dextrose dialysate solution, adding potassium (4 mmol/L) if the patient becomes hypokalemic. Ringer's solution and normal saline have also been used successfully. [45] The rate should be at least 6 L/hour and preferably 10 L/hour. [45]

**Complications**

The Seldinger method has a complication rate of <1%. [46] [47] A "mini-lap" using direct dissection may also be used but may have a higher complication rate. [47] Further

discussion of potential complications is provided in Chapter 46 .

### Conclusions

Peritoneal dialysis is a useful method because it uses readily available fluid and can be done with a self-contained disposable kit. If a hospital also treats trauma victims, the same lavage kit can be used for evaluation of abdominal trauma. If this technique is combined with warm nebulized inhalation, warming rates of 4 °C (7.2 °F)/hour can be achieved. [37]

### Gastrointestinal and bladder rewarming

Gastric or bladder irrigation offers some of the same advantages as peritoneal dialysis without invading the peritoneal cavity. Heat is delivered to structures in close proximity to the core. In the Multicenter Hypothermia Study, gastric/bladder/colon lavage had a first hour rewarming rate of 1.0 to 1.5 °C and a second hour rewarming rate of 1.5 to 2.0 °C for severe hypothermia. [37] In a multifactorial analysis of the Multicenter Hypothermia Study there was a trend toward improved survival in patients on whom this method was used. [11]

Although the amount of heat delivered with gastric lavage appears less than that delivered with peritoneal dialysis, it is somewhat easier to use and less invasive. When combined with other methods, gastric or bladder lavage provides significant warming. [37] [48] Serum electrolyte levels should be monitored if large volumes of tap water are used, because delusional electrolyte disturbances may occur. Children may be more susceptible to electrolyte changes with tap water irrigation. [49]

### Indications and contraindications

Warmed gastric or bladder lavage is indicated in moderate or severe hypothermia. It can be combined with other warming techniques when rapid rewarming is needed. Patients who are obtunded and lack protective airway reflexes should have endotracheal intubation before gastric lavage to prevent aspiration of gastric contents. The reader is referred to the appropriate chapters concerning nasogastric tube placement (see Chapter 43) , gastric lavage (see Chapter 45) , and urethral catheterization (see Chapter 59) for specific contraindications to these procedures.

### Equipment

We recommend using large-diameter 32- to 40-Fr lavage tubes with normal saline or lactated Ringer's solution warmed to 40 to 45 °C (in a microwave or blood warmer with verification of temperature before use), and a Y connector and clamp as described in Chapter 45 . Although smaller tubes are easily passed nasally, we recommend oral placement of the large lavage tubes. A modified Sengstaken tube with gastric and esophageal balloons may also be used. [32]

### Technique

From 200- to 300-mL aliquots of fluid may be instilled into the stomach before removal by gravity drainage. For bladder irrigation, the optimal volume is not known but bladder distension should be avoided (100-200 mL aliquots should be sufficient). The amount of time that the irrigant should be left before removal is not known, but we recommend rapid exchanges with a dwell time of 1 to 2 minutes.

### Complications

The lavage complications include trauma to the nasal turbinates (especially if a large tube is passed nasally), gastric and esophageal perforation, dilutional hyponatremia, inadvertent placement of the tube in the lungs, and pulmonary aspiration. All of these can be minimized by careful, proper technique. Fluid overload or electrolyte disturbances when using tap water are potential complications.

### Conclusions

Gastrointestinal and bladder lavage with heated fluids is easily performed using equipment and solutions available in any hospital. Because of its ease and availability, it can be started early in the resuscitation and combined with any other rewarming method to give a significant added increment of heat.

## More Invasive Techniques

### Thoracic cavity lavage

Thoracic cavity lavage can be performed either *closed*, through chest tubes placed in the one hemithorax, or *open*, after resuscitative thoracotomy. The former approach offers the advantages of being less invasive and being based on procedures more commonly used by the emergency physician. Furthermore, closed-chest CPR can be continued while this technique is used. The open thorax approach offers the theoretical advantage of direct heart warming and the option of open-chest cardiac massage. Rapid warming rates of 6 to 7 °C in 20 minutes have been described. [56]

### Indications and contraindications

Thoracic cavity lavage should be considered for patients requiring rapid core rewarming in the setting of inadequate perfusion (e.g., shock or during CPR) when cardiac bypass is not available. Open thoracic lavage should be considered in those patients who will receive open chest massage or thoracotomy for other reasons (e.g., hypothermic arrest with penetrating trauma). Generally, thoracic lavage is not necessary for patients with mild or moderate hypothermia who can be rewarmed by other less invasive methods. The technique should be avoided in the patient with a coagulopathy unless needed as a

life-saving measure.

**Technique**

**Closed thoracic lavage**

Two large-bore thoracostomy tubes (e.g., 36 to 38 Fr in 70-kg adults) are placed in one hemithorax (see Chapter 9) . Iversen and colleagues [51] recommend one placed in the fourth intercostal space in the posterior axillary line and the other in the third intercostal space in the midclavicular line. A nonrecycled system has been described for thoracic lavage. [51] One chest tube is infused with 3-L bags of heated normal saline (40 to 41 °C [104 to 105.8 °F]) using a high-flow fluid infuser (e.g., Level-1 fluid warmer, Technologies, Inc, Marshfield, Mass). The effluent is collected with an autotransfusion thoracostomy drainage set (e.g., Pleur-evac, Deknatel A-5000-ATS, Fall River, Mass) and the removable reservoir repeatedly emptied as needed. Iversen and associates [51] were able to deliver fluid at an average rate of 180 mL/min for 2.5 hours using this system. Hall and Syverud described a simple and effective method of using large volumes of tap water and two chest tubes with gravity drainage. [56] The use of a single chest tube system using a Y-connector arrangement similar to gastric lavage is also effective. Aliquots of 200 to 300 mL with a 2-minute dwell time followed by suction drainage (at 20 cm $H_2O$) are recommended.

Closed-chest massage is used until adequate spontaneous perfusion occurs. Closed-chest defibrillation may be required in the patient warmed to 30 °C (86 °F) with persistent ventricular fibrillation. Thoracic lavage is generally continued until the patient's temperature approaches 35 °C (95 °F).

**Open thoracic lavage.**

A left thoracotomy is performed as described in Chapter 17 . Saline warmed to 40 to 41 °C can then be continuously poured into the thoracic cavity, bathing the heart while an assistant suctions the excess fluid from the lateral edge of the thoracotomy. Alternatively, fluid may be added to the thorax and mediastinum intermittently and suctioned after several minutes, and more warm saline may be added (see Fig. 71-8) . This technique also allows for direct myocardial temperature monitoring. Direct cardiac massage is used until adequate spontaneous perfusion occurs. Direct cardiac defibrillation may be required in the patient warmed to 30 °C with persistent ventricular fibrillation. When defibrillation is successful, direct myocardial warming should continue until the patient's temperature approaches 35 °C. If defibrillation is unsuccessful at a core temperature of 30 °C, further warming is warranted while oxygenation, perfusion, and other physiologic parameters are optimized before further defibrillation attempts.

**Conclusions**

Although thoracic lavage clinically has not been investigated in a controlled fashion, it has been anecdotally successful in hypothermic arrest patients.  Animal studies of closed thoracic lavage suggest that it is an effective rewarming technique. [41] [50]

Nonetheless, thoracic lavage should be restricted to those patients with inadequate spontaneous perfusion to permit less aggressive techniques and in the setting where more definitive therapy (e.g., cardiac bypass) is not rapidly available.

**Cardiac bypass**

The use of cardiac bypass or an extracorporeal shunt through either the femoral artery-femoral vein or aorta-caval procedure can result in rapid rewarming but requires surgical expertise, availability of appropriate equipment, and technical support. [2] [3] [22] This procedure has not been compared with other rewarming methods in a controlled fashion. Its main advantages would appear to be the rapid rate of warming it produces and optimal patient oxygenation and perfusion. Femoral flow rates of 2 to 3 L/min with the warmer set at 38 to 40 °C (100.4 to 104 °F) will raise the core temperature 1 to 2 °C every 3 to 5 minutes. [57] Drawbacks include potential delays in assembling the appropriate team and equipment, delays due to the time necessary to complete the operation, complications from the operation, the expense of the procedure and bypass equipment, and the potential for infection. Its use in extreme situations that may include cardiac arrest should be based on individual characteristics of the patient, physician team, and hospital resources, with the full knowledge that no consensus concerning its use presently exists. If rapidly available, it should be strongly considered in hypothermic patients with asystole or ventricular fibrillation. [58] If oxygenation is not a consideration, venovenous rewarming with an extracorporeal venovenous rewarmer can achieve rapid rewarming rates (2 to 3 °C [3.6 to 5.4 °F]/hour) but slower than cardiopulmonary bypass. [59] Such a device is relatively easy to use, uses readily available technology, and probably does not require heparin. However, it needs to be assembled prior to patients presenting with hypothermia.

**Hemodialysis**

Core rewarming by hemodialysis has been achieved after placement of a dialysis catheter or with use of an existing shunt. Some of the potential advantages and drawbacks of cardiac bypass also apply to this procedure, although slower warming rates have been reported. For patients who have ingested a dialyzable toxin, hemodialysis can be used to both remove the toxin and rewarm the blood. [60] In such cases its use may be appropriate.

**Experimental Techniques**

Radiowave rewarming appears to be a rapid, safe, noninvasive technique with promise in animal studies. [55] However, the technique seems less effective than immersion therapy and equivalent to passive rewarming techniques in a volunteer study. [61]

Very hot intravenous fluids (65 °C [149 °F]) have been used in animals with little vascular damage or hemolysis and may have promise for future human trials.

# SPECIAL SITUATIONS

## Cardiac Arrest

Rapid rewarming and restoration of cardiac rhythm is essential for patients in cardiopulmonary arrest and can best be achieved by a combination of passive and multiple active core rewarming techniques. Because numerous cases of survival from hypothermic cardiac arrest with prolonged external cardiac compression exist, [37] [48] thoracotomy is not mandatory but does offer some theoretical advantages, such as increased cardiac output with open-chest massage, [63] direct observation of cardiac activity, and direct warming of cardiac tissue with thoracic cavity lavage of warm fluid. The optimal rate of cardiac compression in hypothermia is not known, but because of decreased oxygen consumption of vital organs, the rate required in hypothermic cardiac arrest may be less than that recommended in normothermic cardiac arrest. However, there is no evidence that standard CPR is harmful in the hypothermic patient; therefore, we recommend standard CPR for nonperfusing hypothermic patients.

The duration of CPR depends on the time required to raise the core temperature to a level at which defibrillation should be successful (i.e., >30 °C [86 °F]), but other factors that may occur in individual cases make any specific temperature recommendation for cessation of CPR efforts impossible. Certainly survival is highly unlikely in patients with a core temperature <10 °C (50 °F), and patients who persist in asystole or go from ventricular fibrillation to asystole as they are warmed past 32 °C (89.6 °F) are unlikely to respond. Elevated potassium levels >6.8 mmol/L [64] and blood urea nitrogen levels may portend an irreversible process [11] [22] and should be measured in the early stages of resuscitation. However, whereas high plasma potassium levels have considerable prognostic value in crushed, hypothermic avalanche victims, they are less valuable in patients with hypothermia from cold water submersion. [65]

Isolated reports of survival with prolonged CPR in hypothermic patients make extended efforts to resuscitate such patients reasonable. Under ideal conditions, hypothermic cardiac arrest patients may reasonably be admitted to an intensive care unit for a 4- to 5-hour trial of rewarming with CPR in progress. Manual CPR should be replaced by mechanical methods if equipment is available (see Chapter 16) . Absence of responsiveness to treatment in conjunction with a highly elevated potassium level is an indication for termination of resuscitative efforts.

## Airway Management

A secure functioning airway must be maintained for the hypothermic patient, just as in any critically ill patient. In mild hypothermia, heated humidified oxygen can be delivered effectively by a face mask. The hypothermic patient can be combative and uncooperative and may require arm restraints if a mask is used. For the patient with decreased sensorium who cannot reliably maintain his or her airway or the hypothermic patient who may be hypoxic, endotracheal intubation may be performed safely without the added risk of ventricular dysrhythmias. [20] [37] The technique for endotracheal intubation depends on the specific presenting circumstances and the expertise of the operator. Once an endotracheal tube has been placed and secured, it may be used for

treatment of the patient with warm humidified oxygen.

## Acid-Base Disturbances

The interpretation of arterial blood gases in the hypothermic patient has been the cause of some confusion. Because of dehydration, tissue hypoxia, increased lactate production, and impairments in acid excretion, metabolic acidosis can occur in hypothermic patients. Concurrent ventilatory decreases may increase the systemic acidotic state. Although temperature correction of reported arterial blood gas results to reflect the hypothermic state has been described, the use of *uncorrected* pH to guide therapy with bicarbonate or hyperventilation has more recently been advocated.  This approach appears appropriate to support optimal enzymatic function. A gradual correction of acid-base imbalance will allow for the increased efficiency of the bicarbonate buffering system as the body warms. Arterial pH did not correlate with patient death in the Multicenter Hypothermia Study [37] and should not be used as a prognostic guide to resuscitation.

## Coagulopathies

Abnormal clotting frequently occurs in hypothermia probably because cold inhibits the enzymatic coagulation cascade. [57] Platelet function is also impaired during hypothermia because the production of thromboxane B2 is inhibited. Hypercoagulability with risks of thromboembolism may also occur, but the main importance of cold induced coagulopathy is in patients with coincidental trauma. Such patients are often noted to have bleeding from traumatic injuries that is difficult to control. Replacement of appropriate clotting factors and use of warm blood may limit further blood loss and worsening of hypothermia.

## Trauma and Hypothermia

It is clear that there is an increased mortality in trauma patients with temperatures <32 °C (89.6 °F). It is not clear that this increased mortality is actually a result of hypothermia or that hypothermia is merely an indicator of severe injury and response to a massive transfusion of cold fluid. [68] Patients with severe trauma are prone to hypothermia because their injury often may expose them to environmental heat loss. Concurrent alcohol intoxication may add to the heat loss. Severe injury victims also lose heat because of exposure during resuscitation and rapid administration of cold fluids.

The degree to which correcting the hypothermia improves outcome is unknown. Nevertheless, devices to rapidly infuse warm fluids such as the Level 1 fluid warmer (Level 1 Technologies, Rockland, Mass) and the Thermostat 900 (Arrow International, Reading, Pa) are frequently used to warm large volume fluid transfusions. Although not subjected to controlled trials, these devices seem reasonable to prevent the hypothermia associated with massive transfusions (see Chapter 23) . Their use in hypothermia not associated with severe trauma is limited by the relatively low fluid requirements of environmental exposure hypothermia.

## PHARMACOTHERAPY AND MONITORING

Cardiac irritability, particularly refractory ventricular fibrillation, may be present on the patient's initial arrival or may occur during rewarming. Bretylium tosylate is an antidysrhythmic agent that has been used successfully to treat two hypothermic patients in ventricular fibrillation [69] [70] and may prevent ventricular fibrillation in patients at risk for this dysrhythmia. [71] However, routine administration of this medication to hypothermic patients has not been studied on humans in a controlled fashion. Magnesium also has been used successfully to defibrillate hypothermic ventricular fibrillation. [72] Other pharmacologic agents, including lidocaine, have limited value for ventricular dysrhythmias in hypothermia. [73]

Even though digitalis may be less dysrhythmogenic in hypothermia for a given blood level, there is no clear indication for its use. [74] Most supraventricular dysrhythmias, including atrial fibrillation, convert spontaneously as the patient is warmed and therefore do not necessarily require treatment in the hypothermic state. Dopamine has been used in reports of successful resuscitation of hypotensive hypothermic patients, [73] and there is some experimental support for its use in hypothermia patients needing inotropic support. [75]

Intravenous fluid should be given early because most hypothermic patients have intravascular volume depletion. Dextrose 5% with normal saline has been advocated as the ideal initial resuscitation fluid. [5] Potassium should be avoided until electrolytes are measured and normal renal function is confirmed.

Placement of a Swan-Ganz catheter and close monitoring of urinary output may assist in the fluid management of severely hypothermic patients. The risks of precipitating ventricular fibrillation should be weighed against the potential benefits of the Swan-Ganz catheter.

Elevation of creatine phosphokinase in hypothermic patients may indicate rhabdomyolysis, and careful monitoring of renal function with aggressive fluid replacement may prevent the development of renal failure.

Finally it should be noted that hypothermic patients exhibit a "physiologic" (and probably somewhat protective) hypotension, hypoventilation, and bradycardia, the extent of which depends on the core temperature. The clinician should avoid aggressive therapies or medications that are aimed at providing the hypothermic patient with vital signs that would be desirable in the normothermic patient but which may be supraphysiologic in the hypothermic patient.

## FROSTBITE

Hypothermic patients frequently suffer from frostbite in addition to their systemic hypothermia. Frostbite usually involves the hands, feet, ears, and nose, and the exposed skin goes through a number of progressively deleterious physiologic changes

on exposure to the cold. Mild cold injury is termed *frostnip*, a condition that involves only the skin, sparing the subcutaneous tissues. The skin is blanched and numb, but the injury is immediately reversible with no permanent sequelae if the area is quickly rewarmed. Nonfreezing temperatures also produce *trenchfoot*, an intermediate in the progression to true frostbite.

In frostbite the skin and subcutaneous tissue are actually frozen. The affected extremity is hard, solid, and blanched. Clear or hemorrhagic bullae may be present. Initially there is no pain or feeling in the frostbitten extremity. After rewarming, the affected area develops severe edema and blistering, eventually exhibiting dry gangrene and mummification, leading to tissue sloughing.

Physiologically, frostbite involves the initial extracellular formation of ice crystals, followed by delayed but progressive ischemia in the affected area. Interstitial ice crystal formation is a hypertonic state that leads to cellular dehydration and cell death. Cellular water loss enhances extracellular ice formation, leading to further damage from increased pressure on blood vessels and cells. Cold also increases blood viscosity, promotes vasospasm, and precipitates microthrombus formation. The cascade of injurious events in frostbite may be mediated by prostaglandins.

Rapid rewarming is the treatment of choice for frostbite. [76] The aim is to limit the length of time the tissue remains in the frozen state. The most practical way to rewarm an extremity is to totally immerse the area in warm water at 40 to 42 °C for 15 to 30 minutes. The affected area should be carefully protected to ensure that the tissue is not additionally injured through contact with the sides or rim of the container. After thawing, the area should be meticulously protected from injury. An extremity should be elevated and cotton or gauze placed between the toes/fingers to limit maceration.

The use of topical aloe vera (a thromboxane inhibitor) and systemic antiprostaglandins (such as ibuprofen) may be helpful. There is no proven benefit to the use of heparin or low-molecular-weight dextran, vasodilators, corticosteroids, or immediate surgical sympathectomy. The value of thrombolytic agents is unknown. The use of antibiotics is controversial, although some authors advocate penicillin prophylactically. Debridement of tissue should be avoided in the ED.

## CONCLUSION

As a general guideline, one should take a conservative approach to rewarming the stable hypothermic patient, with avoidance of overtreatment and the selective and careful use of invasive monitoring. The patient's "physiologic" hypotension, hypoventilation, and bradycardia should be evaluated with regard to that which is expected for the core temperature.

In moderate hypothermia, underlying problems should be sought, passive rewarming and basic support started, and less invasive core rewarming begun. This approach should include mask ventilation with warm humidified air or oxygen in the conscious patient and intubation and ventilation in the unconscious patient. In selected patients,

gastric or peritoneal lavage with warm fluid may be considered.

For severely hypothermic, *unstable* patients, cardiac bypass and thoracic lavage may offer additional benefits, including rapid warming rates and direct heart warming. The benefits should be weighed against the time, expense, and danger of complications that these procedures entail.

It is ironic that as we consider costly procedures for resuscitating hypothermic patients, many of whom are elderly and alcoholic, we have not considered preventive measures. In fact, many of the same patients who become interesting hypothermic cases visit EDs as part of a daily quest for shelter. Some physicians may take pride in sending these ED "abusers," without obvious acute medical problems, back out into the streets to make room for "real" sick patients, whom we can help. However, it may well be that the most effective ED procedure to combat hypothermia is to provide a chair in the waiting room on a cold winter night.

# Chapter 72 - Hyperthermia Procedures

**Timothy B. Erickson, Dwight E. Helmrich, Scott A. Syverud**

Human epidemics of heat-related illness have been well documented historically. [1] A Roman army was decimated by heat in 24 B.C., and King Edward's heavily armored crusaders were defeated by "heat and fever" during the final battle of the Holy Land. In Peking, 11,000 residents died during a heat wave in 1743. More than 1000 heat-related deaths occurred during a pilgrimage to Mecca in the early 1960s. In the United States in 1980, 1983, and 1988 (years with prolonged heat waves), 1700, 556, and 454 deaths, respectively, were attributed to heat exposure. [2] More recently, a large number of hyperthermia-related fatalities (465) was reported in Chicago during a severe heat wave in July 1995. [3]

In contrast, malignant hyperthermia and neuroleptic malignant syndrome (NMS) have been recognized and described only since the 1960s. [4] These conditions are largely iatrogenic and are most commonly triggered by modern pharmacologic therapy. In addition, the incidence of hyperthermic conditions induced by psychostimulant drugs of abuse, such as cocaine and amphetamine derivatives, is on the rise. [5]

Heatstroke remains a common clinical problem with significant morbidity and mortality. As is the case with accidental hypothermia, published clinical studies of heatstroke therapeutic techniques have largely been limited to retrospective case series without concurrent control or comparison groups. A variety of cooling techniques have been advocated since World War II. Although some cooling techniques have been compared in controlled human and animal models of heatstroke, practice decisions are not solely based on the theoretical rate of cooling. Other important factors include the ease of use, rapidity of initiation, and safety.

Before considering the various cooling techniques, it is essential that the underlying disorder of hyperthermia be clearly understood. Heat illness presents a spectrum of disease ranging from mild heat exhaustion (primarily a volume loss disorder) to severe heatstroke (with thermal-related end-organ injury). The latter includes disorders such as malignant hyperthermia and NMS. Treatment of this spectrum of disease requires a discriminating approach, including supportive care only for heat exhaustion and rapid cooling for heatstroke. Malignant hyperthermia requires specific pharmacologic therapy (e.g., dantrolene) in addition to cooling measures. A brief discussion of hyperthermic disorders is therefore necessary before describing cooling techniques.

## NORMAL THERMOREGULATION

Body temperature is a balance between heat production and heat dissipation. Heat is produced as a by-product of all metabolic processes and when ambient temperatures exceed the body temperature. The body temperature increases when the rate of heat production exceeds the rate of heat dissipation. In response to rising core temperature, the thermal center (located in the preoptic nucleus of the anterior hypothalamus) activates efferent fibers of the autonomic nervous system to produce vasodilation and

increase the rate of sweating. Vasodilation dissipates heat by convection, and sweat dissipates heat by evaporation. Hyperthermia occurs when thermoregulatory mechanisms are overwhelmed by excessive metabolic production of heat, excessive environmental heat, or impaired heat dissipation. In contrast, fever occurs when the hypothalamic setpoint is increased by the action of circulating pyrogenic cytokines, causing peripheral mechanisms to conserve and generate heat until the body temperature rises to the elevated setpoint. Hyperthermia and fever cannot be differentiated clinically on the basis of magnitude of temperature or on the pattern of its changes.

In the ensuing discussion, temperatures will be given in degrees Celsius (centigrade). A temperature conversion scale is provided in the previous chapter (see Fig. 71-2) .

## TYPES OF HYPERTHERMIA

### Mild Heat Illness

Heat cramps and heat exhaustion are induced by a hot environment. [14] [15] In general, the body's heat dissipation mechanisms are able to keep up with heat production and absorption in these disorders. Symptoms are largely due to the mechanisms used by the body to dissipate heat, and body temperatures remain at or near normal. Rapid cooling techniques are *not* required, and supportive care and hydration in a cool environment are usually adequate therapy.

*Heat cramps* are intensely painful but generally benign, involuntary skeletal muscle spasms (most often in the calves). The pain may also be in the legs, arms, and back. The cramps may be severe and prolonged and rarely may lead to rhabdomyolysis. Heat cramps occur after strenuous exercise or heavy labor in a hot environment. Diaphoresis with inadequate hypotonic fluid replacement (water) is a common historical point. Rest in a cool environment and vigorous oral fluid replacement with isotonic solutions are usually adequate therapy, but in some cases IV saline is required. The pain may be surprisingly resistant to narcotics in the absence of adequate fluid replacement.

*Heat exhaustion* is a poorly defined syndrome with a spectrum of nonspecific symptoms that occur after heat exposure. Malaise, flu-like symptoms, orthostasis, dehydration, nausea, and headache may all occur. As distinct from the more severe heat disorders, mental status is normal and body temperature is normal or mildly elevated. Rehydration (usually IV), rest, and supportive care in a cool environment are adequate therapy for heat exhaustion. Recovery is usually evident within a few minutes to hours. Occasionally heat exhaustion is accompanied by heat cramps, presenting a confusing scenario if the diagnosis is not suspected. Rapid cooling techniques are not required, but patients should be observed for progression to heatstroke.

### Heatstroke

When the body's normal heat dissipation mechanisms are overwhelmed, core temperature elevation and heatstroke rapidly ensue. Two forms of heatstroke are described in the literature. *Classic (nonexertional) heatstroke* usually occurs during summer heat waves. Poor, urban elderly, infants, and persons with impaired mobility are at greatest risk. Dehydration, lack of air conditioning, marginal cardiovascular status, impaired mentation, and medications that interfere with heat dissipation (e.g., phenothiazines and anticholinergics) predispose this population to heatstroke. *Exertional heatstroke*, a consequence of strenuous physical activity, usually afflicts a younger segment of the population. Highly motivated, poorly acclimatized, or unconditioned athletes and military recruits are common victims, as are individuals who perform heavy physical labor in hot, humid conditions.

The degree of hyperthermia necessary to produce heatstroke in humans is unknown. In tissue culture cells, thermal injury is observed in the range of 40 to 45 °C. Studies of hyperthermia in cancer therapy reveal that tissue sensitivity to heat is increased by relative hypoxia, ischemia, and acidosis. [21] The duration of thermal insult, measured as degree-minutes, is also an important variable. [22]

The key clinical findings in the diagnosis of heatstroke are (1) a history of heat stress or exposure, (2) a rectal temperature greater than 40 °C, and (3) central nervous system (CNS) dysfunction (i.e., altered mental status, disorientation, stupor, seizures, or coma). Although anhydrosis is traditionally described as a classic sign of heatstroke, recent investigations have demonstrated that cessation of sweating is only a latent sign. Failure to consider the diagnosis of heatstroke in a diaphoretic patient with mental status changes could prove disastrous.

The sequelae of heatstroke are caused by thermal damage to multiple organ systems. [24] Delirium, seizures, and coma can result as direct effects of heat on the CNS. Cardiovascular collapse results from dehydration, maximal cutaneous vasodilation, and direct heat-induced myocardial depression. Coagulopathies and liver dysfunction (elevated levels of bilirubin and transaminases) occur as consequences of thermal breakdown and consumption of serum proteins, as well as direct heat damage to hepatic cells. Children often demonstrate diarrhea. Renal failure can result from myoglobinuria (related to rhabdomyolysis) and acute tubular necrosis. [24]

The treatment of these sequelae in acute heatstroke does not differ from that in other disorders, with the sole exception that rapid cooling is necessary to prevent further damage and reverse heat stress. Importantly, the human body tolerates hyperthermia poorly. Unlike patients with hypothermia, in whom slow, gentle rewarming and supportive care often result in a favorable outcome, victims of severe heatstroke must be aggressively treated with measures designed to rapidly lower the core temperature.

## Malignant Hyperthermia

Malignant hyperthermia results from a rare inherited autosomal dominant abnormality of the skeletal muscle membrane. [25] In response to certain stresses or drugs (Table 72-1) , patients with this disorder sustain a massive afflux of calcium from skeletal muscle

sarcoplasmic reticulum, resulting in contraction of the sarcomeres; skeletal muscle rigidity; increased skeletal muscle metabolism and heat production; and finally, systemic hyperthermia. Hyperthermia is a late development occurring after rigidity has been present for

some time and the body's normal heat dissipation mechanisms have been overwhelmed. The earliest signs of malignant hyperthermia are increased $CO_2$ production, muscle rigidity, and tachycardia. Cardiac output and cutaneous blood flow also increase to maximize heat loss. Malignant hyperthermia is diagnosed based on the clinical triad of (1) exposure to an agent or stress known to trigger the condition, (2) skeletal muscle rigidity, and (3) hyperthermia.

Malignant hyperthermia is usually encountered in the operating room while patients are undergoing general anesthesia, particularly with halogenated inhalation agents and depolarizing muscle relaxants. However, cases of malignant hyperthermia may be encountered anywhere general anesthetics or neuromuscular blocking agents are used. [27]

As with heatstroke, treatment of malignant hyperthermia requires rapid cooling and supportive care for the sequelae described previously. Unlike heatstroke, malignant hyperthermia requires specific pharmacologic therapy to stop excess heat production by skeletal muscle. Dantrolene sodium induces muscle relaxation in malignant hyperthermia by blocking calcium release from muscle cell sarcoplasmic reticulum. [28] In all cases of malignant hyperthermia, the inciting stimulus (see Table 72-1) should be discontinued immediately and dantrolene therapy administered (2.5 mg/kg IV every 6 hours) until the episode resolves. [25]

It has been suggested that dantrolene administration might speed cooling of heatstroke victims by reducing skeletal muscle heat production. [29] However, in a canine study of externally induced hyperthermia, dantrolene administration did not result in faster

cooling rates than those seen with spontaneous room air cooling alone. [30] Although 1 small study of exercise-induced heatstroke in humans during a religious pilgrimage suggested that dantrolene may speed cooling rates in exertional heatstroke, [31] a larger controlled trial in a similar setting found no benefit. [32] Currently, dantrolene administration is best reserved for patients with clinical muscle rigidity or suspected malignant hyperthermia. Routine use of this drug in heatstroke patients is not recommended.

## Neuroleptic Malignant Syndrome

First described in the late 1960s, NMS is characterized by fever, muscle rigidity, altered level of consciousness, and autonomic instability. [4] This idiosyncratic disorder follows the therapeutic use of neuroleptic drugs, including phenothiazines, butyrophenones, thioxanthenes, lithium, and tricyclic antidepressants. The reaction is triggered by blockade of dopaminergic receptors, resulting in spasticity of skeletal muscle, which generates excessive heat and impairs hypothalamic thermoregulation and heat dissipation. [12] Muscle rigidity, described as "lead-pipe" rigidity in its most severe form, [4] can manifest as oculogyric crisis, dyskinesia, akinesia, dysphagia, dysarthria, or opisthotonos. Temperatures can exceed 42 °C. Initial agitation often progresses to stupor and coma. Catatonia and mutism may also be present. Autonomic instability is manifested as tachycardia, labile blood pressures, sweating, and incontinence. Ventilations may be impaired by chest wall rigidity.

This syndrome is more likely to occur at the initiation of or after an increase in neuroleptic dosage. It may also occur if antiparkinsonian drugs are suddenly discontinued. NMS resembles malignant hyperthermia but usually takes considerably longer to develop (2 to 3 days) and lasts longer (5 to 10 days) after the inciting drug is discontinued. The syndrome may be misinterpreted as a worsening of the underlying psychiatric disorder, drug intoxication (e.g., cocaine, amphetamines), a severe dystonic reaction, tetanus, or a variety of CNS infections. The mortality rate is high (20%), and death is usually caused by respiratory failure, renal failure, cardiovascular collapse, or thromboembolic disease. Unlike malignant hyperthermia, NMS is thought to be caused by a central disorder of thermoregulation.

Treatment of severe NMS (i.e., hypotension, hyperthermia, marked rigidity) closely follows that of malignant hyperthermia, except that therapy must be maintained for several days until symptoms resolve. Discontinuation of the triggering agent, rapid cooling, and supportive treatment for ensuing organ failure remain the cornerstone of therapy. Although the effects are not immediate, pharmaceutical therapy is directed at overriding the dopaminergic blockade caused by offending neuroleptic agents or dopamine depletion resulting from the cessation of antiparkinsonian medications. As with malignant hyperthermia, dantrolene (2 to 3 mg/kg) can be given to treat NMS-induced muscle rigidity. [25] The beneficial response stems not only from the effects at the sarcoplasmic reticulum of skeletal muscles, but also from central dopamine metabolism of calcium in the CNS. [33] In addition, bromocriptine, a central dopamine agonist, has been reported to be efficacious in NMS therapy at doses of 2.5 to 10 mg three times a day. Although both of the above agents have been noted to reduce the duration of hyperthermia, neither has been evaluated in well-controlled trials.

A more recently described disorder that is often confused with NMS is the *serotonin syndrome*. This syndrome involves the newer antidepressants (fluoxetine and sertraline), which are selective serotonin reuptake inhibitors. These drugs can adversely react with other stronger serotonin receptor agents such as monoamine oxidase inhibitors (MAOIs) to induce a clinical presentation similar to that of NMS, only milder. Treatment is primarily supportive and consists of prompt recognition and withdrawal of the offending agent.

### Hyperthermia and Psychostimulant Overdose

As mentioned above, the recognized incidence of hyperthermia induced by sympathomimetic psychostimulant drugs of abuse is on the rise. [5] The offending agents most commonly described are cocaine, phencyclidine, amphetamine, and the amphetamine derivatives such as 3,4-methylenedioxymethamphetamine (MDMA) ("ecstasy") and 3,4-methylenedioxyethamphetamine (MDEA) ("Eve"). [39] Hyperthermia is a common feature of these potentially severe to lethal poisonings and may be the primary cause of fatality in many cases. [5] Some have applied a pathophysiologic model of exertional heatstroke or NMS to profound cocaine intoxication. In addition to profound hyperthermia (>42 °C), acute rhabdomyolysis, renal failure, coma, seizures, and death have been described in these patients. As demonstrated by Roberts and colleagues, even a patient with a core temperature of 114 °F due to acute cocaine intoxication may survive with aggressive cooling methods. [45]

Treatment requires prompt recognition and general supportive care, coupled with rapid cooling, as outlined below, and the aggressive use of sedative and/or paralyzing agents to control agitation. Importantly, the longer that psychostimulant-overdosed patients remain hyperthermic, the higher their morbidity and mortality rates. Agitation and seizures must be chemically controlled, as they lead to continued generation of heat and muscle injury. Therefore, liberal doses of benzodiazepines are recommended. [35] Some have advocated the use of dantrolene [46] and bromocriptine [35] as for malignant hyperthermia and NMS, but their efficacy in the setting of drug-associated hyperthermia remains controversial.

### Hemorrhagic Shock and Encephalopathy Syndrome

The condition of hemorrhagic shock and encephalopathy (HSE) in children (mainly infants, but some older children) resembles heatstroke in adults. The full-blown syndrome includes hyperthermia, coagulopathy, encephalopathy, and renal and hepatic dysfunction. Although there may be an association with concurrent viral illness, the condition generally follows a temperature elevation, which may be triggered by the "bundling" of a child with a low-grade fever. Therapy is largely supportive and includes volume replacement and rapid cooling of the hyperthermic child while sources of bacterial infection are sought and treated.

## COOLING TECHNIQUES

**General Considerations**

Heatstroke mortality is proportional to the magnitude and duration of thermal stress measured in degree-minutes. [51] *Delay in cooling may represent the single most important factor leading to death or residual disability in those who survive.* [52] In addition, advanced age and underlying disease states are significant contributing factors. [53]

Many exertional heatstroke victims are volume depleted and may present with hypotension. As a result, initial stabilization with cooled (room temperature) IV fluids and correction of electrolyte abnormalities are valuable in the hypotensive patient. Traditional sources recommend a rate of 1200 mL over the first 4 hours, [54] whereas others advise a 2 L bolus over the first hour, with an additional 1 L/hour for the following 3 hours. [55] Seraj and colleagues have challenged this more aggressive recommendation. [56] In their study of pilgrims who suffered heatstroke, 65% had a normal or above normal central venous pressure (CVP) measurement on arrival. They found that an average of 1 L of saline was sufficient to normalize the CVP during the cooling period in their patients, who had a mean age of 55 years (range, 31 to 80 years). Hence, in older patients fluid resuscitation should be monitored carefully to avoid pulmonary edema.

Regarding antipyretics, *there is no indication for either salicylates or acetaminophen in the setting of heatstroke,* as their efficacy depends on a normally functioning hypothalamus. In addition, overzealous use of acetaminophen could potentiate hepatic damage, and salicylates may promote bleeding tendencies. [23]

Given that rapid cooling is accepted as the cornerstone of effective heatstroke therapy, the clinician must choose which cooling technique to use. Studies in animal models have been based on the assumption that the fastest cooling technique is the best. In clinical patient care, other factors will also influence the choice of technique. Patient access, monitoring, safety, ease of use, and availability are all considerations, in addition to speed of cooling. A technique that may not be the most rapid but allows easy patient access and is readily available may be preferable to more cumbersome (albeit more rapid, once established) cooling techniques in some clinical settings.

The cooling rates achieved in various human and animal studies of heatstroke are summarized in Table 72-2 . The relative advantages and disadvantages of various cooling techniques are outlined in Table 72-3 .

*In addition to the cooling procedures outlined below, it is imperative that the clinician institute the judicious use of sedation and/or muscle paralysis, which are required to control agitation and to make the patient receptive to sometimes unpleasant therapies.* In general, IV benzodiazepines are the easiest and safest first-line drugs used for sedation.

## Indications for Rapid Cooling

Rapid cooling should be instituted as soon as the diagnosis of heatstroke (rectal temperature >40 °C, altered mental status, history of heat stress or exposure) is made. Rapid cooling is also indicated for the treatment of malignant hyperthermia and NMS but should be instituted concurrently with discontinuation of the triggering agent or drug and administration of dantrolene. Because studies show that the degree of organ damage correlates with the degree and duration of temperature elevation above 40 °C, a reasonable clinical goal is to reduce the temperature to below 40 °C within 1 hour of the start of therapy. [53]

## Contraindications for Rapid Cooling

Rapid cooling, per se, is never contraindicated in the presence of heatstroke. Immersion cooling is relatively contraindicated when cardiac monitoring of an unstable patient is required or when limited personnel make constant patient supervision impossible. Iced gastric lavage is contraindicated in patients with depressed airway reflexes unless the airway is protected by endotracheal intubation. [57] Gastric lavage is also contraindicated by conditions that preclude placement

of an orogastric or nasogastric tube. Cold peritoneal lavage is relatively contraindicated when multiple previous abdominal surgeries make placement of a lavage catheter risky owing to potential bowel perforation (see Chapter 46) .

**Evaporative Cooling**

Evaporating water is thermodynamically a much more effective cooling medium than melting ice. Evaporating 1 g of water requires 540 kcal. Melting 1 g of ice requires only 80 kcal. In theory, therefore, evaporative cooling should be approximately 7 times more efficient than ice packing. In practice, evaporative cooling is more efficient, but not nearly to the degree thermodynamics would predict. [58] In separate human studies, Wyndam and colleagues and Weiner and Khogali found evaporative cooling to be 1.5 to

2.2 times faster than ice water immersion. [58] [59] In human volunteers with mild, exercise-induced hyperthermia, Kielblock and associates found evaporative cooling no faster than whole-body ice packing. [60] In clinical practice, ice water immersion or ice packing causes heat loss by conduction, as well as by heat consumption by the phase change of melting ice.

Despite the continued enthusiasm of some clinicians for ice water immersion, *evaporative cooling is the fastest noninvasive cooling technique in human studies*. To maximize evaporative cooling rates, several factors must be optimized. [61] Air flow rates must be high (large fans are required). The air must be warm (but *not* humid), as evaporation is decreased at lower temperatures. The entire body surface must be exposed to airflow and continuously moistened with water (ideally the patient is suspended in a mesh sling to expose the back to airflow and moisture). Finally, the temperature of the water used to moisten the skin must be tepid (15 °C). If the water is ice cold, evaporation will be slowed. Conversely, if it is hot, conductive heat gain may occur.

Weiner and Khogali have constructed a sophisticated "body cooling unit" (BCU) to maximize evaporative cooling. [59] Patients in the BCU are suspended in a mesh net. High airflow rates (30 m/min) at temperatures of 45 °C are maintained both anterior and posterior to the mesh net. Atomized water at 15 °C is continuously sprayed on all body surfaces. Using this device, Weiner and Khogali achieved rapid cooling rates under laboratory conditions. [59]

The realities of clinical practice make these conditions hard to reproduce. Half the body surface (the back) will usually be unavailable for evaporative cooling. Airflow rates and temperatures are usually limited by the ambient temperature in the treatment facility and by the size and power of the fan available. These realities are reflected in the slower cooling rates Al-Aska and coworkers achieved when treating heatstroke victims with evaporative cooling in a clinical setting (see Table 72-2) . [62]

**Procedure**

Evaporative cooling is accomplished by undressing the patient completely, positioning a fan or fans (usually at the foot of the bed or stretcher) as close to the patient as possible, and then sponging or misting the skin continuously with tepid 15 °C water. A single care provider can continue the technique and monitor the patient once cooling has been initiated. It is important to keep as much body surface as possible moist and exposed to airflow. Covering sheets or clothing will impede skin evaporation and cooling. At one center, the downdraft of a helicopter has been used as an evaporative cooling adjunct. [63]

**Complications**

Complications of evaporative cooling are rare and are more often attributable to the underlying disorder than to the cooling technique. Wet skin may interfere with electrocardiogram (ECG) monitoring, but this can usually be avoided by using electrodes on the patient's back. Shivering occurs infrequently with this technique when

compared with other cooling techniques, because the water is relatively warm (15 °C). [62] Evaporative cooling should be discontinued when the rectal temperature reaches 39 °C. Continued cooling beyond this temperature may lead to subsequent "overshoot hypothermia" due to continued core temperature drop after active evaporative cooling is discontinued. [24]

**Immersion Cooling**

It would seem obvious that the fastest way to cool a heatstroke patient would be immersion in ice water. In one of the first studies of heatstroke cooling techniques, Daily and Harrison demonstrated that rats with hyperthermia cooled faster with ice water immersion than with evaporative cooling. [64] Some contemporary sources continue to recommend ice water immersion as the cooling technique of choice for heatstroke, usually citing Daily and Harrison's work as a reference. [65]

Studies in humans comparing ice water immersion with evaporative cooling have demonstrated evaporative cooling to be considerably faster. An explanation of the discrepancy between Daily and Harrison's results and subsequent human studies can be inferred. Daily and Harrison studied rats with intact coats of fur who were heated until they collapsed in a hot, humid environment. They then compared the cooling rate observed with ice water immersion with that observed when the rat was dunked in ice water and then held in front of a fan. [64]

Clearly, cooling a rat with an intact coat of fur is not the same as cooling a human heatstroke victim. The higher body surface area-to-mass ratio of the rat would make conductive heat loss in ice water relatively more efficient than in humans. Fur impedes evaporative heat loss and is not a factor in humans. Finally, a single dunking in 0 °C water is not the optimal technique for evaporative cooling.

More recently, Costrini and colleagues reported no fatalities in 252 consecutive young marine recruits who were treated for exertional heatstroke over a 15-year period with ice water immersion within 20 minutes of diagnosis. [66] They regard ice water immersion as superior in reducing mortality rates when compared to other conventional methods described in the literature. However, these other descriptive case series reporting higher mortality rates also included older patients, some with underlying disease states, and unknown times of cooling initiation. [66]

In clinical trials, cold water immersion remains the second fastest noninvasive cooling technique available (see Table 72-2) . In situations where evaporative cooling is not available, immersion may be the cooling technique of choice.

Several factors are important in maximizing the rate of immersion cooling. Conductive heat loss is dependent on cutaneous blood flow to maintain a heat gradient from skin to water. Theoretically, contact with ice water causes skin and subcutaneous (SQ) vasoconstriction, blocking heat exchange and turning these structures into insulators. [15] Intense cutaneous vasoconstriction will impede conductive heat loss. Magazanik and associates, in a canine study, have suggested that warmer water (15 °C) may actually cool faster than ice water (0 °C) owing to this factor. [67] The optimal water temperature

for cooling human heatstroke patients has not been defined.

Regardless of the water temperature, it is clear that increasing surface area increases conductive heat loss. Maximizing the body surface area in contact with the water will increase cooling rates with immersion cooling. In clinical practice, this means that complete immersion of the trunk and extremities will cool the patient faster than partial immersion of the trunk (back only) with the extremities extended out of the bath.

**Procedure**

Immersion cooling is accomplished by undressing the patient completely prior to transfer to a tub of water of a depth sufficient to cover the torso and extremities. Various water containers have been used. A regular bathtub, if available, can be used. Most clinical reports have described tubs that can be moved to the emergency treatment area when needed. A child's plastic wading pool and a decontamination tub or stretcher with waterproof sides and drainage capability are examples of the latter approach. The patient's head must be continuously supported out of the bath. Temperature and ECG leads must be securely attached to the patient if monitoring is to be continued during immersion. The patient should be removed from the bath when rectal temperature reaches 39 °C, because core temperature will continue to drop for a short period, even after the patient is removed. An electronic temperature monitor with a long flexible rectal probe is useful for continuous temperature monitoring during immersion.

**Complications**

The common complications of immersion cooling are patient shivering, cutaneous vasoconstriction, and the loss of monitoring capability. Shivering generates considerable heat through muscle metabolism. Cutaneous vasoconstriction impedes conductive heat loss. If significant shivering does occur, it can be reduced with benzodiazepine agents such as diazepam. Although the use of phenothiazines such as chlorpromazine has been advocated for shivering in the past, their use is currently discouraged, because administration of these agents also may impair heat loss by their anticholinergic effects on sweat glands, contribute to hypotension via alpha-adrenergic blockade, lower the seizure threshold, and cause dystonic reactions. In addition, they possess central dopamine-blocking effects that may exacerbate symptoms of NMS.  Benzodiazepines are also valuable if the patient is hyperthermic secondary to sympathomimetic agents such as cocaine. Magazanik and coworkers [67] have also suggested that warmer water temperatures (15 °C) will minimize shivering and increase cutaneous blood flow, thereby increasing cooling rates. Interestingly, Costrini and colleagues reported that shivering occurred only when patient temperatures fell below 36.7 °C and was rarely problematic.

Patient monitoring is a problem under water. Electrodes can be used on the nonimmersed upper shoulders. ECG artifact often becomes a major problem during vigorous shivering. Immersion cooling is not recommended for patients with unstable cardiac rhythms or patients who are at risk for developing these rhythms. A significant change in cardiac rhythm might go undetected during the labor-intensive process of

immersion cooling.

Patient access for resuscitative procedures is also a major problem with this technique. Should the patient develop ventricular fibrillation, he or she must be removed from the bath and dried prior to defibrillation. Invasive and diagnostic procedures (e.g., IV access and radiography) cannot be performed during the cooling period. Care must be taken to avoid displacement of IV lines during placement in and removal from the bath.

As body temperature drops, mental status will improve in many heatstroke victims. When awake, most people find ice water immersion difficult to tolerate. IV sedation may be required.

Finally, this technique is labor intensive. Several caregivers must be present throughout the process. The patient's head must be maintained out of the bath. If massage is used, one or more individuals will need to immerse their own hands in water to continuously massage the patient. Medications should be given IV, and constant attention to temperature and ECG monitors is also necessary. This cooling technique should be used only if adequate personnel are available.

**Whole-Body Ice Packing**

Packing the heatstroke victim in ice may enhance conductive heat loss without the attendant logistical problems caused by water immersion (Fig. 72-1) . Constant attendance, as required for skin moistening with evaporative cooling and as described for immersion cooling, may not be necessary with ice packing. Kielblock and colleagues demonstrated in a human study of mild, exercise-induced hyperthermia that whole-body ice packing cooled just as fast as evaporative cooling (see Table 72-2) . [60] Whether these results will also be observed in heatstroke victims with much higher body temperatures remains to be determined. Further study of this technique is required before a clear recommendation can be made regarding its value in relationship to other heatstroke therapies.

**Procedure**

Whole-body ice packing is accomplished by undressing the patient completely and then covering the extremities and torso with crushed ice. As with any cooling technique, constant temperature monitoring using an electric thermometer and a long, flexible rectal probe is recommended.

The ice should be removed, and the patient should be dried off when the rectal temperature reaches 39 °C. A large supply of crushed ice will be needed whenever this technique is used. Whole-body ice packing can usually be performed on the emergency department (ED) stretcher without additional equipment. As with immersion cooling, ECG monitoring can potentially be difficult owing to shivering artifact and displacement of electrodes.

Alert patients usually do not tolerate ice packing well, and IV sedation or restraint is

usually required. Excessive shivering can be treated with benzodiazepines if the rate of cooling is decreased.

Logistically, ice packing may be problematic. Ideally the patient is placed in a container that facilitates ice contact with the skin and prevents water from dripping onto the floor. This is best accomplished by placing the patient in a child's lightweight plastic pool, which is available in toy stores. Lacking this equipment, plastic cloths or trash bags may be placed under the patient with the edges curled up to form a sling-like apparatus.

## Strategic Ice Packs

Noakes has suggested that selective placement of ice packs over areas of the body where large blood vessels run close to the skin may be an effective cooling technique. [69] Cooling in these areas would occur despite cutaneous vasoconstriction, owing to direct conductive heat loss from the blood within the vessel, across the vessel wall, SQ tissue, and skin, to the ice. The most common areas used for strategic ice packing are the anterior neck (carotid and jugular vessels), the axilla (axillary artery and vein), and the groin (femoral vessels). Kielblock and associates' study of this technique reported a cooling rate slightly slower than that seen with evaporative or whole-body ice pack cooling (see Table 72-2) . [60] In addition, application of ice packs, although easier to perform than immersion or total-body ice packing, limits the conductive cooling offered by the latter two procedures. [24] However, one clinical trial demonstrated that a combination of strategic ice packs with evaporative cooling resulted in faster cooling than either technique alone, although the relative increase achieved by adding ice packs to evaporative cooling was small. [60]

In unconscious patients or in awake patients who can tolerate ice packs without excessive shivering, this technique could be added to evaporative cooling. However, the clinical value of strategic ice packs alone or in combination with other techniques remains to be determined. Anecdotally, during the Chicago heat wave of 1995, the majority of heatstroke patients who presented to EDs survived after being effectively cooled using the evaporation method accompanied by strategic placement of ice packs.

### Procedure

This technique is best accomplished by placing large plastic bags filled with crushed ice or an ice water mixture in both axillae and over both femoral triangles. If the neck is used, the packs must be placed laterally, with care taken not to compress the trachea or apply excessive weight over the carotid arteries. The neck area should probably not be packed in the presence of carotid bruits or a history of cerebrovascular disease. Some sources advocate rubbing the body surface briskly with plastic bags containing ice after the body has been wet down with water. This is effective, provided it is combined with evaporation therapy. [52]

### Complications

Complications of strategic ice packing are limited to shivering and patient discomfort as

described for whole-body ice packing previously. The ice packs should be removed when rectal temperature reaches 39 °C to avoid excessive core temperature drop.

## External vs Core Cooling

All of the external cooling techniques described previously are noninvasive and use heat loss by evaporation or conduction across the skin as the primary cooling mechanism. With each of these techniques, dropping of the central temperature will continue even after the technique is discontinued and the skin is dried. This is due to a delay in the establishment of an equilibrium between the cold skin and the core. The amount of "core afterdrop" can exceed 2 °C. For this reason, cooling should usually be discontinued when the core temperature reaches 39 °C.

Because the sites of significant cell damage with heatstroke are centrally located (e.g., liver, kidney, heart), central cooling techniques theoretically are preferable to external techniques. Iced gastric lavage and peritoneal lavage are the two central techniques that have been studied in both animal models and human heatstroke. Cooling via the respiratory tract has been studied in animals but not investigated clinically. [74] Central cooling techniques are necessarily more invasive than external techniques and therefore have the potential for more significant complications.

## Cold Gastric Lavage

The stomach lies in close proximity to the liver, great vessels, kidneys, and heart. The gastric mucosa is not subject to the intense vasoconstriction observed on skin exposure to ice water. [75] For these reasons, lavage of the stomach might be expected to be an effective central cooling method. In a canine model, lavage with ice water at a rate of 200 mL/min produced cooling rates that were slower than those seen with evaporative cooling. [76] Human heatstroke victims have been successfully cooled with gastric lavage, but only in combination with external techniques. [71] Cold gastric lavage seems best suited for use in patients with severe hyperthermia who are cooling at a slow rate with external techniques alone. The presence of an endotracheal tube and the passage of a large-bore gastric tube make rapid lavage without aspiration possible. This technique should be reserved for patients whose airway is protected by endotracheal intubation and who do not have a contraindication to gastric tube placement (see Chapters 43 and 45) .

### Procedure

Cold gastric lavage is best accomplished by instilling 10 mL/kg of iced tap water into the stomach as rapidly as possible (usually over 30 to 60 seconds). After a 30- to 60-second dwell time, the water is removed by suction or gravity. [57] Cooling will theoretically be faster if a high temperature gradient is maintained in the stomach. To this end, the lavage should proceed quickly. A faster lavage rate is usually maintained if suction is used to withdraw instilled fluid. A large container of ice-temperature water maintained 1 to 1.5 m above the patient's body will facilitate instillation of fluid. This container should be directly connected to the lavage tubing and should ideally allow passage of water but not ice, which may occlude the tube. Since large volumes of water

are needed, it is helpful if additional ice can be added to the container without interrupting the lavage. A large syringe can be used as an alternative to gravity instillation, but this is usually slower.

A simple system that accomplishes this procedure can be devised from readily available equipment in most EDs. A standard lavage setup (for use in drug overdoses) and a large-bore gastric tube are used. The lavage bag is cut open at the top to allow water and ice to be added. It is then suspended above the patient's body and connected to the orogastric tube by Y tubing with clamps. The other arm of the Y tubing is connected to suction. Using the clamps, ice water can intermittently be instilled by gravity and withdrawn by suction.

### Complications

A major potential complication of cold gastric lavage is pulmonary aspiration. The use of a cuffed endotracheal tube should minimize the incidence of this complication. Owing to the large volume of water used and the frequent depression of airway reflexes seen with severe heatstroke, this technique should rarely be used in a patient who is not endotracheally intubated.

If tap water is used, water intoxication, hyponatremia, and other electrolyte disturbances are *potential* complications. Water is absorbed from the stomach and, with large-volume lavage, may pass the pylorus into the small intestine. In canine studies, large-volume gastric lavage with tap water did not cause electrolyte abnormalities. [57] The actual incidence of these potential complications in human heatstroke has not been determined. The use of normal saline instead of tap water would eliminate this potential problem.

Theoretically, the passage of cold water through the esophagus, located directly behind the heart, has the potential to induce cardiac dysrhythmias. Dysrhythmias have not been observed in canine studies or in case reports of human heatstroke victims cooled with this technique.

## Cold Peritoneal Lavage

The surface area and blood flow of the peritoneum greatly exceed those of the stomach. Peritoneal lavage would therefore be expected to exchange heat much faster than is possible with gastric lavage. Bynum and coworkers' study of peritoneal lavage (6 °C fluid) in dogs demonstrated the fastest cooling rate ever reported in large animal or human studies (see Table 72-2) . [70] A case report of peritoneal lavage cooling in human heatstroke also demonstrated rapid cooling. [72] As with gastric lavage, this central cooling technique offers the advantage of directly cooling the core organs that are most susceptible to thermal damage. Unlike with gastric lavage, endotracheal intubation is not required.

Peritoneal lavage is a more invasive cooling technique. Surgical placement of the lavage catheter is necessary. Since heat exchange is more efficient across the

peritoneum, smaller volumes of fluid can be used. This cooling technique is relatively contraindicated by conditions that preclude placement of a lavage catheter (e.g., multiple abdominal surgical scars) (see Chapter 46) .

Peritoneal lavage is the most rapid central cooling technique. It can theoretically be combined with other techniques to speed cooling of the heatstroke patient with refractory hyperthermia. Being the most invasive cooling technique, it requires time, proper equipment, and surgical expertise to institute. Its use is probably best suited to situations in which heatstroke patients are not responding to external cooling and adequate equipment and personnel are readily available.

In a canine investigation, White and associates demonstrated that a simple noninvasive evaporative cooling technique was just as rapid and effective as peritoneal lavage for cooling and treating heatstroke. [73]

**Procedure**

To institute peritoneal lavage cooling, 2 to 8 L of sterile saline should be immersed in an ice water bath to cool while the catheter is being placed. A standard peritoneal lavage catheter (as for diagnostic use in trauma patients) is placed using any of the techniques described in Chapter 46 . [72] Standard contraindications apply. Use of a larger peritoneal dialysis catheter may speed fluid instillation and withdrawal. Actual lavage volumes and rates have not been established. One approach is to instill and withdraw 500 to 1000 mL every 10 minutes until adequate cooling has been achieved. Rectal temperature may be falsely low during the lavage owing to the presence of cold water about the rectum at the level of the rectal temperature probe. [70] It may be preferable to monitor tympanic membrane or esophageal temperature when using this technique. The lavage should be discontinued when core temperature reaches 39 °C to avoid excessive core after-drop.

**Complications**

The potential complications of peritoneal lavage cooling are primarily related to placement of the catheter and include bowel or bladder perforation and placement into the rectus sheath rather than the peritoneum. These potential problems are discussed further in Chapter 46 .

## Other Cooling Techniques

"Rewarming" techniques are used to minimize ongoing heat loss via the respiratory tract in hypothermic patients (see Chapter 71) . [77] Although high-frequency jet ventilation (HFJV) causes core cooling in critically ill patients, [78] [79] efforts to use the respiratory tract to cool heatstroke victims have thus far been unsuccessful. In a canine model of heatstroke, the use of HFJV has shown it to be a relatively ineffective cooling technique. [74] Heat loss by convection (air transfer) is relatively inefficient compared with the conductive heat loss mechanism used by other cooling techniques. The use of dry, hot air to maximize evaporative heat loss from the lungs might cause respiratory

complications. [79]

Ice water lavage of the bladder, colon, or thorax has not been investigated as a cooling technique. Obvious logistical problems decrease the potential effectiveness of these approaches. In addition, the central cooling rate achieved would probably not be faster than the relatively slow rate seen with gastric lavage.

Hemodialysis or partial cardiopulmonary bypass could theoretically be used to cool heatstroke patients. There are no animal or clinical data in the literature evaluating these invasive central cooling techniques.

## CONCLUSION

Rapid cooling is the key step in the emergency management of heatstroke patients. Survival approaches 90% when elevated temperatures are lowered in a timely fashion. [23] The highest documented temperature in the medical literature with survival is 48.8 °C (115 °F). In this case, the patient was rapidly cooled and recovered without neurologic sequelae. [14] Evaporative cooling appears to be the technique of choice. It combines the advantages of simplicity and noninvasiveness with the most rapid cooling rates achieved with any external technique. It is also logistically easier to institute, maintain, and monitor evaporative cooling than any other cooling technique. If a patient is not cooling rapidly with evaporative cooling, other techniques can be added. Strategic ice packs can be used. If the patient is endotracheally intubated, gastric lavage can be instituted. If facilities and personnel are available, peritoneal lavage cooling can be used as a rapid central cooling technique. If muscle rigidity is present or malignant hyperthermia is suspected, dantrolene sodium should be administered. In addition, the clinician should have a heightened index of suspicion for NMS and sympathomimetic drug toxicity. Regardless of the cause, a reasonable clinical goal is to reduce the rectal temperature to 40 °C or below within 60 minutes of instituting therapy.

Immersion cooling is best limited to centers with the proper equipment and skilled medical personnel experienced in managing hyperthermic patients. This method may also be effective in conditions in which electric power for evaporative cooling is unavailable (e.g., in wilderness settings where bodies of cool water are available nearby and the victim is far from more sophisticated medical care). Other cooling techniques require further study before a clear recommendation as to their efficacy can be made.

# Chapter 73 - The Sedative-Hypnotic Interview

**Kenneth V. Iserson**

Emergency physicians occasionally encounter patients who present with complaints of sudden, nontraumatic paresis or paralysis of the extremities or even catatonia-like states. [1] Although experienced emergency physicians usually suspect an underlying primary psychiatric etiology, nagging questions about the presence of exotic or rare organic etiologies often remain. [2] This dilemma, as well as the physician's frequent inability to alleviate acute symptoms, often causes difficulty and confusion in the patient's initial disposition and treatment. The use of a sedative-hypnotic interview in carefully selected patients may quickly resolve such problems. [3] [4] The procedure can be easily accomplished in either the emergency department (ED) or the physician's office in about 20 minutes.

## BACKGROUND

Most sedative-hypnotic interviews have used amobarbital (sodium isoamyl ethyl barbiturate). Indeed the procedure is generally called the "amobarbital interview" because amobarbital is the agent of choice. Amobarbital agent was first synthesized by Eli Lilly and Co in the late 1920s. It is a moderately long-acting barbiturate with a moderately rapid induction time. [5] In 1930, W. J. Bleckwenn began using amobarbital to produce a drug-induced narcosis for the treatment of neuropsychiatric disorders. Much of the psychiatric community quickly picked up and expanded the technique under the generic term "narcoanalysis." It was generally used in institutionalized or long-term patients. World War II brought a resurgent interest in the amobarbital interview. At that time, frontline medical clinics used the technique for soldiers with acute paralysis, amnesia, aphonia, or pseudocatatonic states. At that time, Grinker and Spiegel demonstrated the technique's use for both diagnostic and therapeutic purposes. Since World War II, the psychiatric community has lost interest in narcoanalysis. Current textbooks of psychiatry give little space to narcoanalysis, and many practicing psychiatrists have little familiarity with the technique. [13] However, the emergency medicine community developed an interest in the sedative-hypnotic interview for diagnosing and treating symptoms similar to war neuroses. [14] Use of the technique has been reported for a series of ED cases of catatonic-like symptoms and conversion reactions.

## INDICATIONS

The sedative-hypnotic interview is a rapid and safe method for distinguishing and treating the functional factors that contribute to several types of symptom complexes presenting to the ED. Over the years, a variety of indications have been developed for acute outpatient use of the technique. These indications include the following:

1. To resolve conversion symptoms to avoid their "crystallization" and permanence.
2. To treat acute panic states following such traumatic events as rape, catastrophic loss, or disaster.

3. To diagnose and treat mute and unresponsive patients (benign stupor) or patients with acute hysterical amnesia.
4. To diagnose malingering.
5. To reveal suicidal ideation.
6. To gain information in criminal cases (although this is of presumed dubious merit or legal worth). [16]
7. To differentiate between organic illness or organic psychosis and functional psychosis.
8. To differentiate functional psychiatric disorders, such as multiple personality disorders or pseudodementia, from other psychiatric disorders.

Emergency physicians must have tools to differentiate organic from functional illnesses and to treat life-threatening catatonic-like states. Medical evaluation of the patient with decreased responsiveness is fraught with pitfalls. Patients who appear to be catatonic or in benign stupor have been reported to have such conditions as intracranial infections and hemorrhage, [24] endocrine abnormalities, [25] liver failure, [26] atrioventricular (AV) malformations, tumors, and drug ingestions. [27] Delay in diagnosis and therapy has led to morbidity and deaths in patients with these conditions; adverse outcomes also may be seen with acute lethal catatonia. [28]

The difficulty of differentiating organic from psychiatric findings is highlighted by the report of Gould and colleagues. [29] They found that of 30 patients with proven structural neurologic damage, all demonstrated some characteristics that are classically attributed to hysteria, including the potential for secondary gain, indifference to a serious sign or symptom ("la belle indifference"), a nonphysiologic or nonanatomic sensory or motor examination, giveaway weakness on motor testing, and improvement with reassurance. Likewise, Fishbain and Goldberg [30] described "classic conversion disorders" in three patients with limb paralysis who were subsequently found to have serious underlying organic illness, including cerebral hemorrhage. Hence, clinical examination to seek an organic cause of neurologic symptoms should precede psychiatric evaluation, even when the symptoms appear functional. However, when the clinical examination does not clearly identify an organic basis for the symptoms, a sedative-hypnotic interview may provide additional diagnostic information.

Most ED experience with the sedative-hypnotic interview has been with adults presenting with 1 of 2 specific syndromes: either hysterical conversion reactions that significantly impair the patient's functions or a catatonia-like state. The catatonia-like state is different from the common condition that Plum and Posner describe as psychogenic unresponsiveness. [31] Patients with psychogenic unresponsiveness are usually hysterical, with symptoms lasting for several minutes. They lie with their eyes closed and actively resist opening the lids. When opened, the eyelids flutter or close rapidly rather than with the smooth motion seen in coma. These patients normally respond quickly to noxious stimuli and a firm approach by the ED staff.

Patients in a catatonia-like state, however, often present either in a state of mute wakefulness without response to verbal or tactile stimuli or in a mildly stuporous condition. Patients in a state of mute wakefulness often track the observer with their eyes (coma vigil, akinetic mutism) and may show a waxy flexibility of the extremities. [25]

Those in stupor are sometimes mistakenly assumed to have a neurologic condition or to have ingested drugs.

## CONTRAINDICATIONS

Contraindications to the sedative-hypnotic interview fall into two categories: psychiatric and medical (Table 73-1) . Most psychiatric contraindications are relative rather than absolute; that is, potential benefit from the procedure must be weighed against any potential harm. Patients presenting with an overt paranoid reaction or those unwilling to passively submit to the procedure are unlikely to gain maximum benefit and may incur additional psychiatric trauma from the interview. Likewise, overeager patients may be seeking secondary gain from the procedure. Using this technique on such patients may be both dangerous and unnecessary.

Medical contraindications are both absolute (i.e., porphyria and barbiturate allergy when amobarbital is used) and relative. Relative contraindications include already being under the influence of depressant drugs and having a history of sedative-hypnotic addiction, although the interview also

| | **Medical Contraindications** | **Psychiatric Contraindications** |
|---|---|---|
| | **TABLE 73-1** -- Contraindications to an Amobarbital Interview | |
| Absolute | Porphyria Allergy to barbiturates | None |
| Relative | History of barbiturate addiction<br>Under influence of depressant drugs<br>Severe liver, cardiac, or renal disease<br>Severe hypertension or hypotension (only if >500 mg is used)<br>Pulmonary infection or edema | Paranoid reaction<br>Unwilling patient<br>Overeager patient |

can be used as a test of current addiction. However, even when there is concomitant drug ingestion, the interview may still be performed if the dose of sedative-hypnotic is very carefully titrated. Relative contraindications also include the presence of severe liver, cardiac, or renal disease. Severe hypertension or hypotension may suggest an organic cause, but use of the drug in these states poses a medical risk only if more than

the maximum safe dose (e.g., 500 mg of amobarbital sodium, IV) is given. The presence of mild pulmonary infection, pulmonary edema, or laryngitis poses only the theoretical risk of increasing the chance of laryngospasm. Generally, *in the presence of significant concomitant medical disease, it is best to forego the amobarbital interview* and to concentrate on stabilizing the condition of the patient in the ED. The interview may be performed later during the hospital stay.

## EQUIPMENT

The sedative-hypnotic interview should never be attempted unless the proper time, space, equipment, and ancillary personnel are available. A relatively quiet room, a stretcher or table with side rails up, and basic resuscitation equipment (airway, intubation equipment, bag-valve-mask setup) are the primary requirements. Intravenous access with an injection port and infusion fluid (generally 1 L of 0.9 normal saline) should be routine.

Sodium amobarbital is not the only drug that has been used in this manner. Some psychiatrists now use thiopental and mixtures of thiopental and amobarbital. [32] Others have used chloroform, *Cannabis indica*, paraldehyde, scopolamine, chloral hydrate, and most modern barbiturates for the same purpose. [33] Patients with psychogenic respiratory symptoms (often attributed to conversion disorders) have responded to benzodiazepines and other sedative-hypnotic agents. [34] However, the safety, efficacy, and dosages for optimal results using these drugs for the sedative-hypnotic interview have not been well established. Therefore, amobarbital is recommended for this procedure in the ED.

Amobarbital sodium (Amytal Sodium, Eli Lilly and Co) is supplied as a dry powder that must be reconstituted with sterile water. In reconstituting the amobarbital, it is important to rotate, not shake, the ampule. Five hundred milligrams of amobarbital sodium should be prepared as a 5%-by-weight solution by diluting 500 mg of the powder in 10 mL of sterile water. Note that because amobarbital has relinquished its role as a mainline anticonvulsant drug, many hospitals no longer keep it in stock. Its main use now is for the neurologic diagnostic Wada test (i.e., direct anesthesia of the hemicortex).

## PROCEDURE

A medical history emphasizing prior psychiatric problems, drug overdose and abuse, allergies, medications, and contraindications to the procedure must be obtained from the patient, relatives, or friends. A complete physical examination must be performed to identify any obvious organic problems. Glucose, blood urea nitrogen (BUN), electrolytes, and a complete blood count (CBC) are obtained in cases of stupor to eliminate medical causes. Appropriate specimens for toxicology should be obtained, and administration of glucose, naloxone, and thiamine should be considered for the stuporous patient. Prior records, when obtainable, should be reviewed. If a proper history, physical examination, or laboratory analysis is not possible, the procedure should not be performed. *The physician's zeal to try the procedure should not tempt him*

*or her to take shortcuts or to examine the patient hastily.*

After deciding that the symptoms are possibly of a nonorganic psychiatric origin, the clinician explains the sedative-hypnotic interview procedure to the patient or to the relatives. Reassurance should be given that amobarbital is not, in fact, "truth serum." The patient should be placed in a relatively quiet room with the patient's relative or a chaperone in attendance. It may be extremely helpful for relatives to observe the interview, because it is often difficult for them to comprehend that certain symptoms, such as paralysis, have a psychogenic basis. Successful results may further reinforce the need for the family to arrange for follow-up psychiatric care.

An intravenous (IV) line should be secured in a large peripheral vein. Sodium amobarbital (5% solution) is administered at a rate of 50 mg (0.5 mL)/min. A conversation (or monologue in the case of a stuporous patient) about benign, nonthreatening topics should be held with the patient during induction. A calm, reassuring attitude and suggestions similar to those given during hypnotic inductions are useful, because the effect of the interview may be as great as that of the medication. [35] [36]

A close similarity exists between the state produced with amobarbital and the light stages of hypnosis. [37] Some investigators have, in fact, considered it just another hypnotic medium that allows simple, direct psychotherapy with little or no analysis. [38] If a psychiatrist is present during the interview, some of the information obtained can be beneficial in future analysis. We suggest that whenever possible, the interview should be performed in consultation with a psychiatrist who will be involved in the subsequent care of the patient.

The levels of narcosis are staged using the criteria developed by Lorenz and associates (Table 73-2) . [39] The interview is conducted during stage II narcosis; stage III narcosis (absence of corneal reflexes) should be avoided. When stage II is reached, the actual interview is begun. It usually requires 250 to 500 mg of amobarbital to reach this stage, although some investigators report success with as little as 100 mg. [14]

| TABLE 73-2 -- Stages of Narcosis in the Amobarbital Interview<br>*Data from Lorenz WF, Reese HH, Washburne AC: Physiological observations during intravenous sodium amytal medications. Am J Psychiatry 13:1205, 1934.* |
|---|
| **Stage I: Induction of narcosis** |
| Patient begins to describe symptoms of the amobarbital, e.g., lightheadedness, dizziness, sleepiness, blurred vision |

| |
|---|
| **Stage II: Conduction of the interview** |
| The unresponsive patient begins to communicate or the responsive patient becomes more talkative or euphoric |
| Usually requires a total of 250-500 mg amobarbital (may occur with as little as 100 mg) |
| **Stage III: Obtundation--should be avoided** |
| Patient is unresponsive, corneal reflexes are absent |

The patient is initially questioned regarding such nonthreatening topics as identification data, current personal situation, predisposing factors, and further medical history (including drug ingestion).

The next stage of the interview is tailored to the specific problem. For example, if the patient has paralysis of an arm or leg, the interviewer suggests that the patient try to move and use the affected part. Once the paralysis is overcome, the interviewer reinforces the fact that the extremity is now back to normal and that it will continue to be normal after the patient leaves the hospital. This is analogous to the familiar "posthypnotic suggestion." It is not advisable to confront the patient with a psychiatric diagnosis at this time, even though such a diagnosis is now obvious to the family. If the patient is catatonic or unresponsive, spontaneous speech or movement will return. The clinician should emphasize to the patient that such a responsive state is normal and desirable. Patients with organic and/or toxic psychoses will not respond verbally and will merely fall asleep or become more sedated during the interview. If this occurs during the interview process, the interview can be terminated with the knowledge that the patient's symptoms should be presumed to have an organic origin. Patients who have an organic basis for paresis or paralysis will still show this deficit during the interview.

Near the end of the interview, it is suggested to the patient that he or she remember a pleasant occurrence. This helps to improve the patient's emergence from the interview. A few patients may become slightly upset during the interview. They can be given an extra 50 to 100 mg of amobarbital at the conclusion of the interview to obtain a slightly longer sleep period. [40] Respirations are the only vital sign monitored after the procedure begins. As long as sodium amobarbital is given by this protocol, there are no

significant effects on blood pressure, pulse, or respiratory rate. [39] A cardiac monitor is not required routinely, but it is advised in any patient with cardiovascular disease and in the elderly. Patients who are not hospitalized should be observed for 2 to 4 hours after the interview has been completed. Patients usually fall asleep for 2 to 3 hours following the conclusion of the interview, and when the patient is awakened, the proper disposition should be made.

Catatonic and pseudocatatonic patients who now have established psychiatric diagnoses should be admitted to a psychiatric service. Patients with resolved conversion reactions can be discharged with follow-up. When a psychiatric basis cannot be proven, the patient requires further evaluation for a presumed organic etiology.

## COMPLICATIONS

Many thousands of amobarbital interviews have been conducted with few complications, usually in settings that were not conducive to advanced life support. Nevertheless, resuscitation facilities must be readily available if this procedure is undertaken. The few complications reported have primarily been respiratory depression or apnea and were associated with too-rapid administration (i.e., >50 mg/min) or, occasionally, too much (i.e., >500 mg) of the drug. [42] Vasomotor collapse and laryngospasm also have been reported on rare occasions. (See Chapters 1 , 2 , 3 , and 4 for a discussion of the approach to laryngospasm.) The latter complications are reported to occur only in stage III (usually >700 mg amobarbital) or anesthetic levels of narcosis, and they are not reported at all in most series. Most complications are probably related to physician error or inaccurate calculation of drug doses.

## INTERPRETATION

The patient suspected of having psychiatric symptoms who does not initially respond to the amobarbital interview warrants intensive further investigation for an anatomic or physiologic basis for the deficit. Failure to alleviate symptoms with the amobarbital interview is often due to the failure of the physician to make the proper preinterview diagnosis. This usually results from an inadequate physical examination or incomplete laboratory or radiographic evaluation prior to the technique's being used. If the patient has a firm belief or delusion, such as a feeling that he or she is God or is from outer space, the amobarbital interview will not abolish that belief. Likewise, it will not render a schizophrenic normal while he or she is under the influence of the drug. [43]

Some cases of catatonia may not respond to this technique. It must be emphasized, however, that if a psychiatric diagnosis is not firmly made from the results of the interview, it is mandatory that the patient receive intensive medical care and evaluation before being referred to a psychiatric facility.

In certain organic conditions, the amobarbital also may be therapeutic. For example, drug withdrawal states or seizure disorders may be ameliorated with the technique. Generally, clinical evaluation will permit the differentiation of these "false-positive" conditions from a conversion disorder, although petit mal or partial complex seizure

disorders may be problematic. Finally, malingering may produce a "false-negative" response, as the patient may continue to deceive even an astute observer.

## ALTERNATIVE APPROACH: HYPNOSIS

For clinicians experienced in the technique, hypnosis may be a more rapid, less invasive, and less costly approach to resolving symptoms of conversion reactions and acute catatonia. The simplest induction methods involve gentle suggestions that the patient progressively relax different areas of the body, beginning with the toes. The clinician times the suggestions to correspond with the patient's breathing (i.e., with exhalation). If successful, hypnotic induction and resolution may take only minutes. Unlike stage hypnosis, the results of clinical hypnosis are obvious, if successful; the person moves or speaks. In one case, a "paralyzed" teenager who had been rushed into the ED on a makeshift backboard walked back out to greet his anxious friends <10 minutes later (on his way to his first psychiatry appointment). Hypnosis also has been demonstrated to effectively allow fracture and dislocated joint reductions in emergency medical situations. [44] Training in clinical hypnosis is widely available.

## CONCLUSION

The amobarbital interview has been shown to be a rapid and safe technique that can be readily performed by the emergency physician. It is useful for the confirmation of the psychiatric basis of stupor in patients with catatonic-like states and for diagnosis and resolution of similarly based nontraumatic paresis and paralysis. It is suggested that, when possible, the procedure be carried out in conjunction with a psychiatric consultation and (subsequent) evaluation to obtain the maximum clinical benefit.

# Chapter 74 - Bedside Laboratory and Microbiologic Procedures

Anthony J. Dean, David C. Lee

## ASSESSMENT OF URINE

### Evaluating Bacteriuria

The medical literature can be difficult to interpret with regard to urinalysis (UA) and culture for evaluation of bacteriuria and its clinical significance. Much confusion has arisen because of failure to standardize meatal cleaning procedures or collection techniques, mixing symptomatic patients with asymptomatic ones, and generalizing conclusions across varied patient groups (e.g., men vs women, boys vs girls, circumcised vs uncircumcised males). Although several studies have failed to demonstrate a statistical difference in contamination rate with various urine collection techniques, most studies show trends in favor of more meticulous and/or invasive collection methods. In general, potential contamination is most problematic when low-level bacteriuria is demonstrated in symptomatic, rather than asymptomatic, patients.

Patients with lower urinary tract infection (UTI) symptoms (e.g., urgency, frequency, dysuria, in the absence of fever) can have a UTI with $<10^5$ colony forming units (CFU)/mL in the urine. [1] [2] This important fact had been obscured by studies on *asymptomatic* patients, which demonstrated that the threshold for "significant bacteriuria" in this group is $10^5$ CFU/mL. [3] [4] *Symptomatic* patients with low-count bacteriuria should not be erroneously diagnosed as uninfected, because infection can indeed be present with as few as $10^2$ CFU/mL. [2] Furthermore, specimens are not necessarily contaminated if multiple pathogens are isolated. Up to 50% of symptomatic women may have polymicrobial infections. [5] [6]

### Obtaining a Urine Specimen

Several methods are available for obtaining a urine specimen. These can be listed in order of increasingly precise collection techniques, which tend to come at the cost of increasing difficulty and/or patient discomfort:

1. *Random voided:* Any specimen provided by the patient.
2. *Midstream voided:* No skin preparation, container placed in urinary stream 2 to 3 seconds after the initiation of micturition.
3. *Clean catch:* Same as item 1, with antiseptic cleansing of the urethral area.
4. *Midstream clean-catch* specimen (MSCC): Cleansing as in item 3, with midstream collection as in item 2.
5. *Catheterized:* Obtained from a newly placed catheter.

6. *Suprapubic aspiration* (SPA) (see Chapter 59) .

Since the mid-1950s there have been proponents and opponents for each technique, with arguments that vary according to the clinical context. When the clinician is interpreting findings of tests for bacteriuria and pyuria and culture results, it is important to be cognizant of the method of urine collection used.

The low levels of bacteriuria induced in 2% to 8% of patients after straight catheterization [7] are generally clinically insignificant. Catheterization does cause minor local injury, as reflected by bacteriuria and low-level hematuria (1 to 3 red blood cells [RBCs]/high-powered field [hpf]) in 15% of patients. [7] [8] SPA in neonates continues to be advocated by some in cases in which accurate diagnosis is essential and the risk of infection must be minimized. SPA (see Chapter 59) , has a 10% "failure rate" (i.e., no urine obtained after 3 attempts) in most series and may actually take longer than most methods, especially when multiple attempts are considered. SPA can also cause spuriously lowered leukocyte or bacterial colony counts due to the necessity of maximally filling the bladder prior to performing the procedure. [9]

**Recommendations for Urine Collection**

A selective approach (Fig. 74-1) can be taken in obtaining a urine specimen to evaluate for UTI. The first issue to address is whether the patient is symptomatic. If no symptoms of UTI are present, the urine examination can be considered as a "screening" test. Routine screening for asymptomatic bacteriuria in the general population has been shown to be unwarranted in all but 2 clinical situations: pregnant women and all patients for whom urologic surgery has been scheduled. [10] [11] Although neither of these is a major concern of the emergency physician, testing of urine frequently occurs in the emergency department (ED) in the setting of undifferentiated abdominal pain or fever.  If only a urine culture is to be performed, some would argue that any spontaneously voided specimen would suffice, since the diagnosis of asymptomatic bacteriuria depends on $10^5$ CFU of a single pathogen per milliliter of urine, and with such criteria, contaminants are usually easily identified. [12] However, performing cultures in all such patients is prohibitively costly, so that dipstick and/or UA is usually acceptable for screening. [13] [14] With these screening tests, however, contamination by bacteria, leukocytes, or erythrocytes can still cause diagnostic confusion. Thus, the advantages of a less contaminated specimen are worth the minimal extra effort of asking the patient to provide an MSCC sample. For female patients who are physically capable, the ideal position is sitting astride a toilet, facing backward. This helps to separate the labia and position the cup for a midstream specimen.

The typical ED patient is in some way "symptomatic." This includes patients with classic signs and symptoms of UTI as well as those with systemic signs of infection (e.g., fever and chills) who are unable to accurately report on symptoms. To this group should be added all patients in whom one cannot afford to miss asymptomatic bacteriuria (e.g., the immunocompromised, neonates and infants, pregnant patients, diabetics), or for whom urine cultures are going to be necessary because of a history of relapsing, recurrent, complicated, or childhood UTI. [15] In cooperative, motivated males and females with symptoms of uncomplicated lower UTI or pyelonephritis who are capable of diligently

performing the necessary maneuvers, an MSCC specimen is as accurate as a catheterized specimen, especially when the possibility of urethral and/or prostatic trauma and patient discomfort are considered. [16] In females in whom symptoms are equivocal, and in all patients unable to provide an MSCC specimen, a catheterized specimen is usually warranted.

The above approach covers the vast majority of situations. A few circumstances and techniques deserve special mention.

**Bladder Percussion and the Midstream Specimen in Infant Males**

The emergency physician is familiar with how frequently a urine stream is generated in infants who are confronted by the alarming ED environment and a cold stethoscope. Such responses can be exploited by the application of cold povidone-iodine to the genitalia with an open sterile urine container at hand. Such an approach has been shown to generate a urine sample in a median time of 10 minutes. [17] This is much less than the time needed for an average straight catheterization or suprapubic aspiration, especially since it can be performed during the history and physical examination and avoids the potential for iatrogenic complications. If the urine specimen is not immediately forthcoming, a parent can be instructed to catch the specimen in the sterile container, freeing up ED staff for other tasks.

Two techniques to actively induce voiding in infants have been described. The first, which is useful in newborns, exploits the Perez reflex. [18] After cleansing of the genitalia (with povidone-iodine or some equivalent non-irritative antibacterial agent), the infant is held in one hand while the paraspinal muscles are stroked, cephalad to caudad. This causes extension of the back, and flexion of the hips and induces micturition in <5 minutes in the majority of cases. [18]

The second technique is known as "bladder tapping." After urethral cleansing, if there is still no urine, 2 fingers may be tapped on the suprapubic area at a rate of approximately once per second for a full minute, followed by a minute's rest. The cycle is then repeated until urine is produced. The mean time prior to the production of urine is about 5 minutes. [19]

**Bag Collection in Non-toilet-trained Children**

The incidence of unsuspected UTI in the febrile neonate or infant is about 3 to 5%. Because a true UTI in an infant or child requires a subsequent evaluation for urinary tract pathology, and the disease may produce significant morbidity (e.g., hypertension, renal disease), one must be certain of the presence or absence of infection in this subgroup. Numerous studies demonstrate the disutility of urine specimens obtained for culture from a collection bag stuck to an infant's perineum. Bag specimens obtained for a routine UA in suspected UTI are equally unreliable, with white blood cell (WBC) concentrations routinely 25-fold higher and bacterial counts 1000-fold higher [21] than in a catheterized specimen. In the occasional situation in which urine is needed exclusively for chemical analysis (e.g., glucose, ketones, urobilinogen, pH, or specific gravity), a bag specimen will suffice. The utility of obtaining a bag specimen to "screen" the UA

prior to deciding on antibiotic treatment or whether to send a formal culture is only defensible if the suspicion of UTI is low, as the sensitivity for markers of a UTI (see below), is only 50 to 85%. [20] [22] In summary, an MSCC or catheter or SPA specimen is required for an accurate UA or urine culture in neonates and infants.

**Urine Specimens from Patients with Chronic Urinary Drainage Systems**

Urine obtained from any part of a chronic urinary drainage system is highly inaccurate for bacteriologic purposes. If UTI is suspected, a new catheter should be inserted and fresh bladder urine specimens subsequently obtained. [23] A small study advocating replacement of a chronically applied "Texas sheath" catheter with a fresh one was performed on subjects who did not have symptoms of UTI. [24] Such a method might be sufficiently accurate for screening of asymptomatic patients, but a Foley catheter should be used to obtain urine from patients with sheath catheters who have signs or symptoms of acute UTI.

## Urine Dipstick

Urine dipstick tests are now available to test for 10 separate parameters. Each colored square on a urine dipstick represents a complex technologic assay. It is essential to *meticulously follow the manufacturer's instructions for storage and use.* [25] Even with optimal storage and testing conditions, the false-negative and false-positive rates of these tests are problematic. In addition, most of the tests are susceptible to interference from a variety of substances (Table 74-1) .

**Method**

Urine specimens should be tested as soon as possible after they are collected. If urine has been standing, it should be stirred or shaken well, because cells rapidly sink in a container. The test strip should be completely immersed for 1 second or less. The edge of the strip is drawn along the rim of the specimen container and can also be lightly tapped to remove excess urine, thus avoiding mixing of the reagents between different test patches. Hold the strip horizontally or place it on a clean gauze pad until the recommended time has elapsed. Most strips are designed so that all of the tests can be read together after 1 to 2 minutes.

**Interpretation**

**Glucose**

The urine glucose test is normally negative. Urine glucose testing has limited usefulness in quantitative testing because the serum glucose level at which spillage occurs varies (although in most patients it starts at between 180 and 200 mg/dL). [26] Changes in urine glucose lag behind changes in blood glucose by approximately half the interval between voids. [27] Glycosuria in the absence of hyperglycemia suggests renal tubular dysfunction. Glycosuria may occur in hypothermic patients in the absence of hyperglycemia, and indeed may mask true hypoglycemia in alcoholic patients who are

hypothermic. [28]

**Ketones**

Ketones are found in the urine during starvation, inadequate carbohydrate intake, diabetic and alcoholic ketoacidosis, isopropyl alcohol poisoning, or glycogen storage disease. Urine testing for ketones is not sensitive to all forms of ketonemia or ketonuria, and the absence of a positive ketone test by dipstick should not categorically dismiss a significant ketotic state. Tests for urine ketones are 5 to 10 times as sensitive to acetoacetate as to acetone. Similar to the serum "acetone test," dipsticks do not detect 5-hydroxybutyrate, which comprises 80 to 95% of the 3 "ketone bodies," and is the predominant form in the setting of ketoacidosis. However, urine ketone testing is significantly *more* sensitive than serum ketone testing. [29] Indeed, there is generally no need to obtain "serum acetones" to diagnose or manage diabetic ketoacidosis (DKA) when urine ketone monitoring is coupled with blood gas and anion gap analyses. When an evaluation for an individual ketone body is required, serum should be specifically analyzed for acetone (the major ketone produced by isopropyl alcohol poisoning) or 5-hydroxybutyrate (the predominant ketone of alcoholic or diabetic ketoacidosis).

**Nitrites**

Normally, urine does not contain nitrites. Nitrites are specific (approximately 95%), but not sensitive (approximately 45%) indicators of UTI. Urinary nitrates are converted to nitrites most strongly by enteric coliform bacteria, explaining the nitrite test's 90% sensitivity in detecting UTI caused by *Escherichia coli*. [32] *Enterococcus*, a moderately frequent urinary pathogen, as well as *Pseudomonas* spp. and *Acinetobacter*, do not convert nitrates to nitrite and therefore are not detected by the nitrite test. False-negative results also occur because of lack of dietary nitrate, frequent voiding, and/or diuresis. [9] Early morning-voided specimens are ideal (allowing time for conversion of nitrate to nitrite), but they are rarely available in the ED; if possible, a specimen obtained 4 hours after the last voiding is preferred.

**Protein**

Proteins with molecular weight below 50,000 to 60,000 daltons can pass through the glomerulus to be reabsorbed in the proximal tubule. Normal protein passage in the urine is <150 mg/24 hours, or approximately 10 mg/dL of urine. About 10 to 33% of urinary protein is albumin, 33% is Tamm-Horsfall glycoprotein (secreted by renal tubular cells), and the balance is made up of a variety of immunoglobulins and other proteins. Proteinuria is a finding noted in about 5% of routine urine screens in men. [33] Whether this represents a normal variant is unclear, as 3 to 5% of young healthy adults have postural proteinuria (proteinuria when

**TABLE 74-1** -- Overview of Urine Dipstick Tests

|  | **Sources of Error and Artifact** | **Comments** |
|---|---|---|
| Glucose | False-negative with ascorbate, ketones, and increased SG | Hypothermia may cause glycosuria despite hypoglycemia |
|  | False-positive with peroxide and hypochlorite |  |
| Ketones | False-positive with ascorbate, levodopa, valproate, pyridium, *N*-acetyl cysteine, high-protein diet, phenylketones, phthalein compounds | Very susceptible to deterioration with humidity, causing false-negative |
| Nitrites | False-positive with contamination, pyridium | 75% false-negative rate when dipsticks exposed to air for 15 days |
|  | False-negative with high SG, ascorbate, low urine pH, dilute urine, large urobilinogen, urine standing in specimen cup >2 hr |  |
| Protein | False-positive with pH >7, and chlorhexidine | Only reliable for albumin (glomerular proteinuria) |
|  | False-negative with low pH, very dilute urine |  |

| Blood | False-positive with povidone-iodine, certain (peroxidase- producing) bacteria, hypochlorite (bleach) False-negative with high SG, and high concentrations of urinary nitrites, ascorbate, or captopril | Positive test with speckles or dots implies nonhemolyzed blood Positive test with diffuse pattern implies hemolyzed RBC or myoglobin |
|---|---|---|
| Bilirubin | False-positive with iodine, stool contamination, chlorpromazine, mefenamic acid False-negative after prolonged standing | Hard to read with agents causing marked urine discoloration |
| Urobilinogen | False-positive with pyridium, gantrisin, sulfonamides, porphyrin, methyldopa, procaine, aminosalicylic acid, 5-hydroxyindolacetic acid | Use fresh specimen; rapidly broken down by light and in acid urine |
| | False-negative with gantrisin and pyridium | |
| Leukocyte esterase | False-positive with vaginal contamination (commonest cause), oxidizing agents, eosinophils in the urine, and *Trichomonas* | |
| | False-negative with high glocuse, ketones, protein (especially albumin), pH, or SG and male sex; cephalexin, tetracycline, pyridium, oxalates, ascorbic acid, neutropenia | |

| pH | Urea splitting bacteria elevate pH | Use fresh specimen: standing raises pH by loss of $CO_2$ |
|---|---|---|
| | Run off from protein strip can falsely lower pH | |
| Specific gravity | Overestimates true SG with low pH, ketoacidosis, and protein | Not reliable at SG >1.025 |
| | Underestimates true SG due to glucose, urea, or with pH >7 | |
| S G, specific gravity. | | |

standing, but not when recumbent). [26] The urine dipstick detects negatively charged proteins much more strongly than positively charged ones; it is therefore most sensitive to albumin.

Proteinuria can be due to either systemic or renal causes. The likelihood that a positive urine protein dipstick reflects renal disease increases with an increasingly positive result, and in patients with conditions such as hypertension, diabetes, connective tissue diseases, peripheral edema, gout, or elevated serum creatinine. Mildly elevated proteinuria in patients without systemic disease or renal insufficiency who have an otherwise normal urine sediment and are asymptomatic is likely of no clinical significance. [34] In assessing a patient with proteinuria, it is helpful to divide the list of causes into those associated with hematuria and those not so associated.

The urine dipstick test is positive for protein with pyuria of >6 WBCs/hpf. [35] This is technically a "false-positive" finding but is useful when the urine dipstick is being used to screen for a UTI. Hematuria only slightly elevates urine protein levels. A 2+ to 3+ urine protein dipstick reading with only mild or microscopic hematuria should suggest a glomerular or tubular cause. [36]

**"Blood"**

The blood section of the urine dipstick shows a positive result in the presence of RBCs, hemoglobin, or myoglobin. Guidelines for distinguishing these are outlined in Table 74-2

. Moderate intravascular hemolysis does not cause hemoglobinuria, as the hemoglobin is tightly bound to haptoglobin and is therefore not filtered. Massive intravascular hemolysis gives rise to free plasma hemoglobin with a molecular weight of 32,000 daltons, which can pass through the glomerulus. Myoglobin has a molecular weight of 17,000 daltons, permitting easy passage through the glomerulus.

Urine in young, healthy volunteers contains <7 RBCs/muL (RBCs/mm3 ). [37] Studies have shown that although the

**TABLE 74-2** -- Aids in Distinguishing Hematuria, Intravascular Hemolysis, and Myoglobinuria

| Urine microscopy | RBC, RBC casts, and protein implies glomerular source | Possible occasional RBC and tubular cells secondary to rhabdomyolysis-induced renal damage | Usually unremarkable |
|---|---|---|---|
| | No RBC casts, tubular cells, small protein: nephron source | | |
| | Just RBC: source distal to nephron | | |

urine dipstick is only 93% sensitive compared to microscopy of unspun urine at the very low level of 1 RBC/hpf, it generally is very sensitive to 10 RBCs/mm3 . [37] Hence, false-negative results are confined to clinically insignificant hematuria. [38] [39] In asymptomatic men >50 years old, significant disease can be signaled by intermittent positive dipstick hematuria, mandating careful follow-up of patients with this incidental finding. [40]

Dipsticks are vitiated by humidity and air and give false-negative results after improper storage. [41] Because RBCs lyse rapidly in urine with high pH or low specific gravity, delays in performing a microscopic UA may suggest myoglobinuria or hemoglobinuria. Microscopy or dipstick testing of a *freshly* obtained specimen can clarify this issue. The dipstick pad should be inspected for discreet positive "dots," indicative of nonhemolyzed RBCs. Conversely, urine with high specific gravity or low pH can inhibit the lysis of erythrocytes, which is necessary for the dipstick chemical reaction to occur, thus causing a false-negative result. [42] Povidone-iodine was reported to cause false-positive results in vitro, but a study reproducing typical clinical conditions demonstrated that this does not happen in vivo. [43] Iatrogenically caused trace positive results may occur after straight catheterization in 15% of cases, but at such low levels that they should not be a source of confusion with emergency urologic conditions. [8]

**Urine bilirubin**

Urine bilirubin represents the filtered, soluble, conjugated form of bilirubin. Unconjugated bilirubin is protein-bound, and does not pass through the glomerulus. Bilirubinuria is therefore due to intrahepatic or extrahepatic cholestasis. Bilirubinuria will be detected significantly earlier than clinical jaundice and thus is a sensitive test for early liver disease. Urinary bilirubin excretion is enhanced by alkalosis. A fresh sample of urine should be tested, because bilirubin glucuronide is hydrolyzed when exposed to light. Ascorbic acid and high levels of urinary nitrites decrease the sensitivity of the test

to bilirubin.

In a healthy person, conjugated bilirubin is excreted in bile. In the colon it is broken down into a number of compounds, which includes urobilinogen. Most of these compounds are excreted in the stool, giving the characteristic color. A small amount of urobilinogen is absorbed from the colon, and if it is not taken up on the first pass through the liver, it enters the circulation. Ultimately, some of this urobilinogen is filtered by the glomerulus to enter the urine, so that it is normal to have zero to moderate levels of urinary urobilinogen on dipstick testing. Most diseases causing hepatocyte dysfunction (viral or drug-induced hepatitis, cirrhosis, congestive heart failure with passive liver congestion, or cholangitis) also cause increased urinary urobilinogen excretion. This is because there is greater impairment of hepatic uptake of urobilinogen than there is of hepatic excretion of conjugated bilirubin. As a qualitative test with a wide range of normal values, it is rarely helpful, but in evaluating a patient with jaundice, it can have diagnostic significance (Table 74-3) .

**Leukocyte esterase**

This portion of the dipstick test is designed to detect enzymes from the azurophilic granules in neutrophils. Normally the test is negative. Studies report a wide and clinically important range of thresholds of sensitivity of dipstick testing, from 10 to 100 WBCs/mm3 urine. Studies suggest that the test is between 50 and 96% sensitive in detecting infection. The specificity is between 91 and 99%. The most common cause of a false-positive leukocyte esterase test is vaginal contamination.

**pH**

Average daily excretion of 50 to 100 mmol of H+ in the urine gives rise to a typical urine pH of approximately 6. Dietary protein lowers the urinary pH, whereas fruit and vegetables, especially citrus fruits, tend to increase it. The normal urinary pH ranges from 4.5 to 8. The significance of pH testing is in the assessment of normal renal function. In most states of alkalosis and acidosis, the healthy kidneys maintain homeostasis by conserving or excreting H+ . Failure

 to do so suggests renal disease, especially renal tubular acidoses (an exception is the "paradoxical aciduria" of hypokalemic alkalosis secondary to volume contraction, hypercorticism, or diuretics). In these circumstances, the highest priority of the renal tubule is to conserve sodium. Note that pH is falsely elevated by the action of urea-splitting bacteria, especially *Proteus* spp. This can occur with "stasis" of urine, either in the bladder or in specimen cups awaiting processing in the laboratory. A persistently alkaline urine is seen in patients with struvite (triple phosphate) urolithiasis.

**Specific gravity**

The dipstick test for urine specific gravity assays for the primary urinary cations, sodium and potassium. True specific gravity, which is also dependent on anions, albumin, proteins, urea, and glucose, is therefore not measured. Artifactually low specific gravity readings are obtained in alkaline urine. Acid urine and albumin falsely elevate the specific gravity reading. [49] Some investigators believe that these strips on the dipstick test are of marginal clinical utility at best. [50] Other clinical indicators of a patient's hydration status are probably equally reliable. If necessary, a refractive specific gravitometer or a hygrometer should be used.

## Microscopic Urinalysis

Microscopic UA is done by 1 of 5 methods, considered individually below. Traditionally, the most common laboratory technique of microscopic UA for clinical purposes has been the examination of unstained centrifuged urine (technique 3). It has the advantage of concentrating formed elements that might otherwise be missed. In addition to cells and bacteria, casts, crystals, and other microbes can be recognized (Fig. 74-2) (Figure Not Available) . The disadvantage is that an individual specimen shows different amounts of formed elements after centrifugation, depending on many uncontrolled factors: the volume of the specimen, the time and speed of centrifugation, the fragility of the formed elements, the volume of the "drop" in which the pellet is resuspended after removal of the supernatant, and the size of the microscope's "high-powered field."

1. *Examination of unspun urine in a hemocytometer counting chamber* is a specialized laboratory technique. The hemocytometer uses a specially milled slide

etched with precisely measured squares, allowing for the exact enumeration of cells in each square. Because the distance between the etched surface and the coverslip is exactly known, it is possible to determine the number of cells per unit volume of specimen. Enough fresh unspun urine is placed on the slide to fully cover the counting area, and the cells are counted. There should usually be <1 WBC/mm$^3$ , [54] [55] although >10 WBCs/mm$^3$ and >5 RBCs/mm$^3$ are unequivocally abnormal counts. *Examination of unspun, unstained urine placed on a regular microscope slide* is a qualitative method sometimes used in the diagnosis of UTI. Using 1 organism/hpf as a positive result, the sensitivity and specificity in detecting $10^5$ CFU/mL are between 60% and 90%. [57] Others have used >1 WBC/*low*-powered field as a criterion for infection. [54]

2. *Examination of unstained, centrifuged urine* is performed by centrifuging 10 mL of urine at approximately 450 *g* (1000 to 4000 rpm) for 3 to 5 minutes. Roughly 9 mL of supernatant is poured off, and the pellet is resuspended in the remaining fluid. This suspension is placed on a slide with a coverslip and examined. The larger formed elements, especially casts, tend to migrate to the edge of the coverslip, and they can be seen with low magnification. One or 2 casts, depending on the clinical context, may be normal; more are not. The morphology of the more commonly encountered formed elements of urine sediment is shown in Figure 74-2 (Figure Not Available) . The significance of each is beyond the scope of this text, but this information can be found in a standard textbook of clinical laboratory procedures and diagnostic testing. [26] [27] When examining centrifuged urine, >5 WBCs/hpf seen in the middle of the coverslip has traditionally been taken as being indicative of abnormal pyuria. Most authors have estimated that 10 WBCs/mm$^3$ are equivalent to approximately 1 WBC/hpf, although this is subject to wide variations.  Various numbers of bacteria per high-powered field have been used as criteria for the diagnosis of UTI. A threshold of 10 to 20 organisms/hpf has been recommended. [57] Obviously, the larger the number of organisms seen, the greater the positive predictive value of the test. This test is also only useful in ruling out bacteriuria at the $10^5$ CFU/mL level, and it therefore does not exclude infection in symptomatic patients.

3. *Examination of Gram-stained, noncentrifuged urine* is also a semiquantitative measurement. It is estimated that 1 bacterium/hpf is equivalent to $10^5$ CFU/mL in bacterial culture. This technique is therefore also unable to rule out infection in symptomatic patients and is only 80% to 90% sensitive for $10^5$ CFU/mL.

4. *Gram stain of centrifuged urine* is probably the optimal technique, short of culture, in the assessment of bacteriuria. It is >95% sensitive and >60% specific to $10^4$ CFU/mL: an order of magnitude lower concentration of bacteriuria than the previously described methods. [57] [60] Detection of 1 organism/oil-immersion field constitutes a positive result. ] Specificity is increased to 95% if 5 organisms/hpf are seen. [57]

## Summary

Many clinicians treat female patients who present with signs of uncomplicated lower UTI without obtaining a culture, because treatment is generally benign, and about 95% of positive urine cultures grow either *E. coli* or *Staphylococcus saprophyticus.* Generally, urine dipstick and/or microscopic UA is used to confirm a UTI in this patient group. If the tests are negative, alternative diagnoses should be considered, although some

clinicians will treat empirically while awaiting the results of a urine culture. The rationale for obtaining a microscopic UA is primarily for the detection of formed elements such as cells, casts, or crystals.

In febrile infants, and chilren, pyuria less consistently accompanies infection, rendering the dipstick and UA less sensitive than in adults. Hence, as with adults, there should be a low threshold for sending cultures and/or giving empirical treatment in the presence of a negative test when clinical suspicion is high. Cultures are recommended for febrile infants younger than 2 months.

The extent to which asymptomatic patients and those in whom symptoms are poorly defined (e.g., those being evaluated for nonspecific abdominal pain) are worked up for a UTI depends on the degree of clinical suspicion. When the clinical suspicion is low, a urine dipstick analysis may be sufficient.

## TESTING FOR PREGNANCY

Pregnancy tests are based on the detection of beta-human chorionic gonadotropin (beta-hCG) in serum or urine. beta-hCG is secreted by trophoblastic cells of the placenta starting from the time of implantation of the blastocyst. Qualitative serum tests and the urine test detect beta-hCG levels of between 15 and 25 mIU/mL. [62] The concentration of hCG is usually lower in urine than in serum, which accounts for the slight advantage of serum tests in detection of early pregnancy. Optimal urine pregnancy tests are obtained on first-voided concentrated morning specimens. Home urine pregnancy test kits detect levels of beta-hCG of about 50 mIU/mL in the urine.

beta-hCG levels of 5 to 8 mIU/mL correspond to the 9th to 11th day after ovulation (23 to 25 days after the first day of the last normal menstrual period). In a viable intrauterine pregnancy, the beta-hCG level doubles approximately every 1.5 days during the first 4 weeks of gestation, reaching a serum level of 25 to 300 mIU/mL, detectable by virtually all beta-hCG-based pregnancy tests in urine or blood, on or around the first day of the missed menstrual period. The doubling rate declines to every third day thereafter, [63] [64] with the quantitative beta-hCG reaching a peak of around 100,000 to 200,000 mIU/mL between the 10th to 14th gestational weeks and declining to around 10,000 to 20,000 mIU/mL for the rest of the pregnancy (Table 74-4) . There is a wide range of beta-hCG levels among different women at the same stage of gestation, making definite clinical determinations on the basis of a single quantitative test impossible.

The rate of decline of quantitative beta-hCG after gestation varies depending on the reason for the conclusion of the pregnancy. After a term delivery, beta-hCG falls to zero in 2 weeks. After surgery for an ectopic pregnancy the range is 1 to 31 days, with a median of 8.5 days; after a first-trimester spontaneous abortion, the range is 9 to 35 days (median, 19 days); and after first-trimester elective abortion the range is 16 to 60 days (median, 30 days). [26]

Although a previous quantitative beta-hCG level is rarely available to the emergency physician, doubling rates are an important part of the assessment of a healthy first-trimester pregnancy. Fetal nonviability, ectopic pregnancy, and intrauterine demise

are signaled by abnormalities in the predicted rise in quantitative beta-hCG. A serum quantitative beta-hCG level that does not increase by 66% every 48 hours has a 75% chance of being due to a nonviable pregnancy. [67] [68] The beta-hCG levels in a healthy intrauterine pregnancy (IUP) and associated sonographic findings are listed in Table 74-5 .

The association between beta-hCG levels and gestational dates has led to the concept of a "discriminatory zone" of quantitative beta-hCG for guiding interpretation of pelvic ultrasound testing. Serum beta-hCG levels of >1000 to 1500 mIU/mL should be associated with *transvaginal* ultrasonographic signs of IUP (6500 mIU/mL for transabdominal ultrasonography), or the pregnancy is definitely abnormal, with a significant possibility of ectopic pregnancy. However, the converse--that ectopic pregnancy will always be accompanied by a beta-hCG level 1000 mIU/mL--is *not* true. Only 15% of ectopic gestational sacs examined pathologically have evidence of an embryo. This observation, combined with a variety of pathologic characteristics and sites of implantation, leads to highly variable quantitative beta-hCG levels in ectopic pregnancies. [69] In general, an ectopic pregnancy elaborates quantitatively small amounts of beta-hCG, with 1% of ectopic pregnancies having a quantitative beta-hCG of <10 mIU/mL

| TABLE 74-4 -- Quantitative Immunometric Assay for beta-hCG | |

| 12: | 15,000-220,000 |

**TABLE 74-5** -- Relationship Between Gestational Age, Quantitative beta-hCG Levels, and Ultrasound Findings in Viable Intrauterine Pregnancy

| Time Elapsed from 1st Day of Last Normal Menstrual Period | Quantitative beta-hCG Level (mIU/mL) Using the IRP | Ultrasound Findings |
|---|---|---|
| <28 days | 5-50 | |
| 4-5 wk | 50-500 | From 4.5-5 wk and beta-hCG 1000, TVU can show DDS to confirm IUP |
| 5-6 wk | 100-10,000 | Definitely abnormal if TVU does *not* show DDS after 5 wk or if beta-hCG >1500 |

| | | |
|---|---|---|
| 6-7 wk | 1000-30,000 | TAU should show DDS after 6 wk or if beta-hCG >6500 |
| 7-8 wk | 3500-115,000 | Yolk sac 5-6 wk or beta-hCG >7200; fetal pole/heart 5.5-7 wk or beta-hCG >11,000-17,000 |
| 8-10 wk | 12,000-270,000 | |

DDS, double decidual sac; IRP, international reference preparation; IUP, intrauterine pregnancy; TAU, transabdominal ultrasound; TVU, transvaginal ultrasound. Values for beta-hCG vary somewhat from Table 74-4 since dates are based on last normal menstrual period and different patient set.

and up to 8% having beta-hCG levels of <25 mIU/mL. [70] About 10% of ruptured ectopic pregnancies are associated with a beta-hCG level 100 mIU/mL. [69] In 1 series, at the time of operation, >50% of women with unruptured ectopic pregnancies and 40% of those with ruptured ectopic pregnancies had serum beta-hCG levels of <1000 mIU/mL. [69] Furthermore, patients with abdominal and/or pelvic pain or vaginal bleeding and a beta-hCG level 1000 mIU/mL have a 4-fold increased risk of ectopic pregnancy compared with those with the same symptoms and a beta-hCG level 1000 mIU/mL. [71]

Thus, it can be seen that the "discriminatory zone" can only be used to identify patients in whom ultrasound should definitely demonstrate signs of healthy IUP: a transvaginal ultrasound that fails to show an IUP with a beta-hCG level 1000 is >86% specific for ectopic pregnancy. [72] *Because of the low beta-hCG titers in ectopic pregnancy, the "discriminatory zone" cannot be used as a basis for deciding which first-trimester patients with pelvic pain and/or vaginal bleeding should receive ultrasound evaluation.*

## BLOOD CULTURES

### Indications

Blood cultures are indicated in the ED when there are clinical findings suggestive of a bacteremic state (Table 74-6) . It should be noted that 25% of patients with documented bacteremia have periods without fever. [73] In the elderly the proportion is even higher, with 50% of bacteremic patients over the age of 65 years having a temperature between

| |
|---|

| **Patients with fever and:** |
| Unexplained alterations in mental status, functional status, or autonomic status in a previously healthy patient between the ages of 5 and 65 yr |
| No source, if <2 yr of age, >65 yr, or immunocompromised |
| All infants <3 mo |
| **Patients with or without fever and:** |
| Rigors |
| Toxic or "septic" appearance (e.g., unexplained hypotension, altered mental status, shock) |
| Suspicion of infectious endocarditis |
| Serious focal infections (e.g., meningitis, septic arthritis, osteomyelitis), pneumonia, or pyelonephritis with signs of toxicity |

> Unexplained alterations in mental status, functional status, or autonomic status at extremes of age and in the immunocompromised

°C (97.1 °F) and 38.3 °C (100.9 °F). Up to 13% of elderly bacteremic patients have no documented temperature, >37.3 °C (99.1 °F) at any time. [74] [75] In the elderly, vomiting, altered mental status, increasing age, and >6% band forms reported on a WBC differential cell count are predictive of positive blood culture results. [74] The subjective impression of "having fever" in adults is not a reliable indicator of the presence of fever, although the subjective impression of "no fever" is much more likely to be accurate. [76]

In children, blood cultures have been advocated to identify "occult bacteremia" in patients <2 years of age with fever >38.6 °C (> 101.5 °F) and no identifiable source. In infants <3 months with temperatures >38 °C (> 100.5 °F), many authorities recommend blood cultures regardless of the presence or absence of a source, although this approach is controversial. A child with a normal temperature in the ED and a history from the parents of tactile fever ("felt hot") should be approached in the same way as a patient with documented fever, since parents' tactile impression has been shown to be highly reliable. [77] Bacteremic children, like adults, have intermittent fever, with up to 50% afebrile rates in children with demonstrated bacteremia. [78] Children with significant clinical findings, such as lethargy or nuchal rigidity, should have blood cultures taken regardless of fever history.

**Controversy Regarding "Outpatient Blood Cultures"**

There is a long-standing debate in emergency medicine as to the utility of outpatient blood cultures (i.e., blood sent for cultures on patients subsequently released from the ED pending culture results). Arguments for and against outpatient blood cultures are summarized in Table 74-7 . The paucity of data on the subject of outpatient blood cultures leaves the issue in dispute. Opponents cite medicolegal issues, problems with follow-up, high contamination rates (an often correctable error in technique), low rates of positive cultures, and even lower rates of frequency of patients in whom therapy is changed because of culture results. Proponents also cite medicolegal concerns, positive rates similar to those seen with inpatient blood cultures, cost savings, and the benefit of diagnosing significant, yet subtle, bacteremic states (such as endocarditis).

On the basis of current data, it would seem to be fiscally extravagant to admit all patients in whom a bacteremic state is possible, and injudicious to deny blood cultures solely on the basis of a patient not appearing "toxic enough" to warrant admission. Outpatient blood cultures, with due attention to collection technique, patient selection, and diligent follow-up, would therefore seem to be an appropriate component of emergency medicine practice.

**Technique of Obtaining Blood Cultures**

Studies have demonstrated possible sources of contamination at every stage of the process of obtaining and processing blood cultures. In addition to obvious sources of contamination from the patient's and phlebotomist's skin, both antiseptic agents [82] [83] and gloves [84] have been implicated. Some authorities have argued that the primary source of contamination is in the laboratory processing of specimens. [85] However, the consensus is that the commonest source of contamination is the process of phlebotomy and inoculation of blood culture bottles. Obviously this is the single step over which the emergency physician has control. Contamination rates in most large series are around 3%; if quality assurance review reveals significantly higher rates, it would be prudent to provide special in-service training for ED personnel. [88]

A high degree of sensitivity is required of blood cultures. Many significant bacteremic illnesses have been documented with as little as 1 CFU/10 mL of blood. Human skin has a bacterial concentration between $10^3$ and $10^6$ CFU/cm$^2$ on the forearm and groin, respectively. [89] Designed to detect vanishingly low concentrations of bacteria, blood cultures are clearly susceptible to false-positive results (impaired specificity)

| **TABLE 74-7** -- Summary of Arguments for and Against the Performance of Outpatient Blood Cultures |
| --- |
| **Arguments *against* outpatient blood cultures:** |
| 1. Low true-positive rates |
| 2. True-positives are rarely clinically significant |
| 3. High false-positive rates are expensive and time-consuming for both patient and institution |
| 4. Difficulty of ED follow-up makes positive blood culture results a medicolegal liability |
| **Arguments *for* outpatient blood cultures:** |

| 1. Facilitates outpatient management of some patients, sparing them financial, psychological, and nosocomial costs |
| --- |
| 2. Allows initiation of antibiotics without fear of a potentially irrevocably lost opportunity for blood cultures (e.g., in a patient with a urinary infection, mild constitutional symptoms, and a heart murmur, infectious endocarditis is always possible, but one would want to start treatment of the UTI as the much more likely cause) |
| 3. May give useful etiologic information and antibiotic susceptibility profiles regarding infectious diseases that are being treated on an outpatient basis |

when they must necessarily be obtained by passing a needle through inherently contaminated skin. Most (80%) of the skin flora are transient, superficial, and removable; 20% inhabit the sebaceous ducts and hair follicles, and are not removable without destroying the skin. [89] [90] The former group are predominantly gram-positive and gram-negative aerobes and are the target of skin disinfectants.

The primary agents for skin disinfection are iodine compounds, alcohols, chlorhexidine, and hexachlorophene. Povidone-iodine (Betadine) 10% solution has a much lower free iodine concentration than iodine solution and is therefore less potent. The most effective cleansing agent is tincture of iodine, which is a mixture of 2% iodine solution and 70% alcohol. [92] The iodine-containing agents are superior to hexachlorophene and chlorhexidine in killing gram-negative bacteria. However, iodine, like other antiseptic agents, is inhibited by the presence of organic matter, which emphasizes the need for thorough skin cleansing prior to the application of any skin disinfectant.

Ethyl or isopropyl alcohol should be used in 60 to 80% solution. Alcohol prep pads generally contain 70% isopropanol. Alcohol is a less powerful germicide than iodine in vitro, and only kills 90% of surface bacteria after a full 2 minutes, with reapplication to prevent drying. [91] Alcohol is inactive against fungi, spores, and viruses; however, in vivo studies of blood culture contamination rates have shown it to compare favorably with iodine. [92] [93] Since tincture of iodine solution is often not available, and povidone-iodine solutions are less potent, alcohol still has an important place in skin antisepsis. In addition, alcohol is an excellent solvent, so that alcohol pads are a good tool for skin preparation prior to the application of iodine compounds.

Chlorhexidine (Hibiclens) and hexachlorophene (pHisoHex) are antiseptics that are more effective against gram-positive than gram-negative bacteria. Both agents have intradermal absorption, which causes prolonged antimicrobial activity and is the basis of their popularity as surgical scrub and operative site preparations. This also makes them preferable agents where indwelling lines, especially central lines, are being placed. [94] For routine blood culture phlebotomy, they are not as effective as alcohol and iodine

combinations. Most studies show chlorhexidine to be more potent than hexachlorophene. Prolonged exposure to hexachlorophene has been associated with seizures in infants.

The results of studies of contamination rates with various skin preparation agents are not unanimous. Table 74-8 presents a consensus skin preparation protocol. Optimal results seem to be obtained by alcohol-iodine mixtures. [89] [95] [96] The most important concept in skin disinfection is that bacteria do not die at the instant of contact with disinfectant agents. Iodine (2%), which is twice as potent as 10% povidone-iodine, requires at least 90 seconds in contact with the skin to kill 90% of surface bacteria. [91] In many ED patients it will be necessary to use alcohol prep pads to remove gross dirt and debris from phlebotomy sites prior to initiating the steps of the formal skin preparation.

## Special Considerations

### "Changing the Needle" After Phlebotomy

In considering this issue, it is important to emphasize the distinction between *needle changing* and *needle recapping.* [97]

---

**TABLE 74-8** -- Skin Preparation and Technique for Drawing Blood Cultures

1. Cleanse the skin with alcohol swabs 3 times, or until the swabs appear entirely free of surface dirt after application

2. Allow to dry

3. Apply 10% povidone-iodine, or (preferably) 2% iodine solution, or (ideally) 2% tincture of iodine in 70% alcohol, 3 times, in centrifugal circles from the anticipated site of venipuncture

4. After 3rd swab, allow to dry at least 60 sec

5. During this period, prepare lids of blood culture bottles with iodine and/or alcohol; lay out sterile gloves, and use paper wrapper as a sterile field for the needle and syringe (not necessary if using a Vacutainer system)

| |
|---|
| 6. Wipe off dry iodine at venipuncture site with alcohol; substitute chlorhexidine if placing an indwelling catheter |
| 7. Obtain 20-30 mL ( *at least* 20 mL) of blood; place up to 10 mL in each bottle (these bottles constitute 1 blood culture *set*) |
| 8. Inoculate bottles without changing needles |
| 9. Repeat at different sites for requisite number of sets for *series* |

The latter is a well-established risk to health care workers; it contravenes standard recommendations for universal precautions, *and should not be performed*. Needle replacement using the standard needle removal device on "sharps" containers is an unquantified risk, but it is clearly much less dangerous than recapping.

Based on little scientific data, [98] it was long considered essential to change the phlebotomy needle prior to inoculating blood culture bottles. With increasing awareness of the risk of bloodborne infections associated with needle-stick injuries, this practice has come under scrutiny. One large, well-controlled study showed no difference in contamination rates with or without needle changing. [99] Other studies each show a clear trend *toward* a lower contamination rate with a needle change, but no single study reaches statistical significance. In conclusion, not changing needles prior to blood culture bottle inoculation is acceptable practice for obtaining routine blood cultures. However, in those situations in which the results of the blood culture are of paramount importance (e.g., suspected infectious endocarditis, for which empiric antibiotic coverage will be started immediately), it is suggested that needles be changed prior to inoculation of culture bottles, *but not recapped*.

**Special Access Sites**

Newly placed IV catheters are a reliable source of blood culture specimens, providing that the appropriate measures are taken in skin preparation. Previously placed IV catheters (central and peripheral) and arterial lines have been compared with fresh percutaneous phlebotomy for blood cultures in several studies. Some show clearly increased contamination rates with the use of a chronic line, whereas other authors report a trend toward the same conclusion.In the aggregate, chronically indwelling vascular lines are not an adequate source of blood for culture.

**Miscellaneous Issues**

Although arterial blood may be used for blood cultures, venous blood is usually drawn for culture, even in subacute bacterial endocarditis. Because it is difficult to disinfect the groin skin, the femoral vein should be avoided whenever possible. Clotted blood or citrated blood should not be used for cultures.

**Heel Stick in Neonates**

This technique results in recovery rates of bacteria equivalent to phlebotomy in 2 studies. [110] [111] Because approximately 25% of bacteremic infants have <25 CFU/mL of blood, this proportion (25%) will be missed if 0.2 mL is obtained for culture. For this reason, heel stick should be considered as a source of last resort for blood culture. *Intraosseous specimens* may also be used in circumstances in which phlebotomy is impossible. [112]

## Timing of Blood Cultures

In most circumstances, the timing of blood cultures is a moot issue in the ED. Most patients are either so sick that the expeditious administration of antibiotics is mandated or are well enough for release home, so that 2 or more sets of blood need to be drawn immediately. The situation in which the timing of blood cultures might become a consideration is in a patient who requires admission but for whom the diagnosis of bacteremia is sufficiently in doubt that antibiotic therapy is not to be initiated empirically.

Contrary to the time-honored tradition of obtaining blood cultures during a fever spike, data show a trend toward a higher proportion of true-positive culture results in patients whose blood is drawn in the 12 hours *prior* to a fever spike. [113] [114] Furthermore, excepting infectious endocarditis, most clinically significant bacteremia is thought to be intermittent, so that multiple sets of cultures obtained at one time would heighten the risk of missing the period of bacteremia. [87] Therefore, for patients admitted to the hospital with the tentative diagnosis of bacteremia, it is theoretically advantageous not to draw all 3 sets of blood cultures in the ED, but to draw them at intervals over the following 12 to 24 hours. [115] However, if administration of antibiodies is clinically indicated, 2 or 3 sets of cultures separated by 20 to 30 minutes are obtained in the ED prior to initiation of antibiotic therapy.

## Blood Culture Volumes

**Volumes in Adults**

Multiple studies demonstrate that the sensitivity of blood cultures is directly related to the volume of blood cultured. [116] [117] [118] One representative study [119] showed that culturing a total volume of 20 or 30 mL of blood yielded, respectively, 38% or 62% more true-positive results than did a volume of 10 mL of blood. Another study showed that each additional milliliter of blood yields an average of 3% more true-positive results. [120]

This finding is also consistent with the fact that 40% of adults with bacteremia have <1 CFU/mL of blood, and that 20% have <1 CFU/10 mL. [121] Alternatively expressed, if only 10 mL of blood is obtained for culture, 20% of patients with continuous bacteremia will be missed. Because most bacteremia is intermittent, and because endogenous factors in blood will cause some inhibition of bacterial growth even with modern lysis- and filtration-centrifugation techniques, the false-negative rate in clinical practice will always be significantly higher. On purely mathematical grounds, 10 mL per set of blood cultures (5 mL per bottle) is an absolute bare minimum for culture. In adults, most authorities recommend that at least 30 mL of blood be taken per culture site and/or set and that each bottle be inoculated with 10 mL.

To ensure dilution of the blood's inherent antibacterial properties (e.g., immunoglobulins, complement, WBCs), blood should be placed in the culture medium with a concentration <10% (i.e., not >1 part of blood to 10 parts of medium). [123] Thus, if 30 mL of blood is obtained from 1 site, it should be equally divided into three of the usual 100 mL broth bottles.

**Volumes in Children**

A blood volume of 30 mL drawn from a 70 kg adult is equivalent to 1.5 mL of blood in a 3.5 kg neonate. It has been shown that levels of bacteremia are typically 10-fold higher in infants than in adults. Generally, the sicker the child, the greater the likelihood of a high level of bacteremia. [125] Although one study [127] failed to show any effect on the rate of detection of bacteremia with increasing volumes of blood specimens, many studies have suggested that small culture volumes are at increased risk of false-negative results. Furthermore, the studies showing high rates of colony-forming units per milliliter were performed on neonates. As the immune system matures during infancy, levels of bacteremia might be expected to fall toward those seen in adults. In 2 recent reviews, it was recommended to obtain a similar volume of blood with respect to body mass as would be drawn in adults: approximately 1 mL per 2.5 kg (4 mL per 10 kg of body mass). These recommendations are summarized in Table 74-9 .

## How Many Sets of Blood Cultures Should Be Tested?

A single *set* of blood cultures is the total volume of blood obtained from a single site that is inoculated into media. A 1 mL specimen from a neonate placed in an aerobic bottle, and a 30 mL specimen from an adult divided equally (10 mL per bottle) between fungal, aerobic, and anaerobic bottles, are both a *single set* of blood cultures. Two or more *sets* of blood cultures make up a *series*. [115] [133] The information derived from the blood culture sets is pooled in such a way as to make both the sensitivity and specificity of the series greater than that of the component sets. Sensitivity is enhanced because even with continuous bacteremia, an individual

**TABLE 74-9** -- Optimal Specimen Volumes to Be Drawn per Blood Culture Set D

| Age Group/Weight (kg) | Ideal Volume of Specimen per Set (mL) |
|---|---|
| Neonates | 1-2 |
| Infants/5-10 | 2-4 |
| Children/7-20 | 3-8 |
| Children/>20 | 10 |
| Children/>40 and adults | 20 |
| | 30 |

Do not place more than 10 mL of blood in each 100 mL broth bottle.

set is usually only 80% sensitive. [133] Specificity is improved by determining whether pathogens that are also frequently contaminants are found in >1 set of the series.

While this conceptual process is applied to all blood culture series, the focus of inquiry varies depending on the infectious process being ruled in or out. For example, in an elderly patient with fever and purulent urine, it is extremely unlikely that the causative organism is a typical skin contaminant. The usual causes of "false-positive" blood cultures will therefore be easily recognized, thus lowering the false-positive rate for the series and making for a test with intrinsically higher specificity. At the same time, with typical pathogens in this clinical context being nonfastidious organisms, sensitivity is typically around 99% with 2 sets of 20 mL blood per set. [122] Conversely, in a patient with a prosthetic heart valve, fever, and signs of septic emboli, many likely pathogens are also skin contaminants (this phenomenon lowers the specificity of each individual blood culture set), so at least 2 *sets* of cultures will need to be *positive* with such organisms before the overall test result (i.e., of the *series*) is considered positive. At the same time, this clinical picture indicates a very high pretest probability of disease (diminishing the negative predictive value of a negative set), so that an extremely sensitive overall test (i.e., *series*) will be needed to adequately rule out disease. Thus, in this clinical context, most authorities would recommend four sets of blood cultures, with good volumes in each.  Except in infants, single sets of blood cultures are of insufficient sensitivity or specificity to be of any utility, and they should not be drawn. Recommended numbers of sets of blood cultures as they relate to the pretest probability of disease and causative organism are summarized in Table 74-10 .

**Aerobic vs Anaerobic (vs Other) Bottles**

Anaerobic infections, by their nature, tend to occur in poorly perfused tissues or locations, frequently evolving into abscesses, which further isolate them from the bloodstream, decreasing the likelihood of bacteremia, and making them intrinsically elusive to blood cultures. In addition to these pathophysiologic considerations, a significant decrease in the proportion of positive blood cultures due to anaerobic

organisms has been widely reported over the past 15 years.

| No. of Sets (Minimum) | Clinical Context |
|---|---|
| **TABLE 74-10** -- Numbers of Blood Culture Sets to Be Obtained for an Adequate Series in Various Clinical Situations in Adults | |
| 2 sets | Etiology is likely to be easily distinguished from contaminants *and* pretest probability of bacteremia is low to moderate |
| 3 sets | Skin contaminants are possible causes of infectious process, *or* pretest probability of bacteremia is high, *or* infectious endocarditis is a consideration, but with low to moderate pretest probability |
| 4 sets | Possible infectious endocarditis where *either* the pretest probability is moderate to high *or* the patient has recently been on antibiotics |

| **TABLE 74-11** -- Infectious Processes That Can Cause Anaerobic Bacteremia |
|---|
| Odontogenic head and neck infections |
| Aspiration pneumonia |
| Abdominal/pelvic infections |

| | |
|---|---|
| Deep soft tissue infections (e.g., myofasciitis) | |
| Sepsis with decubitus ulcers or necrotic tissue | |

In recent series, anaerobic pathogens account for only 1 to 5% of positive blood cultures. Clinically significant isolates--those that could not have been predicted on the basis of the clinical picture, or that alter management--are much rarer. [136] Thus, with a typical true-positive blood culture rate of 7% and an anaerobic true-positive rate of 3% of those, approximately 500 *series* of blood cultures need to be drawn for every significant anaerobic blood culture. Since, as noted above, the true-positive rate for each blood culture set is increased by approximately 3% per additional milliliter of blood, and at least 95% of these true-positive findings will be caused by aerobic pathogens, [138] there is a strong argument to be made for devoting the entire specimen to aerobic culture unless there are clinical grounds to suspect anaerobic infection. The vast majority of anaerobic bacteremias occur in one of the clinically identifiable situations listed in Table 74-11 .

The issue of selective use of anaerobic blood cultures is controversial, with some authors still advocating their routine use. [124] [140] However, the arguments for a selective approach are compelling. Based on these considerations and analysis of a number of recent review articles, Table 74-12 suggests guidelines for inoculation of blood obtained for culture.

**Identifying Contaminants**

The emergency physician must be prepared for telephone calls from the laboratory with positive results of cultures obtained on previous shifts. "False-positive" blood cultures

| TABLE 74-12 -- Blood Culture Bottle Type to Be Used in Various Clinical Situations | |
|---|---|
| **Clinical Situation** | **Bottles to Be Obtained** |
| Children <12 yr | Aerobic bottles only unless patient has peritonitis or fasciitis (in which case draw standard aerobic and anaerobic cultures) |

| Adults and children >12 yr | If anaerobic infection is unlikely, use aerobic bottles only unless the patient is immunocompromised |
|---|---|
| | In the immunocompromised, consider a bottle for fungal culture (usually effective in aerobic bottles, but consult the laboratory) |
| | If anaerobic infection is possible, each set consists of 1 aerobic and 1 anaerobic bottle |

can be due to true contamination, but they also may be caused by the intermittent bacteremia that occurs in normal, healthy people. In either case, distinguishing these from clinically significant bacteremia is based on both microbiologic information and correlation with the patient's clinical condition. The following features are often helpful. [122] [133] Notwithstanding these guidelines, it is prudent to contact patients with positive blood cultures, even when contamination is suspected on a microbiologic basis, to confirm improvement in their clinical condition.

Features of false-positive blood cultures are as follows:

1. Coagulase-negative staphylococci ( *S. epidermidis*) and *S. viridans* in a single bottle in patients not suspected of infectious endocarditis and without chronic indwelling IV access catheters are usually contaminants.
2. Corynebacteria (previously known as "diphtheroids"), *Propionibacterium acne*, and *Bacillus* spp. are usually contaminants, but they can be pathogenic in immunocompromised patients.
3. Multiple organisms in a series suggests contamination.
4. Late-appearing growth: species that grow out after prolonged culture have a higher likelihood of being contaminants.
5. The patient's symptoms have resolved or are inconsistent with sepsis (beware of infectious endocarditis, which can have an indolent course).
6. A primary infected source (e.g., sputum or urine) yields a different pathogenic isolate.

**Fungal Cultures**

Generally, fungi are difficult to isolate in blood cultures, and it may take 4 to 6 weeks to obtain a positive yield. If a fungemia is suspected, it is best to discuss culture media and technique with the laboratory before cultures are taken. Cultures of bone marrow are occasionally positive in deep mycoses when blood cultures are negative.

Occasionally, blood cultures are positive in cases of disseminated histoplasmosis or

candidiasis, but other fungi, such as *Cryptococcus* and *Aspergillus* or fungus-like bacteria such as *Nocardia* and *Actinomycosis*, are rarely isolated from the blood.

## DETECTION OF BLOOD IN THE STOOL

The fecal blood test makes use of the peroxidase-like activity of hemoglobin. The test card is impregnated with a compound that exhibits a blue color reaction when oxidized. The original test used guaiac, but current tests use more sensitive and more reliable dyes. The addition of hydrogen peroxide developer solution will oxidize the impregnated dye in the presence of a peroxidase (e.g., hemoglobin).

Testing for occult blood in the stool is associated with false-positive and false-negative results, but in its primary role in emergency medical practice the test is usually reliable in detecting significant acute gastrointestinal (GI) hemorrhage. [27] Low pH, heat, dry stools, reducing substances (e.g., ascorbate), and antacids can cause false-negative findings. Slow bleeding in the upper GI tract in which heme can be converted (denatured) to porphyrin during transit through the gut may not be identified by stool testing. False-positive results have been attributed to the ingestion of partly cooked or large quantities of meat (dietary sources of myoglobin and hemoglobin), and peroxidase-rich food. [141] Most vegetables contain peroxidase, including (in decreasing order) broccoli, turnips, cantaloupe, red radish, horseradish, cauliflower, parsnip, Jerusalem artichoke, bean sprouts, beans, lemon rind, mushrooms, parsley, and zucchini. [141] However, a simple in vivo study convincingly calls into question the possibility of peroxidase passing through the stomach without being denatured. [142] False-positive fecal occult blood tests are uncommon, and a positive test should be considered evidence of the presence of blood until proven otherwise. Routine iron supplementation should *not* be considered as a cause for a false-positive Hemoccult test,  although iron does (like bismuth preparations) cause the stools to appear black on gross examination. Despite this, early in vitro studies demonstrating an artifactual false-positive effect of iron are still frequently cited.

Normal GI blood loss is limited to <2.5 mL/day, which translates to <2 mg of hemoglobin per gram of stool (0.2% by weight). [145] The Hemoccult test is 37 or 95% sensitive to stool containing 2.5 or 20 mg of hemoglobin per gram of stool, respectively. [26] These figures reveal that low to moderate levels of blood may be missed, especially if breakdown of hemoglobin occurs during passage through the gastrointestinal tract or dilution occurs due to diarrheal illness. The test is much more likely to detect lower GI hemorrhage than an identical rate of bleeding from the upper GI tract due to the 100-fold diminution of peroxidase activity of blood during transition through the GI tract. [147]

### Method

The stool specimen is smeared onto the reagent area on the card and a drop of developer is added. A drop of water should be added to very dry specimens and allowed to moisten them prior to addition of developer, because the reaction needs to occur in an aqueous medium. Formation of a blue color on the paper anywhere around

or under the specimen within 60 seconds should be considered a positive result.

## TESTING FOR GASTRIC BLOOD

Heme tests designed for use on stool specimens can be unreliable when applied to gastric juices, with an increasingly high false-negative rate (low sensitivity) as pH decreases. [148] With these limitations in mind, the Gastroccult card was designed to test for blood in gastric juice. The modified guaiac developer contains buffers to neutralize gastric acid, thereby facilitating accurate hemoglobin detection. The test uses the same properties of hemoglobin as a peroxidase as does the fecal guaiac test. In product testing, the Gastroccult card was 100% sensitive in detecting specimens of 500 parts per million of blood by volume, equivalent to 0.05%, or 0.25 mL of blood in 500 mL of gastric contents (Smith Klein Diagnostics--package insert).

### Method

Apply a drop of gastric aspirate to the test area. Apply 2 drops of developer to the sample. Look for formation of a blue dye within 1 minute. Do *not* use fecal blood test developer. In a specimen that is already a bilious green, the test is only considered positive if new *blue* color is formed. The Gastroccult card also contains a pH testing strip located close to the occult blood testing area, which might be useful in testing emesis after an acid or alkali ingestion. False-positive results might be expected to occur (although studies to investigate this have not been performed) with meats and peroxidase-rich foods. False-negative reactions are likely in the presence of reducing substances, such as ascorbic acid. The accuracy of Gastroccult should not be affected by the presence of cimetidine or sucralfate.

## DIAGNOSTIC AND THERAPEUTIC TOXICOLOGIC BEDSIDE PROCEDURES

Patients who present to the ED with drug overdoses or poisoning can be quite difficult to manage if the clinician does not know the ingested drug or toxin. These patients often present with no available history, an inaccurate history, or a change in mental status that can obscure a significant part of the history. [150] Therefore, clinicians must rely heavily on physical examination findings and other sources of information to diagnose or confirm their clinical suspicions of poisoning or overdose. [151]

The hospital toxicology laboratory can be valuable in select cases. Limited screening tests for commonly ingested drugs are available, and ascertaining levels of specific drugs (e.g., acetaminophen, lithium, digoxin, phenytoin) can be helpful. However, most hospital laboratories are not equipped to perform timely analytic procedures for the thousands of possible drugs or toxins. In fact, the results obtained from use of limited drug screening have been shown to rarely influence medical management of patients in the ED.

Diagnostic bedside testing has the advantage of being cost-effective and timely. Selected tests provide immediate information to the clinician and can significantly

influence medical management in a timely manner. This section discusses bedside diagnostic and therapeutic toxicologic procedures.

## Noninvasive Diagnostic Procedures

### Amatoxin: Meixner Test

The ingestion of several types of mushrooms (e.g., *Amanita phalloides*) can be fatal. The most poisonous of these are the mushrooms containing amatoxins. Patients who have ingested these mushrooms often present 6 to 8 hours after ingestion with symptoms consisting of nausea, vomiting, diarrhea, and abdominal cramping. They often bring in specimens of the mushrooms chopped, crushed, cooked, or mixed with stool or gastric contents. Standard hospital laboratories cannot confirm or exclude the diagnosis of amatoxin poisoning; therefore, treatment decisions must be made on clinical grounds. [155]

Meixner reported a simple spot test for detecting amatoxins that can be used on gastric contents, stool, or actual mushroom samples. The basis of this test is the acid-catalyzed color reaction of amatoxins with lignin, a complex organic compound found in wood pulp. Cheaper grades of paper (e.g., newsprint) contain high amounts of lignin. Although there have been no extensive reports of in vivo studies, in vitro tests have shown this method to be highly sensitive and relatively specific for amatoxins.

The *procedure* for a qualitative detection of amatoxin consists of squeezing a drop of liquid from a fresh mushroom sample or squashing a piece of fresh mushroom onto a piece of newspaper. If a stool or a gastric sample is the only available specimen, the sample is mixed with reagent grade methanol (99.8%). The methanol will extract the amatoxin. If the samples are mixed with methanol, they should then be centrifuged and filtered. A drop of the liquid extract should then be placed on newspaper. Gently air dry all specimens at room temperature and avoid direct sunlight. Add 2 to 3 drops of concentrated hydrochloric acid (37%) to the dried specimen. Use an adjacent area for a control. High amounts of amatoxin in the dried samples exhibit a blue color in 1 to 2 minutes. Small amounts of amatoxin show a blue color in the sampled area in 10 to 20 minutes. This procedure has *not* been proven effective using other bodily secretions, such as blood or urine. [156]

### Mothball Identification

Presently, commercial mothballs are composed of either nontoxic paradichlorobenzene or possibly toxic naphthalene. Naphthalene can cause a significant hemolytic reaction in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency and in neonates. [157] In the past, mothballs have also been produced from camphor, which can cause central nervous system (CNS) depression and seizures in overdoses. Fortunately, these mothballs are not commercially available, although they may still exist in some households. A rapid differentiation between these groups of mothballs can expedite patient management and disposition. Several bedside tests have been reported to

facilitate this.

1. Paradichlorobenzene is heavier than naphthalene. In turn, naphthalene is heavier than camphor. [158] In lukewarm tap water, camphor will float and naphthalene and paradichlorobenzene will sink. In a solution of 3 tbsp of table salt thoroughly dissolved in 4 oz of lukewarm water, camphor and naphthalene will float and paradichlorobenzene will sink.
2. Paradichlorobenzene has a lower melting point than naphthalene. Paradichlorobenzene mothballs will melt in a water bath at 53 °C whereas naphthalene requires a water bath of >80 °C. [159]
3. Paradichlorobenzene is described as "wet and oily," whereas naphthalene is described as having a "dry" appearance. Paradichlorobenzene is familiar to many people as a cake of disinfectant used in urinals and diaper pails. [160]

**Body Secretion Analysis**

Careful analysis of bodily secretions, the odor emanating from poisoned patients, and the color of their urine can help identify certain toxins. Some characteristic smells and urine colors are noted in Tables 74-13 (Table Not Available) and 74-14 (Table Not Available) .

**Bedside Toxicologic Tests on Urine**

**Ethylene Glycol.**

Evaluation of the urine of patients who may have been exposed to ethylene glycol can be helpful. Urine should be tested for fluorescence under an ultraviolet light (caused by an additive to antifreeze) and presence of calcium oxalate crystals (a metabolic by-product of ethylene glycol metabolism).

Microscopic inspection of urine for *calcium oxalate crystals* may be helpful in the diagnosis of ethylene glycol exposure. The presence of either envelope-shaped calcium dihydrate crystals or needle-shaped calcium monohydrate indicates high oxalate levels in the serum (Fig. 74-3) (Figure Not Available) . Calcium monohydrate crystals can be easily confused with sodium urate crystals; therefore, the presence of the dihydrate crystal tends to be more specific for ethylene glycol ingestion. The lack of these crystals does not rule out a significant ethylene glycol ingestion, because the excretion of these may occur late in the ingestion (>6 hours) and occasionally does not occur at all.

Visual inspection of urine under a Wood's lamp or ultraviolet light to ascertain *fluorescence* may also be helpful in the diagnosis of ethylene glycol exposure. Antifreeze is the most common source of ingested ethylene glycol. Fluorescein, the actual fluorescing material, is often placed in commercially available antifreeze to enable mechanics to detect radiator leaks with a Wood's lamp or other ultraviolet light source. Fluorescein is a nontoxic inert vegetable dye that is eliminated unchanged in the urine. Therefore, high levels of fluorescein in urine suggest a significant ethylene glycol ingestion. However, a lack of fluorescein does not rule out a significant exposure,

because not all antifreezes contain fluorescein or high concentrations of fluorescein in relation to ethylene glycol. False-positive findings can occur if certain plastic urine containers are used. [168] To perform the test, take the urine sample in a glass test tube and a control urine sample into a dark room and inspect for fluorescence under a Wood's lamp.

**Salicylates.**

Several bedside tests have been developed to qualitatively detect salicylates in urine. These include the addition of 10% ferric chloride solution or Trinder solution to urine or testing with Phenistix reagent strips. All of these are rapid, inexpensive, sensitive tests that give a qualitative rather than a quantitative result. Therefore, a positive result requires a confirmatory quantitative serum salicylate assay.

The *ferric chloride test* is a commonly used rapid, qualitative, urinary screening procedure. To perform this test, several drops of 10% ferric chloride are added to 1 or 2 mL of urine that has been collected in a test tube. The immediate appearance of a bluish purple color signifies that salicylates are present in urine. Acetoacetic acid, acetone, and phenylpyruvic acid will test false-positive for salicylates. Thus this test may be falsely positive in patients with diabetic, alcoholic, or starvation ketoacidosis. This test is very sensitive, and as few as 2 aspirins taken within 24 hours will give a positive result. It will require 90 to 120 minutes from time of ingestion for this reaction to become positive in patients with normal renal function, so early test results may be misleading.

The *Trinder test* uses a mixture of mercuric chloride and ferric nitrate in deionized water. To perform this test, 1 mL of urine is mixed with 1 mL of Trinder solution. A violet or purple color signifies the presence of salicylates. Acetoacetic acid and high levels of phenothiazines may give false-positive results.

*Phenistix reagent strips* were originally developed to detect phenylketonuria. However, Phenistix strips also turn brown in presence of salicylates. False-positive findings for salicylates can occur if phenothiazines are present.

**Bedside Toxicologic Tests on Blood**

**Methemoglobinemia.**

Patients with methemoglobinemia will often have a normal partial pressure of oxygen ($pO_2$ ) on routine arterial blood gas analysis, a normal *calculated* hemoglobin saturation, a nondiagnostic pulse oximeter reading, and cyanosis that does not clear with $O_2$ administration. Bedside visual inspection of venous or arterial blood may be helpful in the diagnosis of methemoglobinemia. Methemoglobinemia occurs when normal hemoglobin is exposed to an oxidant stress ($Fe^{2+}$ converted to $Fe^{3+}$ ). If the erythrocytes are not able to handle such stress, such as in the presence of G6PD deficiency, hemoglobin remains in a oxidized state (methemoglobin), causing a color change in the molecule. Methemoglobin levels >15% are reported to cause a cyanotic

appearance in a patient. [172]

The procedure for evaluating for methemoglobinemia is to place a drop of sample blood on a white background (a white coffee filter is appropriate) in a well-lit environment. Next to this, place a drop of normal blood as a comparison control sample. Blood with methemoglobinemia appears "darker" or "chocolate-brown." [173]

This method relies on the ability of the examiner to distinguish color changes and therefore may have a degree of interobserver variance. Methemoglobin levels of <10% may only slightly alter the color of blood and thereby cause a false-negative finding. Methemoglobin levels of between 12 and 14% may cause a false-negative reading 50% of the time. However, at methemoglobin levels of 35%, the identification of methemoglobinemia by visual inspection is quite accurate. [173] At this level, most patients are obviously cyanotic and quite symptomatic.

## Invasive Diagnostic Procedures

Several invasive diagnostic bedside procedures can be useful in the assessment of possible drug overdoses. The basic premise of these procedures is that patients who have been exposed to a certain drug or poison will respond in a particular fashion if given a diagnostic challenge dose of another particular drug or true antidote.

### Naloxone

Naloxone hydrochloride (Narcan) is an opioid receptor antagonist that has the ability to reverse the effects of chemical agents affecting all opioid receptor sites, particularly respiratory and CNS depression. Because of this, a trial of naloxone has been recommended for all patients with CNS depression. [174] Certain clinical findings such as miosis, decreased respiratory rate, and evidence of illicit drug use can predict many patients who will respond to a diagnostic challenge dose of naloxone. [175]

If a patient's mental status improves significantly after a dose of naloxone, the patient should be considered to have been exposed to an opioid substance. This is true even if a laboratory drug screen is negative for opioids. This is due to the fact that many of the synthetic opioid agents, such as fentanyl, propoxyphene, meperidine, methadone, and pentazocine may not be detected by the routinely used immunoassay drug screen. [176] Although cases have been reported of patients with other non-opioid overdoses (such as alcohol or phencyclidine) responding to naloxone, those single observations have not been confirmed in controlled animal or human studies.

The traditional challenge dose of naloxone in an adult or child is 2 mg every 2 minutes IV until a response is achieved or 10 mg is given. [176] Some clinicians prefer to use much smaller doses (0.1 to 0.2 mg) and titrate to effect. This may partially reverse opioid overdose-related symptoms and confirm the diagnosis without precipitating the opioid withdrawal syndrome seen in patients with opioid dependency. Most patients with an opioid overdose will exhibit some response to 1 to 4 mg of naloxone, but some massive overdoses may require larger amounts. A patient who does not respond at all

to 10 mg of naloxone probably does not have a pure opioid overdose. The high doses of naloxone presently recommended are needed to reverse many synthetic narcotic agents, such as propoxyphene and methadone. Lower doses can be given (0.4 to 0.8 mg in adults or 0.01 mg/kg in children) to reverse known opioid-induced respiratory depression without reversing analgesia. [177] Because naloxone has a half-life between 30 and 60 minutes, a continuous drip of naloxone can be used to avoid resedation. A reasonable choice is to use two thirds of the initial bolus dose that achieved the desired reversal effect as the hourly IV dose. For example, a patient who satisfactorily responded to 1.5 mg of naloxone might receive a naloxone solution of 10 mg of naloxone in 500 mL of normal saline at a rate of 1 mg (50 mL)/hour IV. [178] Nalmefene, a new long-acting opioid receptor antagonist that has a terminal half-life of roughly 11 hours, can also be given to patients with suspected overdoses. Theoretically, a single dose of nalmefene will be effective longer than the effects of heroin or most abused opiate substances. The initial recommended dose is 1.0 to 1.5 mg IV.

Naloxone and nalmefene have minimal significant side effects, other than precipitating withdrawal from patients addicted to opioids. Unlike alcohol withdrawal, naloxone-induced opioid withdrawal in the adult is short-lived and is usually not life-threatening. Withdrawal can be avoided if lower initial doses of naloxone or nalmefene are given and then are slowly titrated upward to the desired effect. [177]

**Flumazenil**

Flumazenil is a competitive benzodiazepine receptor antagonist that has the ability to reverse the CNS and respiratory depression caused by all currently commercially available benzodiazepines. The use of flumazenil as a *routine diagnostic bedside challenge in all obtunded patients is discouraged,* and its use in the setting of possible benzodiazepine overdose is controversial. Unlike naloxone, flumazenil can have significant side effects in certain subsets of patients. [179] These include precipitating seizures or a withdrawal syndrome in benzodiazepine-dependent patients. To minimize the chance of seizures, flumazenil should be avoided in patients who may have ingested epileptogenic drugs (e.g., cyclic antidepressants, cocaine, theophylline, lithium, carbamazepine, or isoniazid). [180]

In overdose settings in which there is obtundation and respiratory depression and no history of seizures or suspicion of involvement of epileptogenic agents, flumazenil can be administered IV at a dose of 0.2 to O.5 mg/min. Most benzodiazepine-overdosed patients show mental status improvement with 1 mg of flumazenil and almost all respond to 3 to 5 mg. It is prudent to use small, escalating doses given very slowly (maximally, 0.5 mg/min). Larger doses can be given at one time as a bolus, although this increases such side effects as anxiety, agitation, and emotional lability; it also increases the chances of precipitating withdrawal in benzodiazepine-dependent patients. [181] Fortunately, seizures that occur after flumazenil use are usually transient and can usually be controlled with additional benzodiazepines. In rare cases, higher doses of benzodiazepines, barbiturates, and phenytoin may be required. [180]

If a patient responds to flumazenil with an improvement in depressed mental status, this only suggests that the patient is under the influence of a benzodiazepine. Flumazenil

can partially reverse the effects of many other agents or conditions that affect the gamma-aminobutyric acid (GABA) pathway, such as zolpidem and hepatic encephalopathy, [182] but it does not have any significant effect on alcohol, barbiturates, and other non-benzodiazepine sedative-hypnotics. [183]

**Physostigmine**

Physostigmine is an acetylcholinesterase inhibitor that can penetrate into the CNS and thus can reverse both the central and peripheral effects of anticholinergic agents. The use of physostigmine as a diagnostic challenge can be helpful in select situations. In the majority of patients with anticholinergic toxicity, no laboratory tests are available to rapidly confirm the diagnosis, and testing for specific drugs is limited. A clinical picture that may consist of mydriasis, dry and flushed skin, dry mucous membranes, urinary incontinence, absent bowel sounds, tachycardia, hyperthermia, hallucinations, agitation, and seizures, suggests an anticholinergic toxicologic syndrome. A rapid and dramatic response to physostigmine often confirms a diagnosis of anticholinergic toxicity. In these patients, physostigmine reduces much of the CNS toxicity of the agents and decreases the degree of agitation and confusion. [184] [185]

As a diagnostic challenge or therapeutic intervention, physostigmine can be administered IV under constant cardiac monitoring at a dose of 1 to 2 mg in adults and 0.02 mg/kg in children, over 5 minutes. Some clinicians empirically pretreat with a benzodiazepine to militate against seizures, but this practice has not been proven effective or necessary. Because the half-life of physostigmine is 30 to 60 minutes, a repeat dose of 2 mg also can be given as clinically indicated. Continuous infusions or multiple repeat doses are strongly discouraged.

Similar to flumazenil, physostigmine has been reported to interact detrimentally with cyclic antidepressants, often causing life-threatening dysrhythmias. Physostigmine also can cause an excess of acetylcholine and a resultant cholinergic crisis. This syndrome includes salivation, lacrimation, urination, defecation, bradycardia, bronchorrhea, and seizures. [186] Dysrhythmias, including asystole, have also been reported. [187] For this reason, 1 mg of atropine, IV, should be readily available to reverse a potential cholinergic excess when using physostigmine.

**Deferoxamine**

Deferoxamine is an organic compound derived from the bacterium *Streptomyces pilosus*. Deferoxamine can chelate iron and can be used as therapy or as a diagnostic challenge in patients with iron overdoses. Patients who have unstable vital signs or significant GI or CNS symptoms usually require therapeutic doses of deferoxamine. *Asymptomatic* patients with a history of iron overdose usually require supportive care only. Patients with persistent but mild GI symptoms, such as vomiting and diarrhea, may be given a diagnostic challenge dose of deferoxamine. The use of iron levels and total iron binding capacity to dictate ED management can be inaccurate, misleading, and time-consuming.

A diagnostic challenge dose of deferoxamine is administered IM or IV over 45 minutes

at doses of 40 to 90 mg/kg up to a maximum of 1 g in children and 2 g in adults. Deferoxamine can also be administered IV as a constant drip of 15 mg/kg/hour. [191] A positive result occurs when chelated iron in the form of ferrioxamine appears in the urine. This usually causes the urine to turn a reddish orange or "vin rose" color in 2 to 3 hours after initiation of treatment. The color change is qualitative only and has no prognostic significance. Color change caused by ferrioxamine is pH and concentration dependent, and false-negative test results occur. [192]

Chronically administered deferoxamine has been reported to have multiple adverse effects, such as adult respiratory distress syndrome (ARDS), visual defects, and enhancement of *Yersinia enterocolitica* infections. [183] In the setting of the single challenge dose, flushing, erythema, tachycardia, urticaria, and hypotension caused by rapid administration of deferoxamine are the most serious side effects. [193]

**Invasive Therapeutic Procedures**

The indications and rationale for use of certain therapeutic procedures in toxicology are often misunderstood.

| **TABLE 74-15** -- Drugs That Have Increased Elimination with Urinary Alkalinization |
|---|

| Formate |
| Methotrexate |
| Phenobarbital |
| Salicylate |

**Alkalinization of Urine and Blood**

Alkalinization of urine consists of manipulating the pH of urine to enhance excretion of certain drugs (Table 74-15) . Weak acids remain in ionic form in a basic milieu. The ionic form often prevents reabsorption of that drug in the proximal tubule, and urinary alkalinization can therefore promote elimination in the urine. For certain drugs, this can play a significant role in their elimination. For example, salicylate elimination increases proportionately to the urinary flow rate, but it increases *exponentially* with increases in the urinary pH.

Recommendations differ on the actual method or formula to achieve urinary alkalinization. No body of literature exists that supports one method of urinary alkalinization over another. [197] In general, this procedure should be titrated to the patient's fluid and acid-base status to achieve a urinary pH of 7.5 to 8.0. Many authors recommend the use of a constant infusion of a relatively isotonic solution consisting of 3 ampules of sodium bicarbonate (44 mmol/ampule) added to 1 L of 5% dextrose in water ($D_5$ W). Another reasonable formula is to begin with a bolus of 2 ampules of IV sodium bicarbonate, or 1 to 2 mmol/kg of body weight. The bolus is followed with a constant infusion of 3 ampules of sodium bicarbonate in 1 L of $D_5$ W solution with 20 to 40 mmol of potassium (if the patient has normal renal function) infused at 100 to 300 mL/hour. Although repetitive boluses of sodium bicarbonate ampules also can be used, this may increase the chances of hypernatremia, hypokalemia, relative hypocalcemia, fluid overload, and alkalemia. All of these are potential adverse effects of aggressive urinary alkalinization. The actual amount of fluids and bicarbonate administered requires titration to the patient's clinical condition. Therefore careful monitoring of electrolyte, pH, and fluid status is encouraged. [198] [199] [200]

Urinary alkalinization can sometimes be difficult to achieve or maintain. Hypovolemia is probably the leading cause of an inability to achieve an alkaline urine. Other theoretical causes are hypokalemia and hypochloremia. Several authors have suggested that in patients with severe salicylate poisoning, urinary alkalinization may be difficult if not impossible to achieve with reasonable doses of bicarbonate.

## Ethanol Infusion

Ethanol can be used as a therapeutic intervention in patients with methanol or ethylene glycol poisoning due to ethanol's much greater affinity for alcohol dehydrogenases. These enzymes metabolize methanol and ethylene glycol to even more toxic by-products. However, with serum ethanol levels of

**TABLE 74-16** -- Ethanol in Methanol or Ethylene Glycol Poisoning [N]

**Intravenous Ethanol: Loading Dose (using a 10% ethanol solution)** [1]
**(A 10% volume/volume concentration yields approximately 100 mg/mL)**

100 mg/dL, minimal amounts of ethylene glycol or methanol are metabolized by alcohol dehydrogenases. [201] [202] Ethanol infusions are not useful in the treatment of isopropyl alcohol poisoning.

Ethanol can be administered orally or IV (Table 74-16) . Intravenous ethanol has the advantages of obtaining therapeutic levels rapidly, ensuring complete absorption, limiting chances of aspiration, and avoiding gastritis. A 5% concentration of ethanol, which can be given in a peripheral vein, requires the use of large fluid volumes. In a 70-kg patient, a loading dose requires 1.4 L of 5% solution, with a maintenance dose of 700 mL/hour. In contrast, oral loading can be achieved using much lower volumes. However, oral loading can be difficult in the uncooperative or unconscious patient or if vomiting or GI hemorrhage is present. A therapeutic level is reached more slowly with oral loading.

Ethanol metabolism can vary widely, and ethanol is dialyzable. Therefore, it may be difficult to maintain appropriate ethanol levels during dialysis therapy of ethylene glycol or methanol. Frequent measurements of ethanol should be obtained and the infusion adjusted accordingly. [203] When patients are given ethanol infusions, CNS depression and hypoglycemia are common adverse effects (the latter is particularly true in diabetics and children). [204] Serial levels of ethanol and glucose should be obtained. If IV ethanol is given, careful attention to fluid status should be maintained.

# Chapter 75 - Universal Precautions

**Kevin Rodgers**

The concept of "universal precautions" implies that health care workers consider all blood and body fluids (B/BF) as potentially infectious and take appropriate precautions to protect themselves and, as a consequence, their patients. This concept is especially relevant to emergency medicine, because emergency patients may present with acute and chronic infectious diseases, and clinical procedures performed in the emergency department (ED) often involve exposure to B/BF. Infectious pathogens of particular concern to emergency physicians include human immunodeficiency virus (HIV), hepatitis B and C viruses (HBV and HCV), *Mycobacterium tuberculosis,* cytomegalovirus, *Clostridium tetani* (tetanus), herpes simplex virus, and *Plasmodium* (malaria). Each year, health care workers suffer considerable morbidity, mortality, and health care costs from occupationally acquired infections.

In 1985, the Centers for Disease Control and Prevention (CDC) first recommended guidelines for the protection of health care workers from B/BF-borne diseases. [1] They asked that hospitals adopt an infection control policy embracing universal precautions. The guidelines delineated methods for minimizing mucous membrane, cutaneous, and percutaneous exposure to B/BF from all patients, especially during the performance of invasive procedures. These guidelines were meant to supplement standard infection control procedures such as hand washing. Although the initial recommendations dealt with the emerging problem of HIV, subsequent updates have recommended universal precautions for protection against transmission of hepatitis and other B/BF-borne pathogens.  In 1991, these recommendations became law under a mandate from the Occupational Safety and Health Administration (OSHA). [5]

In general, the OSHA requirements involve hand washing and barrier protection (gloves, eye protection, gowns, shoe covers, patient barriers) to prevent exposure to B/BF. Although these precautions prevent the mucocutaneous exposures responsible for transmission of most B/BF-borne diseases, including hepatitis, they do little to prevent the typical percutaneous exposure from sharps and needlesticks associated with HIV transmission. Indeed, most of the documented occupational HIV transmissions reported by the CDC have been related to percutaneous exposures. In a study of 1201 health care workers exposed to B/BF of HIV-infected patients, needlestick injuries accounted for 80% of the exposures and sharp instruments accounted for 8%. [6] With this in mind, the original idea of universal precautions has been modified to include methods for prevention of needlestick and sharps injuries. These efforts are aimed at educating health care workers in the proper handling of sharps, the avoidance of needle recapping, provision of easily accessible disposal containers, and the re-engineering of needles and sharps to decrease the likelihood of percutaneous exposure.

The OSHA mandate requires that health care facilities provide their employees with the education and equipment necessary to prevent occupational exposures. Additionally, because health care workers have a 3- to 6-fold greater seropositivity for HBV as compared with the general population and they contract approximately 12,000 new

cases of HBV per year, OSHA also required employers to offer their employees the HBV vaccine. [5] [7] In complying with the OSHA requirements and the CDC recommendations, each health care facility must develop a formal, comprehensive plan for preventing exposures to occupational health hazards. Gerberding has outlined a 3-pronged approach for preventing exposures. [8] The first step is use of equipment with inherent safety features. Second, standardized protocols and techniques designed to maximize safety during work should be used. Personal protective gear is used when hazards cannot be successfully avoided through equipment and work practice controls. Unfortunately, because of the frequent exposure to bloody procedures on patients with unknown health status in the ED, some degree of personal protective equipment is always required. Third, administrative controls, which include personnel assignment, training requirements, and enforcement procedures, are used in implementing safety interventions.

Unfortunately, numerous studies reveal that compliance with universal precautions is far from universal. Kelen and colleagues found only a 44% compliance rate with a comprehensive barrier protection approach by health care workers caring for critically ill and injured ED patients. [9] More disturbing was the fact that compliance was worse during interventions with the highest risk of potential exposure. At another center, ED compliance with various forms of barrier protection as dictated by protocol ranged from negligible to incomplete: gloves were worn with a frequency of 75%; gowns, 25%; eyewear, 19%; and masks, 2%. [10] Stated reasons for noncompliance included lack of time, perception that patients were low-risk exposures, interference with technical skills, lack of necessary supplies, and finally the fact that the protective equipment was uncomfortable. It is clear that mandatory, continuing education centering on the risks of B/BF exposure and the prevention thereof, in conjunction with re-engineering, is critical for the reduction of occupational exposures.

## OCCUPATIONAL DISEASE EXPOSURE

Health care workers are at risk for occupational exposure through contact with B/BF and aerosols for a myriad of diseases, especially HIV infection, hepatitis, and tuberculosis. Factors that affect the risk of exposure include inoculum concentration, quantity of inoculum, duration of exposure, portal of entry, loss of infectivity during transfer, and the immunologic status of both the source patient and the exposed health care worker. Emergency care workers are at increased risk because of the sheer number of exposures and the inability to predict high-risk patients even with rigorous risk factor assessment. [12] [13] Indeed, in a study of 2523 patients presenting to an ED in Baltimore, 24% were infected with either HIV, hepatitis B, or hepatitis C.

Another concern for emergency care workers is the inability to predict which bodily fluids contain blood. The CDC recommends universal precautions for exposure to blood, semen, vaginal secretions, and serous (cerebrospinal, synovial, pleural, peritoneal, pericardial, amniotic) fluids. Previously, feces, nasal secretions, sweat, tears, urine, and vomitus were not included as high-risk exposures unless they contained "visible" blood. However, the CDC subsequently issued specific recommendations for the use of universal precautions during all uncontrolled emergency circumstances because of the inability to predict which fluids will be tainted with blood. [15] Because of their significant

morbidity and mortality and frequency of exposure in the ED, factors associated with the transmission of HIV, hepatitis B and C, and tuberculosis will be reviewed.

## Hepatitis B

Although most attention is focused on HIV with regard to B/BF-borne pathogens, because of its inherent mortality, the risk of developing hepatitis B after a B/BF exposure is significantly greater. Percutaneous exposure to HBV carries a much greater risk of contagion than does similar exposure to HIV (i.e., 10 [8] vs 10 [3] free viral particles/mL). [16] The risk of infection with HBV in a nonimmune person after percutaneous exposure to an HBV surface antigen-positive patient ranges from 6 to 30%. This results in approximately 12,000 cases of HBV in health care workers each year and 200 to 250 deaths. Seroprevalence of HBV antibodies in emergency care workers ranges from 12 to 30%, reflecting a significant exposure rate. Additionally, HIV-positive patients are 4 times more likely to be HBV positive than HIV-negative patients. Although the epidemic nature of HBV among health care workers has declined since the introduction of the HBV vaccine, an estimated 23 to 58% of health care workers remain unvaccinated.

## Hepatitis C

Hepatitis C, formally known as non-A, non-B hepatitis, is no longer simply a disease associated with transfusions. Occupational exposure is firmly established, with a 3 to 4% seroconversion risk after percutaneous exposure to blood positive for the HCV antibody. [19] Several studies have documented an 18% seroprevalence rate among ED patients. The lower transmission rates for HCV as compared with HBV are due to a smaller concentration of viral particles. However, this disease is increasing in prevalence; and with a 10% risk of developing chronic active hepatitis, it cannot be ignored.

## HIV Infection

Through July of 1993, a total of 115 U.S. health care workers had been reported to the CDC for occupational transmission of HIV. [20] Of these, 37 had documented seroconversion associated with documented occupational exposure. [21] Included in this group were 34 percutaneous exposures, 2 mucous membrane exposures, and 2 exposures associated with contact to an open wound or nonintact skin. The combination of statistics from multiple studies has predicted the risk of infection from a single percutaneous exposure to be 0.3% and 0.05% for a single mucous membrane exposure. Although the risk is certainly not zero, Fahey and associates report almost 8000 cutaneous exposures to blood presumably infected with HIV without evidence of HIV transmission. [22]

Thus far, casual contact has not been associated with the transmission of HIV. In one case-control study by the CDC, the risk for developing postexposure HIV infection was associated with *deep injury to the health care worker, visible blood on the injuring device, a device placed in the source patient's artery or vein, and a source patient who died of AIDS within 60 days of the exposure, consistent with a high HIV titer*. [23] Clearly,

there is an occupational risk for transmission of HIV infection; however, the magnitude is small when compared with the risk for transmission of other B/BF-borne diseases.

However, the cumulative risk of HIV conversion due to transmission from patient to physician may not be trivial. Using several theoretical assumptions about emergency physician exposure to HIV-infected patients, Wears and coworkers estimated the *cumulative career risk* of occupational HIV conversion, depending on the use or nonuse of universal precautions, to be from 0.08 to 0.1% in low-risk EDs (i.e., patient seroprevalence of 1%) and from 1.1 to 1.4% in high-risk EDs (i.e., patient seroprevalence 7%). [24]

**Tuberculosis**

Tuberculosis is included in this discussion because of its resurgence especially in HIV-positive and other immunocompromised patients. These patients commonly require acute respiratory procedures in the ED that expose emergency care workers to aerosolized contamination. Risk factors for tuberculosis transmission include a large number of contacts, duration of exposure, poor air circulation, cough-inducing procedures, degree of infectivity, ineffective therapy, and a delay in disease diagnosis. An additional risk, with regard to universal precautions, is the fact that health care workers were least compliant with the wearing of masks. Thus, a low index of suspicion must be exercised in identifying potential tuberculosis patients. They must be quarantined in a room possessing a high rate of air exchange with non-recirculated air. Also, high efficiency particulate air (HEPA) masks capable of screening droplet nuclei 1 to 5 mum in diameter should be worn by health care workers and a surgical mask should be worn by the patient.

## UNIVERSAL PRECAUTIONS

The goal of universal precautions is the prevention of all occupational exposures to B/BF-borne diseases. In the ED where bloody procedures are commonplace and the health status of the patients is unpredictable, appropriate precautions must be viewed as a way of life. It is clear that noncompliance with the guidelines set forth by the CDC and OSHA is actually the greatest risk factor associated with occupational exposure. The guidelines listed below are recommended when performing invasive procedures, or when handling blood, body fluids, or contaminated equipment:

1. Wash hands before and after patient contact. Hands and skin surfaces should be washed immediately and thoroughly if contaminated by blood or body fluids.
2. Use barrier precautions to limit skin and mucous membrane exposure. Gloves should be worn whenever the potential exists for any contact with or handling of B/BF. Gloves should be changed after each patient contact and removed carefully to avoid skin contamination. The added protection gained from wearing double gloves is controversial. Latex gloves seem to be less porous to B/BF than vinyl gloves. [25] However, quality of production, [26] intensity and duration of use, [27] and chemical exposure (including alcohol) [28] are major determinants of leakage. Furthermore, latex allergy affects a sizable minority of health care workers [29] ; hypoallergenic latex and nonlatex gloves may be required. Masks and protective

eyewear should be worn during procedures that generate B/BF droplets (e.g., wound irrigation) whereas gowns and shoe covers should be worn during situations likely to generate exposures to large volumes or splashes of B/BF (e.g, during resuscitation of penetrating thoracic trauma).

3. Use precautions with sharps (needles, scalpels, and other sharp instruments). Ideally, needles should not be recapped, bent, broken, or removed from disposable syringes. Immediately after use, they should be placed in a puncture-resistant container located at the point of use. Whenever possible, re-engineered needles and sharps designed to prevent percutaneous exposures should be used.

4. Use mechanical ventilation devices. Mouthpieces, resuscitation bags, or ventilation devices should be strategically located in areas where resuscitation is predictable, to avoid mouth-to-mouth resuscitation.

5. Use special caution to avoid cutaneous B/BF contact if the health care worker has exudative lesions or weeping dermatitis. When possible, refrain from direct patient contact in these circumstances.

6. Wear a snugly fitting HEPA mask capable of filtering 1- to 5-mum particles when coming in contact with patients who potentially have tuberculosis or immunocompromised patients receiving aerosolized treatments. If possible, the patient should be treated in a high-circulation, negative-pressure room with external exhaust.

7. All health care workers should receive mandatory annual education about infection control and safe work place practices.

## SPECIFIC CLINICAL PROCEDURES AND EXPOSURE RISK

With regard to guidelines for specific procedures, little is known about potential B/BF contact associated with specific procedures performed in the ED. Kelen and coworkers studied 2529 procedures in 1025 patients and found that all 18 procedures examined except IM injections resulted in B/BF contact with the hands. [31] Thus, virtually all procedures performed in the ED warrant glove use.

The potential for health care worker-transmitted cutaneous infectious exposure of immunocompromised patients in the ED also exists. Hand washing or the use of nonsterile examination gloves between patient evaluations appears to represent useful means to reduce the risk of patient exposure and an important rationale for general examination glove use during even minor patient examinations and procedures. [25] [32]

In the study by Kelen and coworkers, chest tube placement, lumbar puncture, and examination of the bleeding patient (from any source including the gastrointestinal tract and during wound care) resulted in B/BF contact with the facial area, suggesting that a mask and eye protection be worn. [31] The study also revealed B/BF contact with the body for many procedures not commonly considered to be at risk for exposure to that area. This study suggests gown protection for all but the simplest procedures. Shoe covers should be worn for all situations associated with large volumes or splashes of blood.

Procedures involving sharps (needles, scalpels, sharp instruments) are particularly

problematic and the most common cause of high-risk exposure. Percutaneous injury may be reduced by modifying specific clinical practices. For example, the use of fingers rather than an instrument to hold tissue being sutured has been associated with health care worker punctures in the operating room setting. [33] The practice of recapping needles also is a common mechanism for health care worker punctures (Fig. 75-1 *A*). Although it is preferred to dispose of syringe needles (and other sharps) immediately after their use, this practice is not always possible in the middle of the procedure. Placement of the sharp in a protected area of the sterile field or Mayo instrument stand is commonly practiced, but this practice may be hazardous when several operators are performing the procedure. Close communication between operators regarding sharps placement is encouraged.

If a needle must be recapped, the protective cap should be placed on a flat surface free of the operator's hand while the operator guides the needle into the cap (Fig. 75-1 *B*). That is, the cap is *not* held by the operator during *placement of the needle into the cap*. Only after the needle is fully enclosed in the cap should the operator secure the cap to the syringe. It is advised that even this final step be performed on the flat surface to enhance control of the needle-syringe-cap unit. It is critical that the operator *personally take responsibility to dispose of all sharps promptly* in puncture-proof containers after a procedure--thus avoiding exposure of other health care workers to these items. [34]

Equipment involved in direct patient care should also receive special attention in accordance with universal precautions. Reusable equipment and devices that enter a patient's bloodstream or body cavities should be washed thoroughly and sterilized between patient uses. Devices that touch intact mucous membranes but do not penetrate the body should be washed thoroughly and undergo high-level disinfection or sterilization if possible. Devices that only touch intact skin should be cleaned with a hospital-grade disinfectant.

## POSTEXPOSURE MANAGEMENT

Unfortunately, universal precautions and our compliance with them are not perfect. When occupational exposures to B/BF do occur, each health care facility must have a protocol that clearly defines the evaluation and management of the health care worker at risk. Because it is well documented that exposures are underreported, the first step in a successful occupational exposure program is encouraging health care workers to report any and all exposures.

Immediately after any exposure, the area should be thoroughly cleaned and clinically evaluated. The HIV, HBV, HCV, and other B/BF-borne disease status of the source patient and the exposed health care worker should be established. If there is no record of a recent negative serologic test for the source patient and health care worker, a hepatitis panel (HBV, HCV) should be done and permission for HIV testing obtained. If the source patient is unknown or refuses to be tested, the health care worker should be treated as though the exposure occurred unless there is strong clinical and epidemiologic evidence to the contrary. The health care worker should be counseled on postexposure prophylaxis, and follow-up testing should be done at 6 weeks, 3 months, and 6 months. During this follow-up period, the CDC recommends that the exposed

person defer pregnancy; refrain from breast feeding and donation of blood, semen, and tissue; and practice safe sex or abstinence.

## HIV Exposure

For known HIV exposure, the role of chemoprophylaxis should be discussed with the health care worker. Current information related to the transmission of HIV and use of zidovudine (ZDV; formerly known as azidothymidine or AZT) and other retroviral agents should be reviewed.

Recommendations for prophylactic use of ZDV are based on the case-controlled study by the CDC, which showed a 79% reduction in the risk for HIV infection among health care workers who used ZDV. [35] If the worker decides to take postexposure prophylaxis, it should begin preferably within 1 to 2 hours of exposure and no later than 24 hours post exposure. The dose of ZDV is 200 mg 3 to 5 times a day for 4 weeks. Lower doses are generally well tolerated whereas higher doses are associated with gastrointestinal symptoms, fatigue, and headache. [36]

This is an area of rapid treatment protocol evolution; multiple antiretroviral therapy may become the norm with high-risk exposures. The emergency physician is encouraged to work closely with his/her infectious disease consultant(s) to maintain a current therapeutic protocol. Other agents (Table 75-1) that may be added to prophylaxis with ZDV include lamivudine [3TC] (150 mg, orally, twice daily), indinavir [IDV] (800 mg, orally, 3 times a day), and saquinavir (600 mg, orally, 3 times a day). [23]

## Hepatitis Exposure

The treatment of hepatitis B exposure depends on the immunization status of the health care worker. Fully immunized (adequate antibody response) health care workers need no treatment. Nonimmunized workers need hepatitis B immune globulin (HBIG) in a dose of 0.06 mL/kg IM. Their initial dose of hepatitis B vaccine (1 mL IM) is given at a separate site. The vaccine is repeated at 1 month and 6 months. Health care workers with an inadequate response to the HBV vaccine (i.e., low antibody level to hepatitis B surface antigen; generally <10 mIU/mL) require a booster dose. Factors associated with an inadequate immunologic response include increasing age, smoking, and obesity. [37] [38] Those who have received a prior vaccination series with good antibody response should have their hepatitis B titer checked and further therapy guided by the current level.

The only treatment for proven hepatitis C exposure is

---

**TABLE 75-1** -- Provisional Public Health Service Recommendations for Chemoprophylaxis After Occupational Exposure to HIV, by Type of Exposure and Source Material--1996

| Type of Exposure | Source Material * | Antiretroviral Prophylaxis | Antiretroviral Regimen |
|---|---|---|---|
| Percutaneous | Blood § | | |
| | Highest risk | Recommend | ZDV plus 3TC plus IDV |
| | Increased risk | Recommend | ZDV plus 3TC, ± IDV |
| | No increased risk | Offer | ZDV plus 3TC |
| | Fluid containing visible blood, other potentially infectious fluid, ¶ or tissue | Offer | ZDV plus 3TC |
| | Other body fluid (e.g., urine) | Not offer | |
| Mucous membrane | Blood | Offer | ZDV plus 3TC, ± IDV |
| | Fluid containing visible blood, other potentially infectious fluid, ¶ or tissue | Offer | ZDV, ± 3TC |
| | Other body fluid (e.g., urine) | Not offer | |

| Skin, increased risk* [*] | Blood | Offer | ZDV plus 3TC, ± IDV |
|---|---|---|---|
| | Fluid containing visible blood, other potentially infectious fluid, [¶] or tissue | Offer | ZDV, ± 3TC |
| | Other body fluid (e.g., urine) | Not offer | |

immune globulin administered in a dose of 0.06 mL/kg IM as soon as possible after the exposure. [39] However, the effectiveness of this regimen has not been established. Currently, there is no vaccine for HCV.

**Tuberculosis Exposure**

The health care worker exposed to tuberculosis who has a negative skin test within the previous year requires interval testing (generally in 8 to 12 weeks) to determine potential conversion during the exposure. Those without a prior conversion, but >1 year since their last negative skin test, also require an immediate skin test to identify any prior interval conversion. Treatment after skin test conversion using antituberculous agents depends on the patient's age, underlying health, and other factors. The health care worker who is exposed, but has a previous positive tuberculosis skin test, would be considered for treatment depending on any subsequent signs or symptoms of the disease.
